MP139 Predicting Hormone Concentrations in Lakes Due to Inputs From Wildlife and Fish E. Osborn, ARCADIS; G. Scheef, Intervet Innovation GmbH; P. Anderson, ARCADIS. Endocrine disrupting chemicals in parts per trillion concentrations have been reported in Minnesota lakes by Writer et al. (2010). Anthropogenic sources for these compounds, such as treated wastewater discharge, are generally assumed. However, some lakes with detectable concentrations of hormones have no known anthropogenic inputs. We developed a mass balance model to predict theoretically possible concentrations of estrogens, androgens, and progestagens in pristine northern lakes due to natural inputs from wildlife and fish. Real lakes were modeled, and inputs from mammals, birds, and fish were estimated using excretion rates from the literature and estimated population parameters. Chemical loss was assumed to follow first-order degradation kinetics, and results are presented for both individual hormones and in terms of 17β-estradiol-equivalent or testosterone-equivalent concentrations. Additionally, all modeled lakes were assumed to be closed systems in order to estimate theoretical maximum concentrations in lake water; inclusion of residence time is planned in future versions of the model. Results of the model are presented and compared to reported concentrations, and implications of natural sources of hormones on hormonal regulation in fish species are discussed.

MP140 Impacts of Sewage Effluents and Ammonia on Reproduction in Zebrafish G. Van Der Kraak, Univ of Guelph, Dept of Integrative Biology; J. Matsumoto, K. Alkema, Univ of Guelph, Integrative Biology; W. Parker, Univ of Waterloo, Dept of Engineering. We have been studying the effects of treated sewage effluents on the reproductive responses of zebrafish. Effluents subjected to a conventional activated sludge treatment with nitrification (CAS-N) or biological nutrient removal (BNR) including nitrifying and denitrifying conditions and phosphorous removal did not impair spawning success in zebrafish whereas effluent subjected to a conventional activated sludge treatment alone (CAS) led to cessation of egg production. The CAS effluent contained high levels of ammonia (about 6-10 mg/L) which led us to also examine the response of zebrafish to ammonia. In subsequent tests we showed that both CAS effluent or ammonia would block egg production. Moreover, both effluents had no effects on the ovarian expression of steroid acute regulatory protein but markedly reduced the expression of aromatase. In other tests both the CAS effluent and ammonia significantly reduced the hepatic expression of vitellogenin mRNA. Collectively these studies suggest that ammonia may contribute to the reproductive toxicity of sewage effluents and does so by acting at multiple sites along the hypothalamic-pituitary-gonadal axis.

MP141 Life History Effects of Organic Wastewater Contaminants in the Freshwater Gastropod, *Physa pomilia* T.O. Luna, Texas Tech Univ/TIEHH, Environmental Toxicology, Texas Tech Univ; C.J. Salice, Texas Tech Univ/TIEHH, Environmental Toxicology, Assistant Professor, Texas Tech Univ. Organic wastewater contaminants (OWCs), including many known endocrine disruptors(EDs) and pharmaceuticals, have been detected in North American surface waters and are cause for toxicological concern. OWCs are not meant to be targeted or applied to the environment, so they haven't been scrutinized or subjected to mandated testing regarding possible adverse environmental effects. OWCs of concern include EDs which have been shown to exert sublethal effects at environmentally relevant exposure concentrations in a wide range of vertebrate test species. The observed sublethal effects may have effects on the fitness of exposed populations and potential community level consequences. Unfortunately, fewer studies have been aimed at understanding the effects of endocrine disruptors on invertebrates. In many systems invertebrates are important components serving a variety of ecosystem roles. Mollusks, particularly, have strong impacts on primary producers, can be the primary food source for small carnivores and can dominate macroinvertebrate biomass. Our objective was to evaluate the effects of commonly found EDs on life history traits in the freshwater gastropod, *Physa pomilia*. In this experiment two EDs were tested. 17-α ethynyl estradiol (EE2) is a synthetic hormone found in many forms of birth control and 4-nonylphenol (4-NP) is a chemical used in many industrial processes. Snails were exposed to one of the chemicals at one of three concentrations (EE2 – 10 µg/l, 1 µg/l, 0.1 µg/l and 4-NP – 100 µg/l, 10µg/l, 1µg/l). Locally found *P. pomilia* juveniles were exposed for two months in a semistatic system with four snails per glass beaker and exposure solutions were changed once per week. We quantified total egg masses laid per beaker per week, total eggs laid per beaker per week, hatching success, and mortality. We found that after two months, snails in the 10 µg/l EE2 laid more egg masses than snails in the 1 µg/l EE2 ($p=0.0087$) and that snails in the 100 µg/l 4-NP laid more eggs per week per beaker than snails in the 10 µg/l 4-NP ($p=0.0298$). We concluded from this experiment that there was some evidence that snails in the higher concentrations of EE2 and 4-NP are possibly showing symptoms of superfeminization because of the increased numbers of eggs laid. Future research will include a long term multigenerational study and several behavioral assays to evaluate ecological impacts of EDs that may be mediated through behavioral effects such as predator avoidance.

MP142 Polybrominated Diphenylether (DE-71) Exposure Alters Reproduction and Endocrine Function in Fathead Minnows (*Pimephales promelas*) D. Fort, Fort Environmental Laboratories, Fort Environmental Laboratories, Inc.; J. Autry, M. Mathis, C. Fort, H. Fort, B. Todhunter, Fort Environmental Laboratories, Inc.; P. Guiney, SC Johnson & Son. Exposure of Silurana tropicalis to DE-71 during development was previously found to increase the proportion of phenotypic females, alter steroidogenesis during sexual differentiation, and induce abnormal ovary development. Previous studies also found that Xenopus laevis exposed to DE-71 for 21–d in the EDSP amphibian metamorphosis assay displayed development delay resulting from changes in downstream thyroid hormone homeostasis but without direct histological signature in the thyroid glands. To determine if DE-71 altered reproduction and endocrine function in fish, the Tier 1 EDSP 21-day Fish Reproduction Screen with fathead minnow (*Pimephales promelas*) was used. Reproductively-active male and female fish were exposed to DE -71 (0 [control], 0.65, 1.3, 2.5, and 5.0 µg/L) via flow-through exposure for 21-d and evaluated for survival, reproductive behaviour, and secondary sexual characteristics. Reproductive fecundity and fertilization success were monitored daily. At termination, the status of the reproductive endocrine system was assessed by the gonad-somatic index (GSI), gonadal histology, plasma steroids (estrogen [E2] and testosterone [T]) and plasma vitellogenin (VTG). Results indicated that the DE-71 exposure did not affect survival or body weight, but reduced male GSI. Reproductive fecundity and gonad histology were altered. Impact on plasma steroid hormone and VTG levels in both sexes will be presented. In general, these results were generally similar to those found in S. tropicalis during gonad differentiation and demonstrate the effects of polybrominated diphenylethers on the reproductive system in fathead minnows.

MP143 Society's Contraceptive Choices and the Resultant Estrogenic Load on the Environment: A US Case Study U. Khan, McGill Univ; J. Nicell, McGill Univ, Dept of Civil Engineering and Applied Mechanics. More than a decade of evidence suggests that the estrogenic content of wastewaters being released to the environment feminizes fish and that such feminizing effects may potentially comprise the reproductive capacity of the effected fish. Environmentally-relevant estrogens can be broadly categorized in two classes; namely, those that are endogenously produced and those that are exogenously consumed. Of the two, the excretion and therefore the subsequent environmental presence of endogenous estrogens can be considered to be omnipresent since they are a fixed characteristic of our biology. When considering exogenously consumed estrogens used for human contraception, the most important by far in terms of amounts consumed and environmental relevance is the female birth control pill, containing the synthetic

estrogen ethynylestradiol as its active ingredient. The pill was first approved 50-years ago as a form of contraception and is currently used by approximately 11 million women in the USA for this purpose. Since the use of ethynylestradiol, and hence the estrogenic content released as a consequence, is a contraceptive choice made by members of society, a logical question arises: When evaluated from an environmental perspective, should the use of ethynylestradiol be mitigated or even eliminated? And if so, do greener alternatives exist to this contraceptive? How does one go about making such an evaluation? Further, the mere suggestion that society's contraceptive choices be altered to mitigate environmental impact should be analyzed in broader context. Are contraceptive choices that are greener also clinically and personally preferred? Would such a switch to more greener contraceptive choices also be financially feasible? This study will present a first attempt at answering these questions.

MP144 Sterols in Sewage Treatment Plant Wastewaters and Their Impacts on Salmon V. Furtula, Environment Canada, Research Scientist; H. Osachoff, Environment Canada, Simon Fraser Univ, Biological Sciences; P. Chambers, Environment Canada, National Water Research Institute; C. Kennedy, Simon Fraser Univ, Dept of Biological Sciences. Fecal material (from sewage treatment plants -STP) contains sterols, which have been recognized as endocrine-disrupting chemicals (EDCs) that can mimic the action of endogenous hormones. The objectives of this study were: (1) to assess the efficiency of STPs for removal of sterols; (2) based on the detected sterol hormones in the effluent, conduct an exposure study of juvenile chinook salmon (Oncorhynchus tshawytscha) to environmentally relevant levels. Samples from secondary and tertiary STPs were analyzed by GCMS method for 23 sterols. Fish experiments were conducted that exposed juveniles for 7 days to 5% STP effluents containing estrone and matching estrone-alone levels (2 ng/L). A comparison was made between the estrogenicity of the sewage versus that of the estrone using gene expression changes of four egg protein-related gene transcripts (vitellogenin, vitelline envelope proteins α, β and _) and four estrogen receptor (ER) gene transcript forms (estrogen receptor α1, α2, β1 and β2). In the STP influent 14 sterols were detected, cholesterol (459~1061 µg L-1), coprostanol (393~913 µg L-1), 24-ethylcoprostanol (145~442 µgL-1). β-sitosterol (154~415 µg L-1), coprostanone (110.75~277.04 µgL-1), campesterol (70.86~176.78 µg L-1), dihydrocholesterol (33~68 µg L-1), stigmastanol (26~58 µg L-1), stigmasterol (26~54 µg L-1), epicoprostanol (10~25 µg L-1), desmosterol (5~11 µg L-1), estriol (10 µg L-1, only detected STP-3), cholestanone (4~8 µg L-1) and epicholestanol (1~2 µg L-1). In effluent the same sterols were detected but in much lower concentrations, cholesterol (1~114 µg L-1), coprostanol (2~99 µgL-1), 24-ethylcoprostanol (0.6~42 µg L-1), β-sitosterol (3~37 µg L-1), stigmasterol (1~20 µg L-1), coprostanone (0.6~18 µg L-1), campesterol (1~15 µg L-1), dihydrocholesterol (0.4~9µg L-1), desmosterol (0.1~8 µg L-1), stigmastanol (0.07~5. µg L-1), epicoprostanol (0.13~4 µg L-1), cholestanone (0.31~3 µg L-1), epicholestanol (0.07~2 µg L-1) and estrone (0.03~0.04 µg L-1). Percentage of sterol removal ranged from 24-100% and varied amongst sterol compounds and with the type of STP. Results of exposure study showed that the ER and egg protein-related transcripts were differentially responsive and somewhat reduced in magnitude in the effluents compared to the estrone-alone. In addition, other endpoints of osmoregulation and vitellogenesis were examined and will be discussed.

MP145 The Effect of Nitrate, Fe(III) and Humic Acid on the Degradation of Naproxen and Ibuprofen in Photolysis K. Zoh, Seoul National Univ, Seoul National Univ, Dept of Environmental Health, School of Public Health; J. Im, Y. Kang, Seoul National Univ. Non-steroidal anti-inflammatory drugs, such as naproxen (NPX) and ibuprofen (IBP), are ones of the most the detected pharmaceutical compounds in water environment. The previous studies have shown that the sewage wastewater treatment plants (WWTPs) have failed to perfectly remove NPX (0~80%) and IBP (> 81%). Therefore, these compounds can coexist with NO3- , Fe(III) or humic acid in natural water environment. The aim of this study is to investigate the effect of these coexisting compounds (NO3-, Fe(III) and humic acid) on the photo-degradation of NPX and IBP in water. We applied single and mixture of environmental factors with various concentrations to NPX and IBP solution under UV-A irradiation. Under photolysis condition with UVA-only (light intensity: 3.5 mW cm-2), the removal efficiency was only 13.7% for NPX and 33.2% for IBP within 180 min, respectively. However, in the presence of 0.47 mg L-1 for Fe(III) and 20 mg L-1 for NO3-, the removal efficiencies of NPX and IBP were enhanced to 49% and 63.1%, respectively. However, under the same condition in the presence of humic acid (30 mg L-1), the removal rates were almost identical with UV-A only reaction. According to these results, Fe(III) and NO3- ions acted as a main source of OH radical while humic acid acted as a sink of OH radical. This result also implies that the removal of NPX and IBP in photolysis (UVA only) is achieved not only directly by photon but also indirectly by OH radical produced by Fe(III) and NO3- in water. Our result can help to understand fate of pharmaceuticals in the aquatic system in the presence of sunlight and typical ions and natural organic matters.

MP146 Triclosan Occurrence in Freshwater Systems in the United States (1999-2010): A Meta-Analysis A.L. Perez, M. Anderle de Sylor, A. Joseph, M.G. Lew, A. Slocombe, E. Donovan, ChemRisk. Triclosan (TCS) is an antimicrobial substance used in pesticides, hand sanitizers, toothpaste, medical devices, and a number of other consumer products. In recent years, concern has grown regarding the presence of TCS in water due to its potential role in ecological and human health effects, such as microbial resistance and endocrine disruption. In the current investigation, we present a statistical analysis of TCS concentrations in freshwater environments in the United States and quantify exposures to TCS via drinking water. A comprehensive literature review of reported TCS concentrations between 1999 and 2011 was conducted. Data from 41 peer-reviewed and unpublished investigations, including results from 47 states and one US territory was included in the meta-analysis and encompassed the following coded water types: waste, effluent, effluent-impacted environmental, environmental, and finished (n=1500). TCS was most frequently detected in waste waters (93% detection frequency (d.f.), n=214) and concentrations were significantly higher than in effluent waters (82% d.f., n=185). In environmental waters impacted by effluent, TCS concentrations ranged from less than the limit of detection to 1,600 ng/L (58% d.f., n=140), and were significantly greater than TCS measured in non-impacted environmental waters. The upper confidence limit on the mean of all drinking water samples was 19 ng/L (4% d.f., n=172). Although no US regulatory standard exists for TCS in waters, the exposures via drinking water are 12,000 times less than the reported chronic reference dose for dietary exposure of 0.3 mg/kg/day. These results suggest that for the US population, drinking water is not a significant source of TCS exposure. However, the data were suggestive of a seasonal effect for TCS in waters, where concentrations were significantly higher in months with the highest precipitation.

MP147 The Evaluation of Control Performance in the Fish Short-term Reproduction Assay Against the OPPTS 890.1350 Guideline L. Sayers, Springborn Smithers Laboratories; R. Biever, US Environmental Protection Agency (USEPA) has begun to execute a new paradigm with the Endocrine Disruptor Screening Program (EDSP). The goal is to prioritize chemicals based on route of exposure and screen them for potential endocrine or thyroid activity. Screening is being conducted using 11 Tier 1 assays. One of those assays is the Fish Short-Term Reproduction Assay. Although the OPPTS 890.1xxx guideline is very specific, it is not a trivial matter to meet the acceptance and performance criteria listed in the assay. Even though this assay has been validated, there are still not enough baseline data to reliably set acceptance or rejection criteria. This presentation will evaluate control performance data from at least 12 assays conducted over the past 10 months and compare this performance against recommended acceptance and performance criteria presented in the OPPTS 890.1350 and OECD 229 guidelines. The pre-exposure endpoints evaluated will include: fecundity expressed as eggs/female/day and number of spawns. The exposure endpoints evaluated will include: survival, fecundity expressed as eggs/female/day, percent fertility, male and female gonad histopathology, gonadal somatic index (GSI) and blood plasma vitellogenin, and male tubercle score. Recommendations regarding acceptance and performance criteria for this guideline will be provided.

MP149 Effects of a Glucocorticoid Receptor Agonist, Dexamethasone, on Fathead Minnow Reproduction and Development C. LaLone, USEPA; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; E. Medlock, DePauw Univ, Dept of Biochemistry; M. Kahl, K.M. Jensen, E. Durhan, E. Makynen, USEPA, Mid-Continent Ecology Division; C. Blanksma, R. Johnson, J. Cavallin, S. Seidl, USEPA; L. Thomas, L. Wehmas, USEPA, Mid-Continent Ecology Division; S.Y. Skolness, Univ of Minnesota, Dept of Biochemistry and Molecular Biology; G.T. Ankley, USEPA, Office of Research and Development, National Health and

Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division. Few studies have examined the effects of synthetic glucocorticoids on the reproductive axis of fish, despite the fact that these chemicals are therapeutically prescribed anti-inflammatory agents that are abundantly produced and consumed.To generate data to assess potential risk to the aquatic environment, this study used a fathead minnow 21 day reproduction assay and a 29 day embryo/larvae exposure assay to determine reproductive toxicity and life stage exposure effects to the common human and veterinary drug, dexamethasone (dex). Exposure to 500 µg dex/L caused significant adverse effects on fathead minnow fecundity, female plasma estradiol concentrations, and increased abnormally hatched fry following the 21 d exposure. Female fish exposed to 500 µg dex/L also displayed a significant increase in plasma vitellogenin (vtg) protein levels potentially due to decreased spawning. A decrease in vtg mRNA expression in ovary tissue from females exposed to the high dex concentration lends support to this hypothesis. Concentrations of 0.1 and 50 µg dex/L significantly increased both gonad mass and gonadal somatic indexes for males and females, respectively. Histological results indicate that 29 day embryo/larvae exposure to 500 µg dex/L caused a significant increase in the development of deformed opercula. Taken together these results indicate that non-lethal concentrations of a model glucocorticoid receptor agonist can impair fish reproduction and development. The contents of this abstract neither constitute nor reflect official USEPA policy.

MP150 Reproductive Impact and Proteomic Analysis of Androgenic and Antiandrogenic Disruptors on the Hermaphroditic Freshwater Gastropod *Lymnaea stagnalis* A. Giusti, Liege Univ, Laboratory of Animal Ecology et Ecotoxicology; V. Ducrot, INRA, Ecotox & Quality of Aquatic Ecosyst, INRA, Ecotoxicology and Quality of Aquatic Ecosystems; C. Joaquim-Justo, Liege Univ, Laboratory of Animal Ecology et Ecotoxicology; L. Lagadic, INRA, Ecotox & Quality of Aquatic. Ecosys; P. Leprince, Liege Univ, GIGA-Neurosciences; E. DePauw, Liege Univ, Laboratory of Mass Spectrometry; J. Thome, Liege Univ, Laboratory of Animal Ecology et Ecotoxicology. Mechanisms of action of endocrine disruptors on gastropods are poorly understood, and knowledge on their impacts is still scarce in most of species. In this study, effects of two androgens (tributyltin and testosterone), one antiandrogen (cyproterone acetate) and one estrogen (chlordecone) on growth and reproduction were investigated in the hermaphrodite gastropod *Lymnaea stagnalis*. In this study, exposure to a range of concentrations (ng/l to µg/l) of each chemical was performed during 21 days. The number of clutches and the number of eggs per clutch were monitored. A decrease in clutches laid per snail was observed after exposure to tributyltin (540, 1180 and 2600 ng/l) and chlordecone (10, 22, 50 and 110 µg/l). A significant decrease in egg laid per snail was observed after exposure to tributyltin (540, 1180 and 2600 ng/l) and chlordecone (50 and 110 µg/l). An increase of egg abnormalities ratio in exposed snails (atrophied albumen, polyembryonicity,...) was observed in *L. stagnalis* following exposure to testosterone (2, 22, 50 and 110 ng/l), cyproterone acetate (4,5 and 50 µg/l), tributyltin (110 and 244 ng/l) and chlordecone (4,5 and 10 µg/l). Investigation of alteration in protein expression in exposed snails was performed using proteomic analysis such as 2D-DIGE. Mass spectrometry identification was performed on proteins with altered expression. We could establish correlation between reproductive endpoints and changes in proteins involved in egg formation and in egg laying were underlined. Egg yolk ferritin, the main protein of egg yolk, was shown to be reduced significantly in relationship with a decrease of egg yolk quality after exposure to tributyltin 540 ng/l and cyproterone acetate 4,5 µg/l. Ovipostatin, a protein proved to reduce egg masses, was significantly over expressed in snails exposed to 50 µg/l of chlordecone and were in relationship with a reduction of clutches laid by individuals. Further western blot analysis on those proteins involved in the reproduction are underway. These analysis will enable us to confirm and refine with more specificity the 2D-DIGE results for the selected proteins. The results of this study can help to establish new biomarkers of exposure of endocrine disruptors in freshwater environment and can provide new insight on mode of action of endocrine disruptors in *L. stagnalis*.

MP151 Effects of Diethylstilbestrol in Fathead Minnows: Part 1. Effects on Reproductive Endocrine Function O. Adedeji, Univ of Ibadan, Veterinary Public Health and Preventive Medicine; E. Durhan, M. Kahl, K.M. Jensen, E. Makynen, D.L. Villeneuve, G. Ankley, USEPA, Mid-Continent Ecology Division. Diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was once widely prescribed to prevent miscarriages, and was used as a growth promoter in feed for beef and poultry production. After it was determined that DES caused significant adverse effects in the offspring of mothers exposed to the compound, its use was limited in both pharmaceutical and veterinarian applications. However, since DES might still be used as a growth enhancer in aquaculture in some countries, it is important to determine possible endocrine impacts it could have on fish, as well as its potential to accumulate in tissues that might result in exposure of human consumers to DES. A fathead minnow (FHM) experiment was conducted in which adult fish were exposed to DES at 1.0, 10 and 100 ng/L for 96 h followed by a 96 h depuration under flow-through conditions. Several endpoints associated with reproductive endocrine function were evaluated at both time periods. There was a significant concentration dependent decrease in male secondary sex characteristics (tubercle score) at the end of the study. Vitellogenin (Vtg) protein levels were significantly increased in the plasma of male fish exposed to DES at 10 and 100 ng/L. Vitellogenin mRNA and estrogen receptor (esr1) mRNA increased significantly in the male liver in the 10 and 100 ng DES/L exposure groups, while insulin like growth factor (igf1) mRNA showed a significant increase in animals from the 100 ng/L treatment. Overall our results show that that DES is a relatively potent estrogen in fish, capable of disrupting normal endocrine function. The contents of this abstract do not reflect USEPA policy.

MP152 Effects of Diethylstilbestrol in Fathead Minnows: Part 2. Concentrations in Water and Tissues E. Durhan, E. Makynen, K.M. Jensen, M. Kahl, USEPA, Mid-Continent Ecology Division; O. Adedeji, Univ of Ibadan, Veterinary Public Health and Preventive Medicine; D.L. Villeneuve, G. Ankley, USEPA, Mid-Continent Ecology Division. Diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was once widely prescribed to prevent miscarriages, and was used as a growth promoter in feed for beef and poultry production. After it was determined that DES caused significant adverse effects in the offspring of mothers exposed to the compound, its use was limited in both pharmaceutical and veterinarian applications. However, since DES might still be used as a growth enhancer in aquaculture in some countries, it is important to determine possible endocrine impacts it could have on fish, as well as its potential to accumulate in tissues that might result in exposure of human consumers to DES. A fathead minnow (FHM) experiment was conducted in which adult fish were exposed to DES at 1.0, 10 and 100 ng/L for 96 h followed by a 96 h depuration period. The direct measurement of DES in tank water and fish tissue samples at ng/L levels proved challenging. The analytical method used was developed on a single quadrupole liquid chromatograph/mass spectrometer (LC/MS). DES was measured on a daily basis using LC/MS with isocratic (tank water) or gradient (fish tissue extract) HPLC elution of a reversed phase column and atmospheric pressure photo-ionization detection. The fish tissue residues were determined by analyzing samples which were extracted using acetonitrile and homogenization techniques. The analytical quantitation limits were 75 ng/L and 2 ng/g for water and tissue samples, respectively. The predicted BCF (bioconcentration factor) of DES based on its log Kow (octanol-water partition coeffiecient) is 5000, while our experimental BCF was determined to be in the range of 50-100. This suggests a low risk of accumulating substantial amounts of DES in fish tissue. The contents of this abstract do not reflect USEPA policy.

MP153 Considering Evolution of Life's Response to Potentially Toxic Chemicals E. Monosson, Independent/UMass. Toxicology has deep evolutionary roots, yet the evolutionary history of how life responds to chemical challenges remains largely unexplored. Even as ecologists, immunologists, medical scientists and others now benefit from more deeply understanding their sciences – toxicologists are just beginning unravel the origins of the toxic response, and apply evolutionary theory to their work. We often consider the adverse human and environmental health impacts caused by chemical toxicants as a modern phenomenon, yet survival of some of the earliest forms of life depended upon the ability to transform, excrete and stow away naturally occurring potentially harmful chemicals. Today, a diversity of species, including humans rely upon these ancient mechanisms which range from highly conserved enzymes like DNA photolyase and metal binding proteins, to p53's role in cancer suppression, integrated defense networks and rapid evolution for protection from both natural and industrial chemical contaminants. This presentation provides specific examples selected from the literature intended to provoke in depth discussion of how and why evolution is relevant to both the basic and applied aspects of toxicology. Would an evolutionary context allow toxicologists and regulators to make

better use of new techniques including 'omics methodologies. Could analysis of chemical mixtures benefit from insights into the networked nature of life's response to chemicals? Might an improved understanding of the evolutionary history and phylogeny of a particular receptor improve predictions of chemical activity across species based on structure activity analysis? How might a greater understanding of contemporary evolution influence assessment of populations inhabiting highly contaminated sites? Considering the most basic origins of the toxic response could add greater depth to a rapidly expanding science, while initiating the growth of new branches on the field's own evolutionary tree.

MP154 Dioxin-related Compounds in New York House Dust: Chlorinated/Brominated Dioxins/Furans, Dioxin-like PCBs and In Vitro Dioxin-like Activities N.M. Tue, S. Takahashi, S. Tanabe, Ehime Univ, Center for Marine Environmental Studies; G. Suzuki, National Institute for Environmental Studies; K. Kannan, New York State Dept of Health, Wadsworth Center. Several studies have reported high levels of polybrominated diphenyl ethers (PBDEs) in American house dust as well as human matrices. However, the occurrence and potential exposure risk of polybrominated dibenzo dioxins and furans (PBDD/Fs), which are impurities in PBDE technical mixtures, or products of PBDE thermal/photolytic degradation, in the American home environment have not been investigated. In this study, PBDD/Fs and the legacy dioxin-related compounds (DRCs), polychlorinated dibenzo dioxins/furans (PCDD/Fs) and dioxin-like polychlorinated biphenyls (DL-PCBs) were analyzed in house dust samples collected from New York State. The total dioxin-like activities of persistent (sulfuric acid-resistant) compounds in the samples were also evaluated using the Dioxin-Related Chemical-Activated LUciferase gene eXpression assay (DR-CALUX). PBDD/Fs, PCDD/Fs and DL-PCBs were detected in the ranges of 0.33-150 (median 2.1), 0.12-80 (median 1.7) and 0.46-35 (median 5.6) ng/g, respectively. Although there were large variations in the concentrations and homolog profiles of DRCs, octa-CDD and hepta-octaBDFs were generally the major homologue groups found in the dust samples. The in vitro dioxin-like activities of the sulfuric acid-treated dust samples were in the range of 30-8000 (median 210) pg BEQ/g, to which PCDD/Fs theoretically contributed < 1%-130%, PBDD/Fs < 1%-21% and DL-PCBs < 1%-6.8% of the total toxicities. With the exception of two samples with very high concentrations of PCDD/Fs (19 and 80 ng/g), a large portion of the DR-CALUX results could not be explained by additive activity of DRCs with known relative potency values (REP). Our results indicate that other persistent compounds in house dust may exert AhR agonist. High levels of dioxin-like activities in American house dust suggest that dust ingestion is a critical pathway for human exposure to DRCs, especially for children.

MP155 Intensive Indoor Measurements and Biomonitoring of Phthalates: Implications for Exposure S.R. Chaudhuri, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry; M.L. Diamond, Univ of Toronto, Dept of Geography and program in planning, Univ of Toronto, Dept of Geography; E. Mukwedeya, S. Verkoeyen, Univ of Toronto; J. Brook, Z. Jiang, Environment Canada; A. Wheeler, Health Canada. With North Americans spending 90% of their time indoors, understanding the sources, and fate of semi-volatile organic compounds in the indoor environment is vital. Phthalates (PAE), a diverse group of organic esters, are a ubiquitous class of plasticizers that can be found in personal care items, residential materials, food-contact products, and medical applications. PAE are recognized as endrocrine disrupting compounds, and several studies have indicated an association between PAE exposure and allergy and asthma development in children. To determine optimal indoor sampling methods that relate to exposure, an intensive multimedia measurement campaign was conducted in 5 Toronto homes. The study consisted of over 150 simultaneous measurements and sample collections in the bedroom, living room, and kitchen of each home. Measurements included: i) urine based biomonitoring of PAE metabolites in participants, ii) direct indoor home characterization (ex: particulate matter concentration, air-exchange rate), iii) PAE concentration measurements in dust, air, and surface films on windows, and iv) time-activity and product use information through questionnaires and diaries. Dust samples were collected via vacuum, while passive air samplers and window wipes were tested as novel methods for measuring PAE concentrations in indoor air and surface films respectively. Heavier molecular weight di(2-ethylhexyl) phthalate (DEHP) and diisononyl phthalate (DiNP) had the highest concentration in window films in all 5 homes, whereas lighter molecular weight diethyl phthalate (DEP) was found to be the lowest in 4 of the 5 homes. Concentrations ranged from as high as 3 ng/cm^2 of surface area of DEHP to less than 10^{-4} ng/cm^2 of DEP. DEHP and DiNP were the most abundant phthalates in all rooms of all homes. Eight urinary PAE metabolites, tested in daily first morning urine samples, varied over an order of magnitude between participants. Investigation of optimal indoor sampling methods will improve the ability to explain fate and exposure of PAE and allow for the suggestion of interventions or preventative measures to minimize exposure to these chemicals.

MP156 Assessing PAH Residues from "Third Hand" Tobacco Smoke: Significant Vector for Exposure or a Non-Issue? T. Fleming, Philadelphia Univ, School of Science and Health; C. Cordeiro, L. Quast, Philadelphia Univ; J. Ashley, Philadelphia Univ, Institute for Textile and Apparel Product Safety. Polycyclic aromatic hydrocarbons (PAHs) are a suite of potentially carcinogenic organic compounds generated during the incomplete combustion of carbon-containing material such as tobacco. Though PAH concentrations have been widely studied in first and second hand smoke, there is a paucity of data sets characterizing levels in 'third hand' smoke, the residue adhering to the smoker and smoking environment after combustion. The purpose of this study was to quantify the levels of various PAHs in tobacco smoke residue, or third-hand smoke, and assess whether these concentrations are significant as a vector for exposure to nonsmokers, especially children. To quantify PAH levels within third hand smoke, test subjects' hands used to hold the cigarette were swiped before and after smoking with solvent-saturated cotton gauze. PAHs were subsequently extracted by sonication with hexane. Hand swipes were analyzed for six PAHs (acenaphthylene, acenaphthene, fluorene, phenanthrene, anthracene, and fluoranthene) using gas chromatography mass spectrometry (GC-MS). Smokers' bodies (e.g., hands, apparel) have significantly higher PAH levels than non-smokers. For example, after only one cigarette smoked under ambient conditions, total PAHs were as high as 120 ng/hand for smokers compared to

MP157 A Potential Protective Effect of Selenium Against Mercury Toxicity in Tropical Coastal Aquatic Species H.A. Kehrig, Universidade Federal do Rio de Janeiro, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho; T.G. Seixas, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho; C.M. Souza, A.M. Di Beneditto, Universidade Estadual do Norte Fluminense, Laboratorio de Ciencias Ambientais; O. Malm, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho. Selenium (Se) is nutritionally important as an essential trace-element for all life forms that have nervous systems, but is harmful at slightly higher concentrations. Se reportedly protects mammals against the toxic effects of mercury (Hg). Hg has no known normal metabolic function and its presence in living organisms is potentially hazardous. Hg accumulates in the aquatic food web. It is the chief exposure route for wildlife and humans. The Se:Hg molar ratios approaching or exceeding 1:1 is thought to provide Se-dependent Health Benefits (Se-HB) as protective against Hg toxicity. Evaluation of the health risk posed by Hg exposure from seafood consumption requires concurrent consideration of Se content in the particular species. Se and Hg concentrations, based on a wet weight basis, were evaluated in 531 individuals' muscle tissue of 179 predatory fish (PF), 60 non-predatory fish (NPF), 24 squids (MC), 153 mussels (MB), 70 shrimps (AC1) and 45 crabs (AC2) from a south-eastern Brazilian coast. These aquatic species are widely distribution in this region and are also often consumed by the human population. All species presented Se in muscle below the maximum allowable selenium concentrations, 2.0 mg.kg^{-1}. Only five PF individuals presented Hg in muscle above the maximum permissible limit of 0.50 mg.kg^{-1} wet wt. established for human consumption of aquatic species by WHO. As Hg exposure from fish consumption has been the focus of this study, the molar ratio between Se and Hg has been investigated. Se was in molar excess of Hg in almost all species, indicating that substantial Se was available to counter the Hg that was also presented in them. Only 7 individuals presented the Se:Hg of less than 1. Se:Hg might decline with increasing fish length, possibly reducing Se protection in larger fish. The relationship between Se:Hg and total length was poor and significant ($r=-0.324$; $p< 0.0001$). Se-HB value was calculated as Kaneko and Ralston (2007) to better describe and integrate Se-specific nutritional benefits in relation to potential Hg-exposure risks presented by these species evaluated. As a result of their rich Se and low Hg contents, all aquatic species presented Se-HBV higher than 1, suggesting that they have Se to potentially protect them and their consumers against Hg toxicity. *Centropomus*

undecimalis (common snook) and *Paralonchurus brasiliensis* (banded croaker) had the most favorable Se-HBV.

MP158 In Vitro Evidence for Biomineralization of the Ternary Hg-Se-S Compound from Inorganic or Methylated Mercury (II) F. Wang, Univ of Manitoba, Centre for Earth Observation Science, Dept of Environment and Geography; M. Khan, M. Lemes, Univ of Manitoba, Dept of Chemistry. The ultimate metabolic product of biological mercury (Hg) – selenium (Se) antagonism is most likely HgSe(s) which is essentially biochemically inert due to the extremely strong Hg-Se bonding. Although the in vivo presence of HgSe(s) granules has been analytically confirmed in the liver and kidneys of numerous species of marine mammals and sea birds, its formation pathway remains unclear. In vitro studies from our laboratory revealed that HgSe(s) could be produced in the presence of Se from either inorganic Hg(II) or methylmercury (MeHg) under conditions relevant to the in vivo environment. Furthermore, the resulting HgSe(s) is not necessarily present as pure tiemannite but rather in the form of the ternary $HgSe_xS_{1-x}$ (*x = 0-1*). In the case of inorganic Hg(II), excess amount of glutathione and selenite results in the formation of soluble $HgSe_xS_{1-x}$ which upon acidification precipitates out and ages into insoluble nanoparticles. In the case of MeHg, both MeHg-thiol and –selenol complexes are found to be kinetically instable, forming $HgSe_xS_{1-x}$ via the intermediate bis(methylmercuric) sulfide or selenide. The demethylation of MeHg is enhanced by the replacement of thiols with selenols and by an increase in the ionic strength. If confirmed in vivo, the presence of the ternary $HgSe_xS_{1-x}$ product would suggest that Hg detoxification with Se supplement needs to consider the participation of intracellular S which is much more abundant than Se.

MP159 Interactive Kinetics of Selenomethionine and Methylmercury in Juvenile White Sturgeon (*Acipenser transmontanus*) S.S. Huang, A.B. Strathe, J.G. Fadel, Univ of California, Davis, Animal Science; P. Lin, National Health Research Institutes, Environmental Health and Occupational Medicine; T. Liu, National Yang Ming Univ, Institute of Environmental and Occupational Health Sciences; S. Hung, Univ of California Davis, Animal Science. Selenium (Se) and mercury (Hg) are prevalent pollutants of industrialized watersheds. However, when co-administered, Se has protective effects on organisms from Hg. The mechanism is not known, but it is thought that Se reduces Hg availability, either by forming biologically inert complexes and/or associating with selenoproteins. Relatively little information on aquatic organisms are available, despite concerns with aquatic contaminations. We hypothesize that the interaction occurs during uptake, deposition and excretion, affecting the fractional rates of these parameters. In the present study, a combined technique of stomach intubation, dorsal aorta cannulation and urinary catheterization was utilized. Selenium and Hg were provided as selenomethionine (SeMet) and methylmercury (MeHg), respectively. Groups of 10 sturgeons were orally intuabated with a single dose of either 0 (control), SeMet (500 µg/kg body weight; BW), MeHg (1000 µg/kg BW), or their combination (SeHg; 500 µg Se/kg and 1000 µg MeHg/kg). The Se and Hg content in the sturgeon blood and urine were tracked through-out the 7 time points and at the end of the 6 time periods, respectively. Brain, liver, kidney, a cubical section of the white muscle and the remaining whole body were collected at 48 hr. The preliminary results showed that the sturgeons intubated with SeHg have significantly lower blood Se and Hg levels than in those intubated with either SeMet or MeHg alone. In the SeHg group, Se absorption was completed at 3 hr and level remained near peak at 48 hr, sharing a similar profile as in those given SeMet alone. In contrast, Hg absorption was very rapid, completed by 3 hr, followed by a sharp decline to half of the peak concentration; whereas, in the MeHg only fish, completion of Hg absorption was much slower, at 12 hr, and levels remained elevated. Levels of Se in tissues, particularly in the kidneys, were significantly decreased in the SeHg group than in those given SeMet alone. In contrast, tissue Hg levels in the SeHg were similar to those given MeHg alone, with the exception to the kidneys, where Hg concentration was decreased. Although similar in profile, the cumulative urine excretion of Se was much lower in the SeHg fish than in those given SeMet alone. Low levels of urinary Hg were detected, between 6-12 hr, in the SeHg group, but were not detectable in the MeHg fish. Results of the kinetics analyses and compartmental modeling will be discussed.

MP160 Abstract not properly submitted T.A. Jarvis, Valdosta State Univ, Dept of Biology.

MP161 Technical Challenges Encountered While Conducting the EDSP Fish Short-term Reproduction Assay (FSTRA) and the Amphibian Metamorphosis Assay (AMA) D. Matlock, C. Banman, T. Alexander, Bayer CropScience; L.S. Ortego, Bayer CropScience, Ecotoxicology, Bayer CropScience. The USEPA has developed a two-tiered system for screening and testing the potential interactions of pesticide and non-pesticide chemicals with the estrogen, androgen and thyroid (EAT) hormonal systems in order to determine if they pose a risk to human health or ecological systems. Assays are currently being conducted to satisfy these requirements, with deadlines due beginning late in 2011. Two of the eleven assays within the tier-1 testing battery are the Fish Short-Term Reproduction Assay (FSTRA) and the Amphibian Metamorphosis Assay (AMA). When conducting these screens, multiple challenges were experienced, including the time, labor and specialized equipment required to conduct the assays. Other challenges included the development of solvent free systems, proper dose selection and the distinction of non-endocrine stressors versus endocrine-mediated effects. Some specific challenges to the FSTRA assay included the variability of reproductive performance common to fathead minnows, unplanned mortality in control or exposure tanks, immature males mistakenly identified as females and insufficient amounts of plasma available for conducting both VTG and sex steroid analysis. Some specific challenges to the AMA included bent spines in developing tadpoles and maintaining adequate development without exceeding stage 60 N&F in control tadpoles. This poster will serve to further discuss these and other challenges encountered while conducting these assays.

MP162 Importance of Supplemental Sampling During the EDSP Tier 1 Amphibian Metamorphosis Assay – Case Studies D. Fort, Fort Environmental Laboratories, Fort Environmental Laboratories, Inc.; J. Autry, M. Mathis, Fort Environmental Laboratories, Inc.; S. Pawlowski, BASF, BASF AG. The use of supplemental sampling beyond the general scope of the standard method guidance to help elucidate potentially ambiguous test results will be discussed using two case studies as examples. The current approach to evaluate data from these tests involves individual assessment from primarily morphological data including, stage of development, thyroid gland histology, hind limb length, and measures of growth for the Tier 1 amphibian metamorphosis assay (AMA). Since each of the endpoints is considered individually, a potential for ambiguous or difficult to assess data sets may be produced by these Tier 1 assays. In an effort, the help define potentially ambiguous data sets; collection of additional samples during these assays, such as plasma for thyroid hormones (TH), tail or hind limb tissue samples for TH receptor β (TRβ) expression and deiodinase (AMA), and liver for TH metabolism. As examples, studies with the PBDE mixture, DE-71; and the antimicrobial agent, triclosan, will be presented. Exposure to DE-71 altered the developmental rate of X. laevis larvae and SVL, but did not alter thyroid pathology or hind limb length. Additional plasma and tissues samples were collected to evaluate effects on TH levels, TRβ expression, and TH metabolism and transport as downstream mechanisms of determining whether the effects were directly or indirectly on the thyroid axis. Results indicated that larvae exposed to DE-71 had lower plasma T4 and T3 levels and that deiodinase (DI-II) expression was induced. These results demonstrate that the peripheral aspects of the thyroid axis were affected by DE-71 exposure although the primary aspects of thyroid axis inhibition were somewhat ambiguous. Triclosan did not alter the rate of development, but did increase the rate of growth as determined by body weight and snout-vent length. An increase in vascularization of the thyroid gland was potentially confused with hypertrophy requiring further examination of thyroid gland metrics.

MP163 Response of 2,4-D in the Amphibian Metamorphosis Assay and the Fish Short Term Reproduction Assay R.J. Currie, The Dow Chemical Company, Toxicology, Environmental Research and Consulting; K. Coady, The Dow Chemical Company, Toxicology & Environmental Research and Consulting, Michigan State Univ, Zoology Dept; T. Marino, J. Thomas, The Dow Chemical Company, Toxicology & Environmental Research and Consulting; V. Kramer, Dow Agrosciences; B. Neal, Exponent; L. Hammond, Industry Task Force II on 2,4-D Research Data. 2,4-dichlorophenoxyacetic acid (2,4-D), a selective postemergence herbicide for the control of broadleaf weeds, was evaluated in both the Amphibian Metamorphosis Assay (AMA) and the Fish Short Term Reproduction Assay (FSTRA). In the AMA, tadpoles were exposed to mean measured 2,4-D concentrations of 0 (water control), 0.273, 3.24, 38.0 and 113 mg/L in a continuous flow-through test system for either 7 or 21 days. In the FSTRA,

fathead minnows were exposed to mean measured 2,4-D concentrations of 0 (water control), 0.245, 3.14, 34.0, and 96.5 mg/L under continuous flow-through conditions for 21 days. These concentrations of 2,4-D were not overtly toxic to either X. laevis tadpoles or fathead minnows. In the AMA, there were no signs of advanced development (as measured by developmental stage and hind limb length) or asynchronous development among 2,4-D exposed tadpoles evaluated on either day 7 or day 21 of the exposure, and no significant histopathological effects were observed among thyroid glands from 2,4-D-exposed tadpoles. Therefore, following the AMA decision logic (OPPTS 890.1100 guideline), 2,4-D is considered "likely thyroid inactive" in the AMA. In the FSTRA, there were no significant differences between control and 2,4-D exposed fish in regard to fertility, male and female wet weight and length, male and female gonadal somatic indices, tubercle scores, or blood plasma concentrations of vitellogenin in male and female fish. Furthermore, there were no treatment-related histopathologic changes in the testes or ovaries in any 2,4-D exposed groups. The only significant effect was a decrease in fecundity among fish exposed to 96.5 mg/L 2,4-D. The cause of the reduced fecundity at the highest concentration of 2,4-D tested in the assay was most likely due to a generalized stress response in the fish, rather than due to a specific endocrine mode of action of 2,4-D. Technical issues associated with the in-life conduct and interpretation of the AMA and FSTRA with 2,4-D will be discussed. These studies were sponsored by the Industry Task Force II on 2,4-D research.

MP164 The Evaluation of Control Performance in the Fish Short-Term Reproduction Assay Against the OPPTS 890.1350 Guideline D. York, Smithers Viscient; L. Sayers, Springborn Smithers Laboratories; R. Biever, Smithers Viscient, Dept of Environmental Toxicology. The United States Environmental Protection Agency (USEPA) has begun to execute a new paradigm with the Endocrine Disruptor Screening Program (EDSP). The goal is to prioritize chemicals based on route of exposure and screen them for potential endocrine or thyroid activity. Screening is being conducted using 11 Tier 1 assays. One of those assays is the Fish Short-Term Reproduction Assay. Although the OPPTS 890.1xxx guideline is very specific, it is not a trivial matter to meet the acceptance and performance criteria listed in the assay. Even though this assay has been validated, there are still not enough baseline data to reliably set acceptance or rejection criteria. This presentation will evaluate control performance data from at least 12 assays conducted over the past 10 months and compare this performance against recommended acceptance and performance criteria presented in the OPPTS 890.1350 and OECD 229 guidelines. The pre-exposure endpoints evaluated will include: fecundity expressed as eggs/female/day and number of spawns. The exposure endpoints evaluated will include: survival, fecundity expressed as eggs/female/day, percent fertility, male and female gonad histopathology, gonadal somatic index (GSI) and blood plasma vitellogenin, and male and female tubercle score. Recommendations regarding acceptance and performance criteria for this guideline will be provided.

MP165 The Evaluation of Control Performance in the Amphibian Metamorphosis Assay Against the OPPTS 890.1100 Guideline M. Lee, L. Sayers, Smithers Viscient; R. Biever, Smithers Viscient, Dept of Environmental Toxicology. The United States Environmental Protection Agency (USEPA) has begun to execute a new paradigm with the Endocrine Disruptor Screening Program (EDSP). The goal is to prioritize chemicals based on route of exposure and screen them for potential endocrine or thyroid activity. Screening is being conducted using 11 Tier 1 assays. One of those assays is the Amphibian Metamorphosis Assay. Although the OPPTS 890.1100 guideline is very specific, it is not a trivial matter to meet the acceptance and performance criteria listed in the assay. Even though this assay has been validated, there are still not enough baseline data to reliably set acceptance or rejection criteria. This presentation will evaluate control performance data from at least 8 assays conducted over the past 10 months and compare this performance against recommended acceptance and performance criteria presented in the OPPTS 890.1100 and OECD 231 guidelines. The endpoints evaluated will include: number of day to stage 51; Day 7 developmental stage, hind limb length, snout to vent length and weight; and Day 21 developmental stage, hind limb length, snout to vent length, weight and thyroid histopathology. Recommendations regarding acceptance and performance criteria for this guideline will be provided.

MP166 The Androgenised Female Stickleback Screen (AFSS) for Detecting Environmental (Anti) Androgens I. Katsiadaki, Cefas, Environment and Animal Health. The current OECD test guidelines for screening chemicals with potential endocrine disrupting activity (TG 229 and TG 230) cannot clearly identify androgen antagonists due to the lack of a specific end-point in the 3 core species involved (fathead minnow, zebrafish and medaka). The reported antiandrogenic activity in the aquatic environment based on the Yeast Androgen Screen (YAS), a suitable in vitro test, is substantial. The evidence of high levels of antiandrogens in the environment emphasises the need to develop a suitable assay for chemical screening. The design of the androgenised female stickleback screen (AFSS), currently an OECD guidance document, is highly suited as a screen due to its simplicity and reproducibility in any laboratory. The fish are simultaneously treated with a model androgen (dihydro-testosterone, DHT) at 5_g/L and a range of concentrations of the putative antiandrogen. Any antiandrogenic activity is detected by the degree of reduction/inhibition of spiggin induction by the DHT treatment. Here we present the results from a retrospective validation of a large dataset using the AFSS produced over a period of 10 years with the participation of four laboratories in Europe. The in vivo exposures included testing of four antiandrogenic compounds using kidney spiggin levels as an end-point. Spiggin was measured by a validated ELISA method. Independent statistical analysis of the dataset revealed that the AFSS can unambiguously and reproducibly detect antiandrogens. All four tested compounds (Flutamide, Fenitrothion, Vinclozolin and Linuron) were characterised as antiandrogens on the basis of the AFSS whilst ammonia (tested as an endocrine negative substance had no effect. These data were used for validating the AFSS as an OECD guidance document for the detection of EDCs with androgen modulating activity. Key words: antiandrogens, stickleback, validation, OECD guidance document

MP167 Multi-disciplinary and Multi-scale Climate Change Vulnerability Assessment and Response T. Wickwire, Exponent; C. Menzie, Exponent, Inc., Exponent, Principal; R. Cantor, Exponent. Though the potential impacts of climate change on the environment remain challenging to pinpoint, there is little doubt that as impacts emerge, those with management response strategies in place will be in the best position to adapt and minimize interruptions to achieving management goals. Drawing on a diverse expertise in ecological management, environmental service assessment, hydrological modeling, climate modeling, human health assessment, infrastructure planning and economic analysis, we propose a multi-tiered strategic approach by which to prepare for the uncertain effects of climate change. The approach incorporates assessments for three broad characteristics of managed facilities including integrity and sustainability of assets and infrastructure, the health and well being of personnel or communities, and the stability of ecological resources. The target of the approach ranges from multi-national businesses to government agencies that operate facilities and land holdings across the US and around the world. The two-tiered approach will yield assessments at (inter)national, regional, and facility scales. Tier 1 provides a national assessment of climate-change vulnerabilities associated with predicted regional changes in climate. Tier 2 is designed to provide detailed assessments at the regional and facility scale. While the approaches are conceptually similar, Tier 2 involves more spatial refinement and facility-specific assessment of activities. Uncertainties related to forecasts and associated implications must be characterized and used as a basis for identifying means to reduce uncertainties and develop probabilistic representations of potential future conditions. Our approach will assist in enhancing long-term planning with respect to climate change vulnerabilities, and improve the review and comparison of design and management alternatives. Additionally, it will provide a framework for application to any type of business or government entity, identifying the key metrics for preparing a national climate change vulnerability map library based on the most current model outputs, improving inter- and intra-facility communication regarding vulnerabilities through the relative risk model, and encouraging prioritization of management of vulnerabilities.

MP168 Assessing Risk to Salmon from Estrogens in a Water Reuse Project K. Warner, Golder Associates Inc. One consideration regarding environmental applications for water reuse projects is the presence of estrogenic chemicals in wastewater treatment plant (WWTP) effluent. While the concentrations of natural and synthetic estrogens in surface waters are not currently regulated under state or federal guidelines, reproductive toxicity to aquatic biota from estrogenic compounds has been demonstrated in scientific reports, raising concern about the potential ecological impacts of water reuse projects. The information here presents an ecological risk assessment

performed for a proposed reuse project in Kitsap County, Washington that was designed to deliver reclaimed water from a WWTP to a wetland area and salmon-bearing stream in order to benefit flow in both systems. A hydrologic analysis and review of the current scientific literature were performed to develop an ecological risk assessment modeling the quantities of estrone, estradiol, and ethinyl-estradiol in the WWTP influent and effluent, and the fate of these compounds in the receiving stream. Conservative estimates from the risk assessment and water quality analysis suggest potential salmon exposure to less than 1.5 ng/L of each estrogenic compound modeled, and minimal reproductive toxicity risk to fish after WWTP upgrades and under predicted receiving stream conditions. A discussion of risk assessment considerations for other water quality parameters in reclaimed water projects is included.

MP169 Development of Models to Predict Pesticide Spray Drift Deposition from Aerial, Airblast and Groundspray Applications S. Rodney, R.L. Breton, Intrinsik Environmental Sciences, Inc.; T.M. Wolf, Agriculture and Agri-Food Canada; P. Whatling, Cheminova, Inc.; D.R. Moore, Intrinsik Environmental Sciences Inc.; T.L. Estes, J. Hanzas, Stone Environmental Inc. AgDISP is a theoretical, physics-based model used to estimate drift of pesticides from treated fields and to derive buffer widths required to reduce risk to biota. AgDISP is a component of AgDrift and is used to estimate buffer widths. The outputs from the AgDISP model have been shown to overestimate far-field drift, resulting in overly conservative buffer width estimates. We describe an alternative method for estimating drift deposition using models fit to field trial measurements. Drift curves that show the relationship between deposition and downwind distance were developed for aerial, airblast and groundspray application methods. The theoretical constraints of drift deposition were used to select appropriate models to fit to the data (e.g., negative deposition is not possible). The models were tested for goodness-of-fit and the best-fitting models selected. Best-fitting models included two- and three-parameter Weibull and Burr Type III models fit to percent loss versus distance. Selected models were input into Drift BUD v1, an MS Excel-based tool for estimating risk to non-target biota from pesticide spray drift. This tool also calculates buffer sizes for selected protection levels. Drift curves and Drift BUD v1 buffer results were compared with AgDISP/AgDrift estimates.

MP170 Environmental Risk Assessment of the Intense Sweetener Sucralose D.B. Huggett, Univ of North Texas, Dept of Biological Sciences; A. Lillicrap, K. Tollefsen, Norwegian Institute for Water Research. Emerging contaminants, such as pharmaceuticals, personal care products and food additives, are receiving considerable attention with respect to their environmental fate and toxicological properties. These contaminants are in constant commercial use and are thus being continually introduced into the environment via wastewater treatment plants (WWTP). This constant exposure scenario suggests that comprehensive environmental fate and ecotoxicological studies are needed to evaluate the environmental risks of emerging contaminants. Sucralose (1,6-dichloro-1,6-dideoxy-b-D-fructo-furanosyl 4-chloro-4-deoxy-a-D-galactopyranoside), is an intense sweetener sold under the trade name SplendaTM. The majority of orally ingested sucralose is excreted as unchanged parent compound, with < 1% of the original oral dose excreted as two glucuronide adduct metabolites. Once excreted, sucralose is not readily degraded within the wastewater treatment process and has been detected in municipal effluents and surface waters. Sucralose bioconcentrations factors are < 2.2 in algae, crustaceans and fish, indicating a low potential to bioaccumulate in the food chain. A battery of acute (rainbow trout, bluegill sunfish, *Daphnia magna*, green algae) and chronic (mysid shrimp, *Daphnia magna*, Lemna gibba) ecotoxicological studies have been conducted to evaluate the potential of sucralose to elicit toxicity on aquatic organisms. Sucralose concentrations ≥ 93 mg/L did not elicit changes in survival, growth or reproduction in any of the standard testing organisms. A wide margin of safety exists when ecotoxicological data are compared to predicted or measured aqueous sucralose concentrations, indicating that sucralose presents a low risk to the environment.

MP171 Estimating the Potential Significance of Dermal Exposure of Birds, Reptiles, Amphibians, and Mammals to Pesticides T. Crk, E. Odenkirchen, US Environmental Protection Agency, Office of Pesticide Programs, Environmental Fate and Effects Division; T. Purucker, US Environmental Protection Agency, Office of Research and Development; D. Spatz, N. Mastrota, K. Garber, J. Housenger, F. Farruggia, M. Wagman, M. Clock-Rust, V. Woodard, T. Dowen, H. Yingling, US Environmental Protection Agency, Office of Pesticide Programs, Environmental Fate and Effects Division. The Dermal Uptake Screening Tool (DUST v. 1.0) is a model developed by the United States Environmental Protection Agency's Office of Pesticide Programs. The output of the model will be used in the problem formulation phase of ecological risk assessment to assess the potential significance of chemical exposure to the dermis of birds, reptiles, amphibians, and mammals as a result of pesticide application. Exposure estimates are based on pesticide application rate, application method, and biology of the non-target organism. DUST evaluates dermal exposures via contact with soil and foliar residues and interception of spray. Soil exposure estimates for terrestrial wildlife account for contact with soil particulates via dust bathing and treading the soil surface. Dermal contact estimates vary across terrestrial taxa more than for other exposure pathways, for example, amphibian dermal contact from enhanced skin permeability can be a key exposure pathway due to high dermis-soil water uptake rates that allow amphibians to regulate hydration. DUST output is used to establish a rationale in problem formulation to either dismiss dermal exposure concerns for soil residues and other dermal contact routes or support further consideration in data collection and analysis phases of the ecological risk assessment. This poster includes the following elements of the model: exposure estimation, preliminary effects endpoint estimation, integration of exposure and effects, decision criteria, model assumptions, and model evaluation.

MP172 Guidance for a Weight-of-Evidence Approach to Ecological Risk Assessments in British Columbia M.E. McArdle, Exponent, Inc.; A. Fairbrother, Exponent, EcoSciences, Exponent, Inc., EcoSciences; S. Kane Driscoll, Exponent Inc.; C. Menzie, Exponent, Inc., Exponent, Principal. This poster presents guidance for developing a weight-of-evidence (WOE) approach for conducting detailed ecological risk assessments (DERAs) in British Columbia. While WOE has many definitions, it is defined here as the process by which measurement endpoints, which are closely linked to lines of evidence (LOEs), are integrated to evaluate the likelihood and magnitude of ecological risk for an assessment endpoint. This guidance was written to help risk assessors develop WOE assessments that are objective, transparent, and scientifically rigorous. The approach presented in the guidance is anticipated to be the default WOE approach for conducting DERAs in British Columbia; however, alternative approaches may be employed in conjunction with a clear and defensible communication of the structure and merits of the alternative. The guidance describes the use of WOE to select LOEs and assign weighting factors that reflect the quality and relevance of each LOE to its corresponding assessment endpoint. During the risk characterization stage, the weight given to each LOE is revisited and adjusted to account for any unforeseen events during the collection or analysis of a sample that affected the quality or quantity of data, the appropriateness of an established data analysis method, and/or the sensitivity or representativeness of the LOE. The risk assessor considers the magnitude of response for each LOE, together with the weight of each LOE, to reach a conclusion regarding risk. Examples are provided at key steps in the WOE process.

MP173 Indicators of Ecological Integrity evaluated in Tecolutla, Veracruz, Mexico P. Ramirez Romero, Universidad Autonoma Metropolitana, Hidrobiologia, U.A.M. Iztapalapa, Depto. De Hidrobiologia; X. Guzman Garcia, G. Barrera Escorcia, S. Gonzalez Rebollar, L. Elizalde Ramirez, Universidad Autonoma Metropolitana, Hidrobiologia. The development of environmental monitoring programs in Mexico is scarce. Mexican standards demand the assessment of recognized indicators in environmental monitoring, including analysis of water sanitary quality by fecal coliform bacteria and chemical contaminants such as metals. Currently we are developing a research project at the Metropolitan Autonomous Univ to generate data on several indicators of ecological integrity in aquatic environments in Mexico, which began in Tecolutla estuary, Veracruz. We generated data on physicochemical parameters of the estuary, including some contaminants such as coliform bacteria, metals (Cr and Cu), and the toxicity of water and sediments of five collection sites. Bioassays were conducted with *Artemia salina* in water samples and with *Daphnia magna* with sediments after extraction of contaminants by sonication. So far, the analysis indicates poor sanitary quality in two locations, and the concentrations of Cr and Cu are right in line, or above the accepted limits in water, for all locations. The LC_{50} with 95% confidence intervals did not allow detection of water toxicity, but in the sediment, it fluctuated between 29.82 % and 41.41% in the first three

sites, and 15.65 % and 13.01% at stations 4 and 5, respectively. This first approach indicates a strong influence of human activities on the estuary.

MP174 Reduction of PCBs in Striped Bass (*Morone saxatilis*) from Chesapeake Bay Through Adipose Tissue Removal B. wang, Univ of Maryland, Baltimore County (UMBC), Civil and Environmental Engineering; P. Paul, U. Ghosh, Univ of Maryland, Baltimore County (UMBC). The work presented is an effort to assess human health risks associated with carcinogenic chemicals found in fish caught in Maryland. The Maryland Dept of the Environment (MDE) collects fish samples from Maryland waters to evaluate human health risks from toxic chemical accumulation. Polychlorinated biphenyls (PCBs), a class of anthropogenic chemicals, are the major risk drivers for fish species in the Chesapeake Bay and its tributaries. The PCB concentrations in fish tissues are compared across geographical regions and to Maryland fish consumption advisory levels. In this study we analyzed striped bass (*Morone saxatilis*) samples, a popular gamefish from the Bay in Maryland, collected during fall 2009 and spring 2010 for the measurement of total PCBs and to study the impact of fat trimming on the PCB concentration in the fish tissue. Fillets of the samples were prepared in two different ways- with skin and ribs on and with skin and ribs removed. A total of 34 samples were analyzed. The measurement shows a significant decline, more than half, in the level of PCBs in striped bass compared to analysis from 2001 to 2005. It means the recommended meal limits for the general population for smaller striped bass caught in the Chesapeake Bay increased by 50 percent. Meanwhile, differences were found between PCB concentrations and lipid contents in different prepared samples. Removal of skin and ribs reduces an average of PCB and lipid 84% and 75% respectively for the 2009 fish samples and 88% and 92% respectively for the 2010 fish samples. A strong correlation (r^2 = 0.8) was observed between PCB concentration and lipid percent in the whole fillet tissues from fall 2009. For spring 2010 samples a weak correlation (r^2= 0.2) was observed, which could be attributed to spawning which occurs during spring. The correlation verifies that lipid content has the direct effect of increasing accumulation of PCBs in fish tissues. To minimize exposure to lipophilic pollutants, Maryland fish consumption advisories also provide the general guidelines for healthy fish consumption. For example, it is suggested to cut off the fat or use cooking methods such as baking, grilling, or broiling to drip away fat.

MP175 Risks of Carbofuran Formulations to Birds in Colombia D.R. Moore, Intrinsik Environmental Sciences (US), Inc; K.J. Beckett, Stantec Consulting Services, Senior Scientist; S. Teed, Intrinsik Environmental Science Inc., Intrinsik Environment Sciences Inc. Carbofuran is a contact and systemic insecticide, nematicide, and miticide belonging to the carbamate class of cholinesterase-inhibiting chemicals. Flowable and granular formulations of carbofuran are commercialized in Colombia. For the flowable formulation, we undertook a refined avian assessment using a recently developed model, the Liquid Pesticide Avian Risk Assessment Model (LiquidPARAM). The focus of the flowable formulation assessment was on one or two banded or in-furrow applications to potato fields in Colombia because this use pattern is the most widespread and has the highest application rate. For each of nine bird species assessed for potato fields in Colombia, LiquidPARAM estimated the maximum retained dose (i.e., maximum body residue level) that occurred over a period of 28 days following application of the flowable formulation in each of 20 birds on each of 1000 potato fields in Colombia. The model has a one-hour time step. For each bird, the maximum retained dose was compared to a randomly chosen value from the appropriate dose-response curve to determine whether the bird survived (maximum retained dose < randomly chosen value from dose-response curve) or died. Collectively, the modeling line of evidence indicated that the community of birds foraging in treated potato fields in Colombia would have greater than 99% survival for both banded and in-furrow application of the flowable formulation. The focus of the assessment for the granular formulation was a single banded or in-furrow application of the granular formulation to potato fields because this use pattern is the most widespread in Colombia. This assessment relied on an advanced probabilistic risk model for birds called the Granular Pesticide Avian Risk Assessment Model (GranPARAM). The modeling line of evidence indicated that application of granular carbofuran would result in 99% and 98% of the bird community surviving following in-furrow and banded applications, respectively. However, highly sensitive, small passerine species with high grit intake rates are predicted to experience 28% mortality following banded application. No bird species experienced high mortality with in-furrow application of granular formulation to potato fields in Colombia. Field studies conducted in the United States corroborate the predictions of LiquidPARAM and GranPARAM. The assessment indicates acceptable risks of flowable and granular formulations to birds in Colombia.

MP176 The Use of Pesticide Ecological Incident Data in the US Environmental Protection Agency's Pesticide Ecological Risk Assessments M. Panger, USEPA, Environmental Fate and Effects Division. The US Environmental Protection Agency (USEPA) uses data on ecological incidents (information on adverse effects to the environment from pesticide use) in its pesticide ecological risk assessments. Incident data can provide evidence that the risk predictions from screening level assessments are supported by actual effects in the field. Additionally, pesticide incidents can help raise awareness of potential risk issues not previously predicted by other standard assessment methodologies. The EPA relies on three primary sources of ecological incident data: the Ecological Incident Information System (EIIS); the Incident Data System (IDS) (for aggregate reports); and the American Bird Conservancy's Avian Incident Monitoring System (AIMS) (specifically for pesticide incidents involving birds). Information in these databases comes from a variety of sources, including pesticide companies (the 'registrants'), government agencies (both federal and state), public interest groups, and others (e.g., the National Pesticide Information Center). Registrants have reporting requirements for pesticide ecological incidents under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA); however, reporting of incidents from non-registrants is voluntary. The limitations and benefits of each database will be discussed along with how incident information is specifically used in EPA's pesticide ecological risk assessments.

MP177 TVA Kingston Ash Spill: A Preliminary Sediment Triad Analysis for Metals and Legacy Contaminants in the Clinch River A.R. Stojak, ARCADIS; T.F. Baker, Tennessee Valley Authority; R.M. Sherrard, Tennessee Valley Authority, Kingston Ash Recovery Project; J.G. Smith, ORNL, UT-Battelle, Environmental Sciences Division; J. Iannuzzi, D. Jones, S. Young, ARCADIS; N.E. Carriker, TVA Kingston Ash Recovery Project, Kingston Fly Ash Recovery Project. The 2008 Kingston Fossil Plant ash spill discharged fly ash into the Emory River, with subsequent migration of part of the ash into the Clinch and Tennessee Rivers. The river system sampling and analysis plan includes investigations of sediment, ash, porewater, and surface water chemistries, and potential effects on benthic invertebrates, fish, and wildlife receptors. A sediment quality triad analysis was performed as part of the baseline ecological risk assessment. Sediment chemistry, sediment toxicity, and benthic invertebrate community data formed the three primary lines of evidence. Analyses were completed first for the Clinch River, which is the focus of the triad analysis outlined below. Physical and chemical analysis focused on ash, metals, and metalloids, but included legacy constituents (PCBs, pesticides, and radionuclides) for a subset of samples. Clinch River results showed a spatial distribution of percent ash content and, to varying degrees, metals and metalloids. Laboratory toxicity tests included *Ceriodaphnia dubia* 3-brood survival and reproduction tests; and *Hyalella azteca* and *Chironomus dilutus* 10-day and long-term survival and growth tests. Clinch River screening tests indicated: no significant reductions in survival; significant reductions in growth of *C. dilutus* in 2 of 8 samples; and significant reductions in growth of *H. azteca* in 3 of 8 samples. The definitive tests showed significant effects for survival and emergence (*C. dilutus*) and growth (*H. azteca*) in CRM 1.5, and growth (*H. azteca*) in CRM 4.5. Benthic invertebrate community surveys were performed at fixed transect locations approximately annually. Community composition varied among Clinch River sites, but appeared due primarily to variations in habitat rather than proximity to the release. The sediment quality triad analysis systematically weighed and integrated the lines of evidence to characterize potential risks and identify likely causes. This included qualitative and multivariate analysis of sediment and porewater chemistries, laboratory toxicity responses, community composition, and habitat characteristics. This poster presents an overview of the sediment triad approach and preliminary findings for the Clinch River system.

MP178 Use of Best Available Data in a Pacific Salmonid Endangered Species Assessment for Prometryn J. Overmyer, Syngenta Crop Protection, LLC, Ecological Sciences, Americas; J. Bang, Syngenta Crop Protection, LLC, Environmental Safety; K. Henry, Syngenta Crop Protection, LLC, Ecological Sciences; K. Kabler, J. Perine, D. Perkins, N. Peranginangin, S. Pyles, Syngenta Crop Protection, LLC; S.B. Wall,

Syngenta Crop Protection, LLC., Ecological Sciences. Prometryn is an s-triazine herbicide used to control annual broadleaf weeds and grasses in cotton, celery, carrots and other vegetable crops. A biological opinion (BiOp) for the use of prometryn near Pacific salmonid habitats in the states of California, Oregon, Washington and Idaho is scheduled for development by the National Marine Fisheries Service (NMFS). In regard to the pending BiOp, Syngenta is working to identify the best available data for determining the potential exposure/effects of prometryn uses near salmonid habitats in these states. Information to be used in the risk assessment includes data from guideline environmental fate and toxicity tests and other sources. Geospatial approaches used to identify areas of overlap between salmonid habitat and crops with prometryn use as well as to evaluate vegetation within riparian areas near historical prometryn use areas will be presented. In addition, watershed modeling will be presented to contextualize field monitoring residues. The use of these data and other pertinent information for evaluating the potential exposure and effects of prometryn on Pacific salmonids will be discussed.

MP179 Using Scientific Principles to Expedite Site Closure J. Gravenmier, A. Francisco, J. Nedoff, E. Kalve, ARCADIS. When evaluating risks to ecological receptors from exposure to contaminated sediments, uptake and accumulation of constituents through the food web is often a critical exposure pathway. Food web exposures are controlled by various physicochemical factors internal and external to the ecosystem (climate, seasonality, sediment and water quality conditions, habitat types/conditions, species composition, carbon sources/types/quality, etc.). These factors control the bioaccessibility and bioavailability of chemicals in the sediments and the system. Methods for assessing bioavailability of chemicals in sediments on a site-specific basis are inconsistent, and too often risk evaluations are based on either generic information (such as literature-based screening levels or other thresholds) or the total concentration of a chemical(s) in sediments. This can result in an overestimation of risk for particular chemicals, and perhaps leading to unnecessary remediation. A California intertidal salt marsh that has had a variety of historical industrial and municipal inputs provides a good case study for using scientific principles to expedite site closure. The marsh has been investigated for many years under a voluntary program to assess the sediment, surface water, and habitat quality. Although useful data were collected, the investigation program lacked a scientific basis and little progress was made toward site closure. Using a two-tiered screening process, we were able to first conservatively identify site-specific constituents of potential concern (COPCs) in sediment and surface water, and then narrow the list of COPCs through an evaluation of the available site-specific toxicity test data. The combination of the tiered screening evaluation and the development and use of site-specific conceptual site models (CSMs) for the identified receptors provides a scientific basis to assess the additional site data needs, appropriately identify potential risks from COPC exposure, and evaluate if remedial actions are necessary to mitigate those risks.

MP180 Whole Body to Liver Ratio of Dioxins, Furans, and PCBs in Small Mammals from the Tittabawassee River Floodplain Y.B. Atalay, Cardno Entrix, Civil and Environmental Engineering Dept; D. Kay, M. Johnstone, P. Bradley, Cardno – ENTRIX; M.J. Zwiernik, Michigan State Univ, Dept of Animal Science. Shrews and voles were collected from the Tittabawassee River floodplain and analyzed for dioxins, furans, and PCBs for ecological risk assessment purposes. Specifically, these small mammals were collected, and whole bodies were analyzed to support the dietary exposure assessment of apical predators. The liver was removed from a subset of the small mammals and analyzed separately from the liverless body. Polychlorinated dibenzo-*p*-dioxins (PCDDs), dibenzofurans (PCDFs), and biphenyls (PCBs) are persistent contaminants that occur throughout the environment as a result of anthropogenic activities and bioaccumulation. These compounds activate the aryl hydrocarbon receptor signal transduction pathway which involves the induction of cytochrome P450 enzymes including CYP1A1 and CYP1A2. CYP1A2 is highly expressed in the liver and is thought to function in hepatic sequestration. Consequently, much of the toxicity data available in the literature is based on chemical burdens in the liver rather than the whole body. Therefore, while whole body analysis of small mammals provides valuable information for dietary risk assessment of higher trophic levels it has limited value for considering risk to the small mammals themselves. The paired liver and liverless body analysis for 11 small mammals, including two shrew species and meadow vole, was conducted to establish the relationship between liver and whole body concentrations. There is a linear relationship for lipid normalized concentrations of dioxins, furans and PCBs in liver and whole body with an R2 of >0.9 for masked shrew, short tailed shrew, and meadow vole. Dioxin, furan, and PCB congener-specific liver to whole body ratios generally range from 1 to 15. Overall, ratios are lower for meadow voles compared to shrews. These ratios can be applied to extrapolate from whole body to liver concentrations to facilitate risk assessment by allowing comparisons to existing small mammal toxicity laboratory studies.

MP181 A New Rapid Test to Estimate the Influence of Chemical Substance on Algal Growth Based on Delayed Fluorescence M. Katsumata, Hamamatsu Photonics K.K., Central Research Laboratory; T. Koike, Hamamatsu Photonics K. K., Electron Tube Center; K. Kazumura, A. Takeuchi, Y. Kobayashi, Y. Sato, Hamamatsu Photonics K. K., Central Research Laboratory; N. Tatarazako, National Institute for Environmental Studies, Center for Environmental Risk Research, National Institute for Environmental Studies, Endocrine Disrupter Research Laboratory; Y. Sugaya, National Institute for Environmental Studies, Research Center for Environmental Risk. We are investigating the utility of delayed fluorescence (DF) from algae as a rapid and simple measurement method to estimate algal growth inhibition. The DF is a special type of luminescence; it detects the growth of only those cells that have photosynthetic capability. Since the DF originates from re-excitation of chlorophyll by a reverse reaction of photosynthetic electron transfer, the DF inhibition reflects inhibition of photosynthetic activity that is necessary for growth. Therefore the DF is a potential endpoint for estimation of the influence of chemical substance of algal growth in a shorter time than the conventional 72 hours growth inhibition test (e.g., OECD test guideline 201, TG201). We have developed a rapid and simple test protocol for the DF inhibition test using an ultra-sensitive luminometer that measures the DF in a simple operation. The test protocol uses the green alga *Pseudokirchneriella subcapitata* (*Selenastrum capricornutum*). In our protocol, the algae is prepared as a frozen (-80°C) sample. The test algae are prepared by thawing the frozen algae 1 hour prior to the start of the experiment in order that the cultured cells are in the exponential growth phase. The prepared test algae can be immediately exposed to a test chemical substance in small culture tubes (volume is 10 ml). The DF from algae in the culture tube is directly measured by the ultra-sensitive luminometer at 15 minutes, 1 hour, 4 hours, 8 hours and 24 hours after exposing of the sample. The culture tube does not need to be opened. The DF is inhibited by the influence of the test chemical substance. From the relationship between the exposure concentration and the DF inhibition, the median effective concentration (EC_{50}) is calculated. Our results of 40 substances for which the EC_{50} values are already known (9 phenols, 8 anilines, 6 amines, 9 carboxylic acids, 3 alcohols and 5 others).measured at 15 minutes to 24 hours after the exposure have good correlation with the EC_{50} values obtained according to the TG201 standard method. In addition, even after 15 minutes, there is good correlation.

MP182 An Analysis of T-REX for Use in Assessing Pesticide Risk to Threatened and Endangered Birds J. Sullivan, Ardea Consulting; J.D. Wisk, BASF Corporation, Ecotoxicology. The US Environmental Protection Agency developed and uses the Terrestrial Residue EXposure (T-REX) model to estimate pesticide residues on wildlife food. The specific food categories included are tall and short grass, broad-leafed plants, seeds, fruits, pods, and large and small insects. Three bird body sizes (20 g, 100 g, and 1000 g) are included in the standard T-REX output. The US Fish and Wildlife Service lists 93 bird species, subspecies, or populations as threatened or endangered (T&E). We assessed whether T-REX adequately estimates pesticide exposures for T&E birds. The avian food-body size combination with the highest estimated residues is short grass and 20 g birds. We discovered that no T&E bird weighing approximately 20 g that eats short grass exists. Many listed species are represented when T-REX considers risk for listed insectivorous species in the 20 g size class. However, no species in the larger size classes of 100 and 1000 g are predominantly insectivorous. Fruit and seed eating listed species occur in each of the size classes that T-REX uses, so the T-REX analysis will appropriately represent the potential risk for fruit or seed-eating listed birds. T-REX does not include any EECs for aquatic dietary items or nectar, terrestrial vertebrates and non-insect invertebrates. Roughly one-third of the listed species have diets that do not emphasize any of the dietary items included in T-REX. Slightly more than half the species have diets that include large contributions by dietary items not included in T-REX.

MP183 Application of LiDAR-derived High-resolution Elevation Data for Characterizing Natural and Agricultural Features Affecting the Transport of Pesticides J. Amos, Waterborne Environmental, Inc., GIS Specialist, Waterborne Environmental, Incorporated, GIS Specialist; C.M. Holmes, Waterborne Environmental, Inc.; J. Bang, Syngenta Crop Protection, LLC, Environmental Safety; L. Fish, Sygnenta Crop Protection, LLC , Environmental Safety; P. Hendley, Syngenta Crop Protection, LLC., Senior Syngenta Fellow. Terrain elevation data play an important role in characterizing natural and anthropogenic agricultural features affecting the transport of water, sediment, nutrient, and chemicals at the field and watershed scale. LiDAR (LIght Detection And Ranging) is emerging as a technology of choice due to their high resolution and accuracy and increasing public availability. This study was conducted to examine the utility of a LiDAR -derived DEM (digital elevation model) in assessing natural and managed agricultural features potentially affecting runoff covering a 60 square mile region in Nebraska. Processing was conducted using publically available LiDAR and Geographic Information System (GIS) data within standard GIS software and functions. Quantitative metrics describing the topography, hydrology, and natural vegetation elevation were calculated from the LiDAR data and summarized for all fields in the study area. Integrating high resolution aerial imagery with the LiDAR data enabled the identification of engineered features such as terracing, overhead irrigation, and intakes for tile terracing systems. Natural processes identified in the data include concentrated and diffuse flow patterns towards the edge of a field; in-field depressions with the potential for surface water storage; and vegetation diversity of riparian areas characterized by canopy height and density. This study is intended as an initial examination into the utility of LiDAR to assess field runoff vulnerability and assist with stewardship and best management practices.

MP184 Application of the SWAT Model to Assess California Red-legged Frog Exposure to an Insecticide with Agricultural and Residential Uses M. Winchell, Stone Environmental, Inc., Senior GIS Specialist, Stone Environmental, Inc., Senior GIS Specialist, Hydrologist; S. Folle, Stone Environmental, Inc.; R.L. Breton, Intrinsik Environmental Sciences, Inc.; P. Whatling, Cheminova, Inc., Senior Manager of Regulatory Science. The estimation of environmental concentrations of pesticides for use in quantifying the risk of exposure to endangered species for regulatory purposes is based upon a single field model (PRZM) draining into a static pond model (EXAMS). While this approach provides conservative estimations of environmental concentrations (EECs) that could potentially impact species such as the California Red-Legged Frog (CRLF), it does not represent the concentrations that would be expected to occur in habitat areas that are influenced by more complex hydrology and heterogeneous land use/agronomic conditions. To evaluate pesticide concentrations in these more complex aquatic habitats, a Soil and Water Assessment Tool (SWAT) model was developed for a highly vulnerable watershed of significant importance to CRLF habitat. Several candidate watersheds were identified through a spatial analysis exercise that assessed cumulative upstream pesticide use in each NHDPlus stream segment flowing through CRLF core and critical habitat areas. The soil characteristics of the watersheds containing stream segments with the highest pesticide use intensity were assessed and the watershed with the greatest proportion of vulnerable soils was selected. The SWAT model was constructed to allow a wide range of pesticide application scenarios based upon historical use patterns extracted from the California PUR database. Given the uncertainty of the spatial and temporal distribution of pesticide applications at the watershed scale, a Monte Carlo approach was adopted to simulate a large number of possible 30-year pesticide application scenarios. This allowed for the prediction of a more complete range of possible pesticide EECs to which the CRLF may be exposed. The approach developed expands upon standard field-scale modeling methods, resulting in a more realistic simulation of complex environments important to ecological risk assessments.

MP185 Are Measures of Biochemical Parameters Reliable Predictors of Long-term Ecologically Significant Effects? K. Jenkins, S. Brenda, S. Huntley, J. Holder, P. Goodrum, ERM. Evaluations of risk/injuries to ecological receptors have most often focused on measures of mortality, impaired growth and reproduction. These measures of injury are easily understood and provide information on both acute and chronic toxicity. These data can also be incorporated into quantitative population models that can be used to evaluate the effects of increased mortality or reduced reproduction on the sustainability of local populations. Field studies evaluating metrics such as species abundance and diversity have also been used to directly measure the condition of populations or ecological communities in the field. However, field studies are challenging for very large sites such as that being evaluated following the Deepwater Horizon Oil Spill. Further it is often difficult to relate changes at the population/community level to specific events. Recently, it has been suggested that biochemical parameters used to evaluate chemical exposure history as well as possible mechanisms of toxicity, can also be used as measures of possible ecologically significant effects. For example in response to an oil spill, the cytochrome P450 1A (CYP1A) enzyme, can be induced in response to exposure to certain petroleum related compounds is often used as an indicator of exposure. It has also been proposed as a measure of deleterious effects. However, in the absence of a comprehensive evaluation of the relationship between biochemical responses and overt toxic responses, the reliability of biochemical parameters such as CYP1A to predict overt toxicity to individuals, is equivocal at best. Such an evaluation must consider, at a minimum: (1) the specificity of the biochemical parameter; (2) the mode of action for the toxic response of interest; (3) the implications of various intervening and confounding variables; and (4) the degree of parallelism in dose-response between the biochemical parameter and the toxic response or higher level service losses. Based on an evaluation of the available data for several biomarkers including CYP1A in fish we conclude that while some biochemical parameters may provide indirect information regarding exposure to classes of chemicals, they are not reliable predictors of ecologically significant risk or injury to individuals or populations. The basis for these conclusions will be discussed.

MP186 Comparison of Three Leaching Models of Different Complexity for Estimating Shallow Groundwater Concentrations T.L. Estes, Stone Environmental, Inc.; W. Chen, Syngenta Crop Protection LLC. Leaching of agricultural chemicals in soil depends on a number of factors, including field hydrological properties, local meteorology, use patterns and environmental fate characteristics of the agricultural chemical. Computer models for chemical soil leaching assessment take into account these factors to a varying degree. This presentation evaluates three models, SCI-GROW, PRZM, and WINPRZM, each of which has a different level of representation for these factors. SCI-GROW is a Tier 1 US Environmental Protection Agency (EPA) regulatory model which is based on a regression calibrated with shallow groundwater monitoring data. PRZM, also an EPA regulatory model, is a comprehensive field scale model which takes into account all major hydrological, meteorological, and environmental fate factors in an agricultural field. WINPRZM is a European regulatory model which was developed based on PRZM with an enhanced environmental fate subroutine incorporating time-dependent sorption. For each of the models, a regional scale soil data set is used and distributions of model outputs will be compared using a group of statistical metrics to evaluate the sensitivity of the processes each model represents. Propagation of variability in inputs and simplification of the environmental fate processes as well as the validity of using simple models for regional scale leaching assessments will be examined.

MP187 Conceptual Model for Ecological Risk Assessment in the Aquatic Environment Using Environmental Monitoring Programs K. Tallini, Federal Institute of Education, Science and Technology of Rio Grande do Sul, Porto Alegre Campus, Biotecnology; R.d. Magali, Federal Institute of Education, Science and Technology of Rio Grande do Sul, Porto Alegre Campus, Environmental; M.T. Raya-Rodrigues, Federal Univ of Rio Grande do Sul, Ecology Center. The aim of this study was to establish a conceptual model for ecological risk assessment for the aquatic environment using data from environmental monitoring programs for surface water and sediment compartments, usually established by environmental monitoring agencies in Brazil. The investigative scenario was based on chemical, ecotoxicological and biological data from environmental monitoring in Baixo Jacuí, in the town of São Jerônimo, in the State of Rio Grande do Sul, Brazil. The proposed model for ecological risk assessment in aquatic environments is composed of four stages. The first stage of the risk assessment model entails collecting chemical, ecotoxicological and biological information on surface water and sediments in four different sampling locations of the environment under study. The second stage involves investigating the chemical and ecotoxicological evidence on the basis of applying Brazilian environmental legislation to the Resolutions of the National Environmental Council No. 357/2005 for surface water and No. 344/2004 for sediments. In this model, the lines of evidence registered in the abiotic compartments were treated as an explanatory variable. The chemical evidence resulted from the presence of

Hg, Pb and Zn and the ecotoxicological evidence from the aquatic toxicity tests with *Ceriodaphinia dubia* for surface water and *Hyalella azteca* for sediment. In the third stage, the biological evidence was evaluated as a response variable, composed of the richness data, Shannon-Weaver index, species evenness and numerical density of the zooplanktonic and benthic communities. In the final stage, the relationship between the explanatory and response variables was evaluated statistically. In this model, the ecological risk assessment was categorized as Low, Medium and High and was associated with the environmental quality of Excellent, Warning and Critical, respectively, established by the lines of evidence recorded at the sites monitored. The results showed that the investigative line of the chemical evidence, when compared to the lines of the ecotoxicological and biological evidence, clearly indicated signs of greater risk for both environmental compartments. The results enable the consideration that it is possible to use environmental monitoring programs for ecological risk assessment, if they contain, in addition to chemical and ecotoxicological data required by environmental legislation, monitoring data of the resident biota.

MP188 Construction of Chemical Toxicity Prediction Model by Using Experiment Date, Mainly on Branched Nonylphenol Isomers K. Arizono, Prefectural Univ of Kumamoto, Faculty of Env. & Symbiotic Science; H. Ji, Kumamoto Prefectural Univ; C. Sun, Kumamoto Prefectural Univ. The eighteen kinds of branched Nonylphenol (NP) isomers were used to build a Quantitative Structure-Activity Relationship (QSAR) model for predicting the toxicity of all the branched Nonylphenol Isomers. Acute toxicity evaluation of these 18 kinds of NP isomers was performed. The toxicity of these NP isomers was found relating to their chemical structure. Basing on the relationship between toxicity and chemical structure of these NP isomers, QSAR model was built for predicting toxicity of branched NP isomers. This QSAR model realized the toxicity prediction for all the branched NP isomer. In addition, toxicity effect evaluation of NP isomers mixture existing in the environment was performed by this QSAR model. The result showed that this QSAR model has a good applicability on evaluating the toxicity effect of NP isomers mixture existing in the environment.

MP189 Crude Oil Impacts in an Amazonian Wetland S.C. Peterson, Environmental Resources Management (ERM); K.A. Morris, D. Ross, H. Pirela, ERM; S. Stout, NewFields. An oil exploration and production facility located in an otherwise undisturbed area of the Amazonian lowland rainforest experienced releases of crude oil and produced water over a period of years, resulting in a large impacted area. Historical and recent aerial photographs and satellite imagery were used to define the extent and progression of the impact and subsequent natural recovery. This evidence, along with on-site observations, indicated that the oil was highly weathered, and the majority of the Site was undergoing significant natural re-vegetation of the impacted soils by both native and non-native wetland flora. To guide planning for an accelerated remediation and restoration of the Site, a comprehensive investigation and an ecological risk assessment was performed. Soil, surface water, and sediment samples were collected along transects in several distinct areas of the Site, as well as from offsite non-impacted areas, and submitted for detailed analysis of petroleum hydrocarbons using forensic chemical techniques. The chemistry results were used to identify and evaluate the degree of weathering of the crude oil, and to assess the potential bioavailability and ecological risks from residual constituents such as TPH fractions and PAHs. Samples were also submitted for microbial analysis to evaluate the presence and level of activity of petroleum degrading bacteria. In conjunction with the laboratory analyses, a field investigation was conducted to characterize vegetative diversity and vigor of plant growth. The chemical and microbial data confirmed that the oil is weathering and degrading due to the activity of a consortium of indigenous microbes, and significant mass removal of petroleum hydrocarbons is occurring naturally. The more bioavailable, lower carbon range fractions of petroleum hydrocarbons have been largely eliminated, leaving only a weathered and tarlike residual that is unlikely to cause significant toxicity to native fauna and flora. Parameters of vegetative succession were correlated with the degree of petroleum degradation, showing the potential for plant and animal communities to return to a more natural condition. Based on these results, the concept of exposure zones was used to identify areas of varying risk and to provide a framework for remedial planning.

MP190 Current Conditions of *Pteria sterna* (Gould, 1851) in Bahia de la Paz, Baja California, Mexico P. Ramirez Romero, Universidad Autonoma Metropolitana, Hidrobiologia, U.A.M. Iztapalapa, Depto. De Hidrobiologia; M.G. Miranda Arce, L. Espejel Pina, X. Guzman Garcia, I. Hernandez-Calderas, G. Barrera Escorcia, Universidad Autonoma Metropolitana, Hidrobiologia; I. Wong Chang, C.L. Fernandez Rendon, Universidad Nacional Autonoma de Mexico, ICMYL *Pteria sterna* (Gould, 1851) is a protected species that produces high quality pearls. Even though there are some investigation about its culture, the decline of numerous populations due to environmental deterioration implies the need of integral studies to detect the effects of human activities on this resource. The objective of the present work was to obtain an histological description of the clam and to describe the concentrations of some contaminants that may affect them (metals and fecal coliform bacteria). Clams, water and sediments were collected in Bahia de La Paz in 2010. Histological analysis followed standardized methods, routine Hematoxyline-Eosine stain and PAS and Masson histochemical techiniques. Cd, Cu, Cr, Pb y Zn concentrations in sediments were determined with an Solar AA spectrophotometer. Sanitary quality was evaluated following Mexican standards and enteric bacteria identification was done through traditional culture. Some histological characteristics indicated good conditions of the clam, like the male gonads; however the presence of mucopolisacarids and fibers suggest defense reactions in response to environmental stressors. Metal sediment concentrations do not represent any risk for the clam, only cadmium was above sediment guidelines during the rainy season in the site called La Sirena. Microbiological analysis indicated that the water sanitary quality occasionally exceeded the quality guidelines, but the clam had an acceptable quality for consumption. *Escherichia coli* was isolated from clams, *Salmonella* spp. from sediments and *S. choleraesuis* from water, this implies the need for systematic monitoring.

MP191 Development of Evaluation Approach Towards Ecological Effect of Gaseous Sample on *Orius strigicollis* S. Komatsu, R. Shichi, Tokyo National College of Technology, Chemical Science and Engineering; R. Shoji, Tokyo National College of Technology. Dichlorovos (dimethyl dichlorovinyl phosphate) is one of the most widely used volatile organic pesticide known for its high toxicity and volatile behavior. Though, there are many toxicity tests for dichlorvos were done in aqueous solution, in gaseous environment is yet to be developed. In this study, *Orius strigicollis* were used as a test organism to determine the toxicity of dichlorovos under vaporized condition. Also, authorized methods such as ROTAS® (Rapid Onsite Toxicity Audit System) and acute toxicity test using *Artemia salima* were conducted for comparison. As for result, toxicity test using *Orius strigicollis* showed similar sensitivity to those authorized methods. Therefore, toxicity test using *Orius strigicollis* can be a promising toxicity test on volatile organic pesticide.

MP192 Development of Site-specific TCDD Bioaccumulation Equivalency Factors for Estimating Chlorinated Dioxin TEQs in Discharges to San Francisco Bay S. Klosterhaus, D. Yee, J. Ross, San Francisco Estuary Institute. The use of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) bioaccumulation equivalency factors (BEFs) has been proposed for consideration in the determination of chlorinated dioxin toxic equivalent (TEQ) concentrations in wastewater effluent. BEFs, which have been adopted for use by the USEPA to account for differing levels of bioaccumulation potential among dioxin and furan congeners, have been derived using fish tissue and sediment data from the Great Lakes and are assumed to be representative of all ecosytems. In this study, TCDD BEFs derived from dioxin concentrations in two species of San Francisco Bay sport fish (white croaker and shiner surfperch) and surface sediments collected in 2009 were compared to the BEFs derived from the Great Lakes data. Both sets of BEFs were applied to San Francisco Bay wastewater effluent data to assess differences in the resulting TEQ concentrations. The dioxin biota-sediment bioaccumulation factors (BSAFs) used to derive BEFs for San Francisco Bay will be presented and discussed along with the BEF and TEQ results. Results from this work will contribute to the development of a water quality management strategy for dioxins (e.g., TMDL), which is currently being considered for San Francisco Bay.

MP193 Differential Body Burdens of Various Compounds in Co-Occurring Marine Bivalves J. Cura, Woods Hole Group, Risk Assessor, The Science Collaborative, Risk Assessor; J. Occhialini, Alpha Analytical; D. Vorhees, The Science Collaborative North Shore. Research over the past ten years has demonstrated that bioaccumulation of chemicals depends variously on the chemical properties, the species of organism, temporal differences,

environmental conditions, and the exposure history of an organism. There is ample evidence that under field and laboratory conditions, contaminant concentrations in tissue are often species-specific. For example, investigators have observed species differences in bioaccumulation of: Zinc between two filter feeding co-located epibenthic organisms (mussels and barnacles); PCBs between a deposit feeding and a filter feeding bivalve in laboratory uptake experiments; Various metals and PCBs between mussels and oysters observed in long term regional monitoring data in San Francisco Bay; Cadmium and copper among grass shrimp, mussels, and quahogs in controlled muti-element laboratory exposures; PAHs among various benthic species. These authors comment upon the implications of differential uptake and accumulation when selecting organisms for toxicity testing, bioaccumulation testing, or monitoring. These differences pose an uncertainty of generally unknown magnitude in ecological and human health risk assessments which often depend upon a small number of representative species. Risk assessors commonly select representative species to represent various trophic levels or vulnerabilities (ecological risk assessors) or ingested food types (human health risk assessors) with uncertain knowledge regarding the range of differences in bioaccumulation that may occur even among species of the same feeding type or taxonomic family. This work measures the range of tissue concentrations for various metals and organic chemicals among co-located bivalves that are both prey for local animal species and a regular food source for recreational shell fishers. We discuss the implications for selecting representative species in ecological risk assessment and selection of recreationally caught species in human health risk assessment.

MP194 Differential mRNA Expression of Metallothionein and Vitellogenin in *Chironomus riparius* Larvae Exposed to Various Environmental Pollutants K. Park, Chonnam National Univ, Fisheries and Ocean Science; I. Kwak, Chonnam National Univ. We characterized the metallothionein (MT) and vitellogenin (VTG) cDNA in *Chironomus riparius* and evaluated their mRNA expression profiles following treatment with different environmental pollutants. The objective of this study was to identify the possibility for the use of Chironomus MT and VTG as biomarkers of stress caused by endocrine-disrupting chemicals (EDCs), heavy metals, herbicides and veterinary antibiotics. The gene expression analysis showed that the MT mRNA levels increased significantly after long-term exposure to cadmium (Cd), copper (Cu), Lead (Pb), di(2-ethylhexyl) phthalate (DEHP), and 2,4-dichlorophenoxyacetic acid (2,4-D). Additionally, down regulation of the MT mRNA was observed in *C. riparius* exposed to 4-nonylphenol (NP) and fenbendazole (FBZ). However, bisphenol A (BPA) treatment did not activate the MT mRNA level. Moreover, the VTG mRNA expression increased significantly in *C. riparius* larvae exposed to BPA, NP, DEHP, Cd, 2,4-D and FBZ. Evaluation of the long-term effects of environmental pollutants revealed up regulation of Chironomus MT mRNA in response to DEHP exposure of the EDCs, and the level of the VTG mRNA was increased significantly following treatment with Cd and herbicide 2,4-D at all concentrations in a dose-dependent manner. These results indicate that MT and VTG could be used as potential biomarkers of herbicide and veterinary antibiotics as well as heavy metals and EDCs in aquatic environments.

MP195 Does Size Matter? Accounting for Scale of Use in Bird and Mammal Risk Assessment M. Reed, Chemicals Regulation Directorate; J. Crocker, Food and Environment Research Agency. Current approaches to regulatory risk assessment for birds and mammals in Europe are based on exposure of animals visiting treated crops. The assessment is the same for minor and major crops. Whilst at the single field scale the risk is the same at the regional scale the area a pesticide could be used would have an effect on the level of risk to the regional population. Where a risk assessment for a major crop shows an acceptable risk but for a minor crop it does not it is necessary to decide whether the small area treated can count in mitigation for the product's use on a minor crop. The aim of this poster is to present 3 approaches to including the area of crops in the risk assessment: 1. Extrapolation from the major crop to the minor crop. If the minor crop is similar to the major it may be possible to adopt the refined risk assessment from the major crop for the minor crop. 2. A rule of thumb setting the area below which pesticide effects on birds or mammals would be acceptable. This relies on being able to determine this area. It could be a rule in which a scale of use that would affect e.g., < 1% of arable land is authorised. 3. Isoclines describe an acceptable level of pesticide effects on populations and show how the corresponding acceptable area of pesticide use varies with the TER calculated in the risk assessment. This approach combines both severity of effects and the area affected. Isoclines predict realistic worst-case effects of a pesticide on mortality and breeding success and place these local effects into a broader context, predicting effects at the population level. The isoclines have been drawn using the output from population models. Current decision making uses the first approach where possible. If extrapolation is not possible an alternative is required. The rule of thumb accepts as a premise that local effects on bird or mammal populations could occur (up to failure to breed successfully) but that these would be over a small enough area not to effect the population on a regional scale. This is not in line with current risk assessment which aims to protect the edge of field population. The isoclines approach also accepts that there could be some effects on local populations. The use of population models attempts to quantify the level of effect to allow decisions to be based on the level of risk and the area affected. There remains a question over whether any level of effects can be accepted for a species of bird that is already in decline.

MP196 Evaluating the Ecotoxicity of American Petroleum Institute-sludge, a Petrochemical Waste, in Various Soil Types Using Three Soil Organisms M. Van Wyk, Univ of Stellenbosch, Deptartment of Botany and Zoology, Univ of Stellenbosch, Dept of Botany and Zoology; S.A. Reinecke, Univ of Stellenbosch; A.J. Reinecke, Univ of Stellenbosch, Dept of Botany anf Zoology – Stress Ecology Research Group; R. Albertus, Sasol Technology. American Petroleum Institute (API) -sludge consists of a mixture of oil and water soluble contaminants originating from the process of separating refinery waste from reusable water and oil. To establish the soil toxicity of such API-sludge to soil organisms, different standardized soil types as well natural soil obtained from a South African refinery was used. Bioassays together with chemical analyses of the API-sludge were executed to thoroughly investigate the effects of different contaminants present in the mixture and its bioavailable fraction. Two standardized soil types, OECD soil and LUFA2.2 soil, were used in these experiments. A third natural soil, obtained from a site close to a South African refinery, was also included in this study to represent a soil type with potential risk of being contaminated by such petrochemical wastes. This soil was analyzed physically and chemically and included in the bioassays. Three soil species were used in the standardized tests: Two Oligochaetes, *Eisenia andrei*, *Enchytraeus doerjesi* and a Collembolan species, *Folsomia candida* were exposed to the respective soils to study their survival, growth (for *E. andrei*) and reproduction success. *F. candida* showed juvenile production of 479.89 ± 30.42 where as *E. doerjesi* produced only 57 ± 34.39 juveniles in the natural soil. *E. andrei* produced 18.5 ± 9.7 cocoons when exposed to the natural soil. To determine the sensitivity of the organisms to the API-sludge, they were exposed to a concentration series of API-sludge-spiked control soils. The effect concentrations were calculated as the concentration of API-sludge that will decrease the studied endpoints by 50% of the control soils (EC_{50}). The EC_{50}s varied for each species exposed in the different control soils showing that the toxicity of the API-sludge is to a certain extent dependent on the physical soil properties. The reproduction of *F. candida* were most sensitive to the API-sludge in natural soil (EC_{50} = 90 mg/kg) and the *E. doerjesi* the least sensitive in LUFA2.2 soil (EC_{50} = 36000 mg/kg). From the chemical analysis can be suggested that it is the volatile organic carbon fraction in the API-sludge that is responsable for its toxicity.

MP197 Evaluating the Human Relevance for a Potential Carcinogenic Mode of Action for Naphthalene – an Hypothesis-based Weight of Evidence (HBWoE) Approach L. Bailey, J. Goodman, L. Rhomberg, Gradient. Human health risk assessment consists of bringing to bear a large body of in vitro, animal, and epidemiologic studies on the question of whether environmental exposures to a substance are a potential risk to humans. However, the body of scientific information is typically unclear and often contains apparent contradictions; therefore, often only possible conclusions about potential human risks may be surmised from the data and may vary from very strong to tenuous. The task, therefore, is to also effectively communicate the uncertainties within the data, giving proper consideration to contrary data and alternative scientifically plausible interpretations. The National Toxicology Program (NTP) inhalation bioassay data for naphthalene showed an increased risk for nasal tumors in rats and lung tumors in mice, and although cytotoxicity and hyperplasia were observed in mouse nasal and to some extent in rat lung tissue, tumors were not observed in these tissues. CYP2F metabolism of naphthalene to its epoxide and cytotoxicity has been invoked as a potential carcinogenic mode of action (MOA) for naphthalene, and there is CYP2F activity in

mouse lung and in rat and mouse nasal epithelium. The lack of mouse nasal tumors, despite the observation in the mouse nose of other key events in the proposed MoA, needs to be accounted for, and the weight of evidence for the proposed MoA (and its application to potential human risk) depends on the degree to which a supportable explanation can be identified that is in accord with known science and makes sparing use of post-hoc assumptions to accommodate the apparent discrepancy. We evaluate the available data for naphthalene, through the Hypothesis-Based Weight of Evidence (HBWoE) approach, considering potential key events in the MOA in each species and tissue: metabolism by CYP2F, cytotoxicity, chronic inflammation, potential genotoxicity, regenerative hyperplasia, and tumor formation. We evaluate the weight of evidence in support of a cytotoxic MOA, in addition to alternative MOAs that have also been offered in the scientific community, noting the explanatory power of the proposed hypotheses, considering consistencies, inconsistencies, and contradictions within the data set, and how compelling each endpoint is as evidence of a similar MOA in humans from low levels of naphthalene exposure.

MP198 Generic Population Models for Ecological Risk Assessment N. Hanson, Univ of Gothenburg, Dept of Plant and Environmental Sciences, Univ of Gothenburg, Plant and Environmental Sciences; J.D. Stark, Washington State Univ, Puyallup Research and Extension Center, Dept of Entomology, Washington State Univ, Dept of Entomology. It has been argued that current approaches for ecological risk assessment (ERA) do not provide value relevance for risk managers, and that the uncertainty in the predictions is large. One important reason for this is that current approaches are based on individual level endpoints, while the environmental protection goals are found on the population level. Population models may be a useful tool to link the individual with the population, and thereby increase value relevance and reduce uncertainty. However, population models are often considered too complex compared to traditional measures of acute mortality and reproductive effects. Therefore, simple models, and guidance on how to use them, needs to be made available for risk assessors. Only if such models are available can population models gain momentum in ERA. In the present paper, generic models were developed for ERA of fish populations. Fish have high ecological and economic value, and are frequently used in ERA. It is, therefore, highly desirable to develop better methods for ERA of fish populations. The models were based on five types of life-histories, and they were set up to be useful in a number of different management scenarios based on different environmental protection goals. A decision framework was set up for three Tiers of models, and three levels of environmental protection. Data from previously published studies were tested at Tier I for two of the environmental protection levels. The models provided maximum acceptable concentrations (MAC) that fell between the MACs of traditional ERA based on acute or chronic data, respectively. Although this does not prove that the models provide better risk assessments, it clearly shows that traditional methods are likely to lead to erroneous estimates of safe limits (either over- or underprotective).

MP199 Hazardous Pollution in Tien-Shen I. Hadjamberdiev, Toxic Action Network Central Asia. There was Uranium Boiler of former USSR in Tien-Shen-Pamir areas, especially near settlements Adrasman, Ak-Tjuz, Chkalovsk, Kadji-Say, Mailuu-Suu, Min-Kush, Taboshar. There were obsolete methods of uranium wastages had been used in 50th. Uranium wastage pulp had been kept in the mountain gorges, coved by concrete with sands and soil, lie about 6-10 m only. There are tenth old tailings and dumps with other toxicants (mercury, cyanide, etc). Tremendous Mailuu-Suu uran mining area (West Tien-Shen), 23 tailings with total volume 2 mln m^3, contaminated river Mailuu-Suu water – uran 250-750 mg/L. Khaidarken (the mercury combine production volume was second in the World) situated in South-West Tien-Shen. The wastes contain (volume 4 mln tones), beside Hg, fluoric ore elements (Ar, Sb, F compounds). The tailings and damps permanent contaminated living area. Additionally, tailings are situated on height of 1700 m above sea level near river Zarhar, and can produce pollution of neighboring territory of Uzbekistan. Cyanide problem: gold combine in Tien-Shen produced biggest in Asia toxic tailing, 100 mln cubic m, but new lake situated upper the dump (which saved the tailing), can destroy dump, and wastes will flow down to river Arabel and Narin. Several big uranium tailings polluting during latest ten years, and could produce danger pollution of territory by throw down to rivers: 1) MinKush uran mining area (Central Tien-Shen), Tujuk-Suu tailing can be pour out to the rivers net Min-Kush – Kokomeren – Naryn and Toktogul water deposit; infiltrating throw dam steadfast increasing last 5 years; 2) North Pamir – Degmay uranium tailing – in cost of river Karamazar-Say, and 8 km near main CA Syr-Darja river; 3) Radioactivity in several points (former building of Adrasman) 160 mkR/hour. We study uranium and mercury pollution of the rivers water, groundwater, vegetables in the rivers cost. The health consequences (heritage and cancer diseases) due uranium and mercury exposure in the areas have been documented several years.

MP200 In Vitro Screening of 1,2- Dibromo-4-(1, 2-dibromoethyl) cyclohexane in Multiple Human Cancer Cell Lines for Possible Endocrine Disrupting Effects H. Scherr, Simon Fraser Univ, Biological Sciences; T. Beischlag, Simon Fraser Univ, Health Sciences; J.E. Elliott, Environment Canada, Pacific Wildlife Research Centre, Science and Technology Branch, Environment Canada, Pacific Wildlife Research Centre, Environment Canada, Canadian Wildlife Service. Many brominated flame retardants (BFRs) can be classified as endocrine disrupting compounds. Various health problems in both humans and animals have been attributed to BFRs. One BFR, TBECH (1,2- dibromo-4-(1, 2-dibromoethyl) cyclohexane), has recently been detected in the environment and biota, but very little is known of its environmental impacts. To identify whether or not TBECH has any endocrine disrupting capabilities, it was run through an in vitro screening process that included real-time PCR techniques in two different cell lines (human endometrial carcinoma cell line ECC-1, and human prostate cancer cell line LNCaPs), and use of the CALUX assay in the human breast cancer cell line T-47Luc4ARE (Androgen Response Element CALUX). We were interested in whether or not TBECH was able to cause expression in human androgen, estrogen, progesterone, and aryl hydrocarbon receptors. All cells were treated with environmentally comparable levels of TBECH alone and in combination with the respective steroid hormones to determine if the compound acts as an agonist, antagonist, or amplifies the effects of the hormones. For the aryl hydrocarbon receptors, cells were treated with environmentally comparable levels of TBECH alone and in combination with TCDD, a xenobiotics known to activate this receptor. RNA extraction and real-time PCR techniques were used to measure any gene expression that occurred due to activation or inhibition of the various receptors in ECC-1 and LNCaP cell lines. For the T-47Luc4ARE cell line, androgen expression was measured by the concentration of proteins produced from activation of the androgen receptor. Initial results indicate that TBECH does not act as an agonist in any of the receptors tested, however dihydrotestosterone activation potential is significantly decreased when in combination with TBECH in the T-47Luc4ARE cell line. These tests were meant to be preliminary steps in order to determine endpoints that will be examined more closely later on in a live zebra finch model.

MP201 Influence of Species-specific Attributes on Dietary and Tissue-based Exposure Assessments of Two Fish-eating Bird Species Exposed to PCDFs and PCDDs R.M. Seston, Dow Corning Corporation, Health & Environmental Sciences; T.B. Fredricks, Monsanto, Zoology; D. Tazelaar, Michigan State Univ, Animal Science, Cardno Entrix; W.R. Folland, M.W. Nadeau, P.W. Bradley, Michigan State Univ, Dept of Animal Science; J. Newsted, D. Kay, Cardno Entrix; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science; M.J. Zwiernik, Michigan State Univ, Dept of Animal Science. Selection of receptor species is a critical step in formulating the study design of ecological risk assessments (ERAs). The great blue heron (*Ardea herodias*; GBH) and belted kingfisher (*Ceryle alcyon*; BKF) are piscivorous predators that are often selected as receptor species for ERAs pertaining to persistent bioaccumulative contaminants in aquatic environments. Both species have similar dietary compositions, however their exposure characteristics including metabolic rates, foraging range, and site fidelity may differ. Matching receptor characteristics to site attributes and risk management goals ultimately determines the value of any ERA. The primary objective of the present study was to investigate the influence of species' life history characteristics in the selection of the most effective receptor. Sediments and floodplain soils of the Tittabawassee River (TR) downstream of Midland, MI, USA contain total concentrations of the seventeen 2,3,7,8-substituted polychlorinated dibenzofurans (PCDFs) and dibenzo-*p*-dioxins (PCDDs) ranging from $1.0x10^2$ to $5.4x10^4$ ng/kg dw. These concentrations of PCDD/DFs in sediments and soils are some of the greatest reported and are 10- to 20-fold greater than the regional background. As apical avian piscivorous predators, GBH and BKF were selected as aquatic-based receptor species within a broad group of receptors in support of an ERA. Both were

considered appropriate species for inclusion based on their presence on-site and great potential to experience elevated exposures to bioaccumulative PCDD/DFs. Exposure for both the GBH and BKF was quantified by predicting dietary exposure to contaminants and direct measurement of contaminants in tissues of each species. The degree to which these two lines of evidence converged for each species was evaluated by comparing biomagnification factors (BMFs) of select congeners between the two species. Ratios of site-specific predominant PCDD/DF congeners indicate that both species were foraging within the TR floodplain. However, BMFs for the GBH are lesser than those for the BKF. Differences in BMFs may stem from either species-specific metabolism or foraging behavior. Concentrations of PCDD/DFs in BKF tissues were greater than those observed in GBH, suggesting the restricted foraging range of BKF within 1 km of the nest burrow offers greater spatial resolution and maximal exposure compared to GBH.

MP202 Integration of Ecological Assessment in Computing Service Loss Thresholds M. Schuck, Geosyntec Consultants, Sr. Staff Risk Assessment Scientist, Geosyntec Consultants, Risk Assessment Scientist; A. Brandon, K. Kroeger, H. Cumberland, J. Tolson, Geosyntec Consultants. Estimating service loss for natural resource damage assessments (NRDA) under a habitat equivalence analysis (HEA) approach requires numerical service loss thresholds to be established for each chemical stressor impacting the ecosystem. For example, sediment PAH levels of 1 and 10 ppm could be established for service loss thresholds of 5 and 20 percent, respectively. These service loss thresholds are often developed through a literature review of toxicity studies linked to ecological effect levels (e.g., LOAEL, NOAEL). Cumulative effects from multiple stressors are then calculated by a multiplicative process in which the percent service loss from each individual stressor is applied successively to the remaining service level after accounting for other stressors. The process results in a service loss that can range from 1 to 100 percent and is reflective of cumulative effects based on literature-derived effects levels. However, calculated theoretical service losses based on effects levels are often not supported by site-specific evidence collected for CERCLA ecological assessments. In addition to concentration-based comparisons, ecological assessments utilize in situ toxicity studies and benthic and fish community assessments to evaluate the health of the ecosystem. A novel approach is proposed that calculates cumulative service loss in the context of the results of the ecological assessment. The results from the ecological assessment are utilized to establish a limit of potential service loss. Services loss estimates within the established limits are then calculated using the existing framework for concentration-based assessment and cumulative effects calculation. This novel approach provides a more realistic estimation of service loss and additional accuracy in the process for assessing natural resource damages.

MP203 Mitochondrial Dynamics and Autophagy Aid in Removal of Persistent Mitochondrial DNA Damage A.S. Bess, T. Crocker, I. Ryde, J.N. Meyer, Duke Univ, Nicholas School of the Environment. Mitochondrial DNA (mtDNA) integrity is critical for human health; however, it is unclear how persistent, helix-distorting mtDNA damage formed after exposure to environmentally important genotoxins such as ultraviolet radiation, mycotoxins and PAHs are handled. mtDNA may be particularly susceptible to these genotoxins due to the absence of nucleotide excision repair, the primary repair mechanism for such DNA damage in nuclear DNA. Mitochondrial dynamics and autophagy play key roles in maintenance of mitochondrial function and degradation. We investigated the removal of persistent mtDNA damage via mitochondrial fusion, fission and autophagy in *Caenorhabditis elegans*. We performed RNAi knockdown of mitochondrial fusion, fission and autophagy genes in UVC treated adult *glp-1 C. elegans*. Using a quantitative PCR assay, we observed significant removal of UVC-induced mtDNA damage in empty vector controls following five day recovery from exposure. Knockdown of autophagy, fusion and fission genes inhibited removal of UVC-induced mtDNA damage. These data indicate that autophagy, fusion and fission processes are required for the removal of persistent DNA damage in mitochondria in *C.elegans*. To better understand the mechanism by which mitochondrial dynamics aid in removal of persistent mtDNA damage, we investigated changes in mitochondrial dynamics (fusion/fission) following UVC exposure in mouse embryonic fibroblasts (MEFs). MEFs were transfected with mitochondrial matrix-targeted photoactivatable GFP (PA-GFP) and diffusion of PA-GFP through the mitochondrial network was measured following 405 nm laser activation of PA-GFP within a subset of mitochondria. UVC exposure significantly increased GFP diffusion in the mitochondrial network indicating an increase in mitochondrial fusion and/or a hyperfused mitochondrial morphology. Therefore, we propose a model whereby UVC-induced mtDNA damage is removed via fusion-mediated mitochondrial remodeling and subsequent fission and autophagy.

MP204 Multiple Line of Evidence Assessment of Sediments from Southern California Using California's New Sediment Quality Objective Protocols D.J. Greenstein, Southern California Coastal Water Research Project, Dept of Toxicology; S.M. Bay, Southern California Coastal Water Research Project, Toxicology Dept; K. Schiff, K. Ritter, A. Ranasinghe, Southern California Coastal Water Research Project; L. Tiefenthaler, Southern California Coastal Water Research Project, Watersheds. The California Sediment Quality Objectives (SQO) assessment framework was approved for use in 2009 to assess sediment quality in the state's enclosed bays and estuaries. The SQO framework uses sediment chemistry, toxicity and benthic community analysis in a multiple line of evidence approach. Each line of evidence has multiple endpoints and interpretation thresholds that were developed using novel statistical methods. The Southern California Bight 2008 Regional Monitoring Program (Bight'08) represents the first large-scale study designed to utilize the SQO framework. Assessments were performed on approximately 180 stations located in predominantly marine bays and estuaries. The random stratified sampling design of Bight'08 allowed for the calculation of the total area and percentage of area that fell into five assessment categories for four different strata (Bay, Marina, Port and Estuary). Estuary sites generally had the greatest magnitude and prevalence of chemical exposure and biological effects. Temporal trends in sediment quality over the last decade, as well as predictive relationships between the sediment toxicity or chemistry lines of evidence and benthic community impacts were also examined.

MP205 Next Steps in Endangered Species Risk Assessments C. Habig, Exponent, Inc., Compliance Services, Inc., Principal Scientist. As an integral part of its registration review program, EPA is conducting screening level endangered species risk assessments for pesticides. These assessments, which evaluate potential effects on endangered birds, non-target mammals, fish, aquatic invertebrates, and non-target plants, typically consist of EPA's standard, national-level screening risk assessments for pesticides. These screening-level assessments are inherently intended to be conservative, so if a pesticide-use combination passes this initial assessment, there is a relatively high degree of confidence that those uses of the product will not adversely impact endangered or threatened species. However, if the use of a product fails this initial assessment, the conclusion should not be that use of the product is likely to adversely impact endangered species; rather, the conclusion should be that the risk assessment should be refined. However, EPA does not conduct a refined assessment. Instead, those uses of the product that fail the initial assessment may be referred to the Fish and Wildlife Service (FWS) or the National Marine Fisheries Service (NMFS; collectively, the Services)) for further evaluation in a Biological Opinion (BiOp). The Services approach to risk assessments of pesticides differs considerably from the approach that EPA and registrants typically use. Therefore, registrants are encouraged to conduct a higher-tier risk assessment to evaluate the potential for uses of a product that fails a screening level risk assessment to impact endangered species. A higher-tier risk assessment can involve several levels of refinement. This paper provides examples of several types of refinements, including more detailed, specific use information, more specific information relating to endangered species that may be impacted, refinements in potential exposure, and refinements in toxicity endpoints, that can used to address endangered species concerns.

MP206 Spatially Defining Relationships Between ESA-listed Species and Pesticide Uses in Agricultural Crops A. Frank, Compliance Services International, Principal Consultant; G. Konkel, Compliance Services International; T. Hall, Bayer CropScience, Ecotoxicology. In the conduct of FIFRA risk assessments related to evaluating the potential risk to species listed by the Endangered Species Act (ESA), the Environmental Protection Agency (EPA) Office of Pesticide Programs (OPP) relies upon various sources of data, including spatial and temporal data that can help define "proximity" of a known species location or habitat to potential product use. Additionally, the Services (US Fish & Wildlife Service and National Marine Fisheries Service) are interested in the spatial representation of a crop when FIFRA endangered species matters are forwarded to them for consultation.

When a proposed use is associated with a given crop, spatial definition of where that crop occurs is achievable through various mechanisms: the soil or climate conditions required to support the crop, USDA Agricultural Statistics on where the crop is, or has been, grown, and land cover data on the distribution of the crop, as provided through USGS, NASS and other resources. This poster will illustrate how different data sets can be used in the FIFRA risk assessment setting to spatially define relationships between ESA-listed species and proposed product use in agricultural crops. A process for defining these relationships in rotational crop systems, or in crop systems over time, will also be explored.

MP207 Standardization of Wildlife Toxicity Reference Values Proves Elusive D.B. Mayfield, Gradient; A. Fairbrother, Exponent, EcoSciences, Exponent, Inc., EcoSciences. Wildlife toxicity reference values (TRVs) are routinely developed during screening level and baseline ecological risk assessments (ERAs). Risk assessment professionals often adopt TRVs from published sources in order to expedite risk analyses. The USEPA developed Ecological Soil Screening Levels (EcoSSLs) to provide a source of TRVs that would increase the consistency among screening analyses conducted for contaminated sites. We conducted a survey of publically available ERAs to evaluate uniformity in the use of wildlife TRVs across the United States. We evaluated more than 50 large-scale ERAs published in the last decade in order to understand current practices for wildlife TRV use and development within the risk assessment community. The use of no observed and lowest observed adverse effect levels (NOAELs and LOAELs) culled from published compendia was common practice among the majority of ERAs reviewed. We found increasing use of TRVs established in the EcoSSL documents; however, EcoSSL values were not used in the majority of the ERAs reviewed. There is still wide varability in TRVs selected for commonly studied contaminants (e.g., metals, pesticides, PAHs, and PCBs). Differences in selection of key studies used to derive the TRVs, in dose estimation, and in use of uncertainty factors result in TRVs that span multiple orders of magnitude for any one pollutant. This lack of consistency in TRV development leads to inconsistent and unbalanced remedial decisions on the national scale.

MP209 The Influence of Reproductive Strategy of Fishes on Sampling Protocols for Environmental Monitoring Programs for Industrial Effluents in Canada T.J. Barrett, Univeristy of New Brunswick, Dept of Biology; K. Munkittrick, Univ of New Brunswick, Canadian Rivers Institute, Univ of New Brunswick, Dept of Biology; M.R. van den Heuvel, Univeristy of Prince Edward Island, Dept of Biology. National environmental effects monitoring (EEM) programs in Canada have been developed for the pulp and paper and metal mining industries and a program is currently in development for municipal wastewater. The EEM programs include a fish population survey to assess impacts of these effluents of fish populations. A review of the pulp and paper EEM program has identified many surveys were conducted outside of the optimal period to identify reproductive impacts. A review of the more than 60 different species used in the EEM fish surveys identified different female reproductive patterns based on the number of spawning events per year and the timing and duration of gonadal recrudescence in females. Examination of temporal stability, minimum variability, and maximum development in female gonad size over a reproductive cycle for species of each reproductive pattern revealed optimal sampling periods to assess reproductive impacts for each reproductive pattern. The variability in ovary weight: body weight relationships and the variability in oocyte development in pre-spawning female fishes in Atlantic Canada were also examined to identify patterns that could be used to predict the reproductive strategies of fishes. The optimal sampling times will reduce the variability in the reproductive endpoints for the EEM fish survey and hence reduce sample sizes for lethal sampling. Predicting the reproductive strategy of fishes will enable researchers to gather baseline information on the reproductive biology of fishes and therefore identify optimal sampling periods to identify reproductive impacts for species whose life history is not well studied.

MP210 The Response of Benthic Organisms at Population and Community Levels Against Heavy Metal and Organic Pollution Gradients in Contaminated Sediments J. Khim, Korea Univ, Division of Environmental Science and Ecological Engineering; J. Ryu, Korea Ocean Research and Development Institute, Office of Policy Research; S. Kang, Korea Ocean Research and Development Institute, Maritime & Ocean Engineering Research Institute; C. Koh, Seoul National Univ, School of Earth and Environmental Sciences. The effect of sediment pollution on benthic organisms was investigated in the vicinity of a large sewage treatment outflow at Incheon North Harbor, Korea. Animal size, vertical distribution and standard community parameters were analyzed along a 3 km transect line (n=7). Univariate parameters showed a general trend of increasing species diversity with increasing distance from the pollution source. Multi-dimensional scaling analysis led to the clear separation of 3 locational groups, supporting gradient-dependent faunal composition. The innermost location was dominated by small sub-surface dwellers while the outer locations by large mid to deep burrowers. Looking for the size-frequency distribution, most abundance species (*Heteromastus filiformis*) showed the presence of larger size animals with increasing proximity to the pollution source. Meanwhile, species-specific vertical distributions, regardless of the pollution gradient, indicated that such shifts were due to species replacement resulting from a higher tolerance to sedimentary pollutants over some species. Overall, the present study highlighted that community and population level response to the polluted environment of the harbour reflected an integration effect, together with biological interactions.

MP211 The Responses of ERR Gamma Gene on *Chironomus riparius* Exposed to Endocrine-disrupting Chemicals K. Park, Chonnam National Univ, Fisheries and Ocean Science; I. Kwak, Chonnam National Univ. There is global concern with regard to the potential impacts of endocrine-disrupting chemicals (EDCs) on the aquatic environment. EDCs can interfere with the endocrine systems of a variety of organisms. In order to evaluate the effects of EDCs on the estrogen-related receptors (ERR) of *Chironomus*, we characterized full-length cDNA sequences of the ERR gene from *Chironomus riparius*. The complete cDNA sequence of the ERR gene was measured to be 1332 bp in length. The results of our phylogenetic analysis demonstrated that *C. riparius* ERR is most closely related to that of mosquitoes. The basal level of ERR mRNA was expressed abundantly during different life-history stages, with the exception of adult male. Additionally, ERR gene expression was induced to a significant degree in *C. riparius* exposed to bisphenol (BPA) and nonylphenol (NP) at all concentrations for short periods. After short periods of exposure to di(2-ethylhexyl)phthalate (DEHP), the response of the ERR gene was increased significantly at only 50 mg L-1 DEHP. However, under long-term exposure conditions, ERR expression was induced to a significant degree after BPA, NP, and DEHP exposures at all concentrations. Furthermore, increased ERR expression was also noted in the results of Western blotting with ERRγ antibody and on the luciferase reporter gene assay. Collectively, these findings indicate that EDCs influence the functions of ERR in Chironomus species.

MP212 Upper Columbia River Sediment Toxicity Evaluation Using a Reference Envelope Approach C. Irvine, CH2M Hill, Ecosystem Services; E. Byron, CH2M Hill, Environmental Services; F. Dillon, CH2M Hill. Remedial investigations are ongoing to assess the potential risks to ecological receptors in the Upper Columbia River (UCR), WA, where contaminants, primarily metals, may be present in sediment at concentrations that pose an unacceptable risk to benthic/epibenthic resources. A sediment sampling and laboratory toxicity testing program was conducted to assess the toxicity to benthic/ epibenthic resources from sediments. Over 387 samples were collected over the 150 mile Site for chemical analyses, 50 of which were also tested for toxicity. Toxicity testing included 10-day whole-sediment toxicity tests with the midge, *Chironomus dilutus*; 28-day whole-sediment toxicity tests with the amphipod, *Hyalella azteca*; and 7-day toxicity tests with the cladoceran, *Ceriodaphnia dubia*. A reference envelope approach, use of toxicity metrics (e.g., AVS-SEM, PEC-Qs, PW-TUs), and statistical analyses were used to identify relationships between sediment chemistry and sediment toxicity. At least one of the toxicity endpoints (i.e., survival, growth, biomass, or reproduction) for at least one test organism, was reduced relative to a reference envelope in 43 of 50 site sediment samples. However, only 16 samples differed from the reference envelope by what might be considered an environmentally relevant amount (< 80 percent of the reference envelope criteria). Statistically significant effects were observed in a total of 28 samples and occurred throughout the sampled length of the UCR. Effects were generally more prevalent closest to the US-Canada border and were more variable downstream. *Hyalella* growth and biomass were the most sensitive endpoints with the most number of samples with significant effects and with significant effects for all samples where effects were also observed for either Chironomids or *Ceriodaphnia*. Statistically significant but weak relationships existed between toxicity endpoints and metrics of sediment metals (i.e.,

SEM-AVS, mean PEC-Qmetals, summed PEC-Qmetals) and PEC-Qs for chromium, copper, and zinc. Zinc and copper PEC-Qs were the highest in most samples, suggesting that these two metals were drivers of adverse effects in sediment samples. The weight-of-evidence indicated that benthic/epibenthic resources are at risk. However, there was moderate uncertainty about these results because of the poor ability of the exposure metric-response / concentration-response relationships to predict toxicity.

MP213 Use of the Plant Bioindicator *L. multiflorum* for Ecological Risk Analysis of Air Emissions R.d. Magali, Federal Institute of Education, Science and Technology of Rio Grande do Sul, Porto Alegre Campus, Environmental; K. Tallini, Federal Institute of Education, Science and Technology of Rio Grande do Sul, Porto Alegre Campus, Biotecnology; M.T. Raya-Rodrigues, Federal Univ of Rio Grande do Sul, Ecology Center. Ecological Risk Analysis (ERA) is a tool used to assess the sustainability of ecosystems, allowing for a more accurate assessment of actual risk to ecological receptors affected by contaminants (Junger, *et al.*, 2005, Sousa, 2005; Nakagome, *et al.*, 2006; Arias, *et al.*, 2007; Niemeyer, 2007, Froehmer & Martins, 2008, Parkhurst, 1996). It is a scientific methodology for quantifying or perceiving the adverse effect risks of a pollutant on the environment (Mines & Lackey, 2009). The study was conducted in the vicinity of an oil refinery (January 2005 to March 2008) in Esteio (29°49´16″ S 51°08´09″ O), Rio Grande do Sul, Brazil. The aim was to develop and implement an ERA model in order to classify the risks associated with air emissions on the basis of using the bioindicator *Lolium multiflorum.* The latter associated the information from the effect of the stressors, derived from the atmospheric emissions of sulfur compounds, in the receptors, that is, in the tissue of the bioindicator. The percentage of accumulated sulfur was evaluated in the bioindicators, classified, in this study, as a response variable. This was integrated with the data of the SO_2 concentration in the atmosphere, which gave rise to the explanatory variables, toxic potential unit (TPU) and toxic exposure unit (TEU). TPU was defined as the quotient between the average concentration of SO_2 that exceeded the primary air quality standard and secondary air quality standard (CONAMA 03/90), indicating environmental concentrations of SO_2 that can affect the growth of the bioindicators through chronic effect. TEU was defined as the product of TPU and the exposure period of the bioindicators to a higher concentration than the primary air quality standard, indicating SO_2 concentrations that can affect bioindicators through acute effect. The classification TPU £ 1 unlikely ecological risk and TPU > 1 potential adverse effects were considered as evidence of risk. On the basis of the environmental quality data (Crittenden & Read, 1979; CONAMA 03/90; USEPA, 1989, Tarazona, 2000, Klumpp, 2001) the classes of ecological risk were established (low, medium and high). The integration between the explanatory and response variables on the basis of multivariate statistical correlation analysis with the use of SPSS software, version 13.0 for Windows, showed evidence of risk to vegetation surrounding the refinery when exposed to TPU greater than the unit.

MP214 Using Web-based Tools for Data and Project Management R. O'Boyle, C. Kessel, J. Ma, Exponent. The complexity of environmental projects and personnel involved have led to situations where data can be distributed across many organizations. This distribution of data and how it is handled at each level plays a significant role in the overall project evaluation and assessment. Distributed data can cause project delays, missed project deadlines, and excessive expenditures due to data contamination, the need to complete repetitive quality reviews, and loss of data, all of which could have regulatory impacts to the project. A database tool that is accessible to all project participants via web interface is one of the best avenues to get data and project information into the hands of potential users and decision-makers. This type of tool can be accessed from any location with internet access, allows for a central depository of all relevant project material, and can provide various levels of data access and retrieval. This poster will display a variety of web-based tools and concepts that can efficiently and effectively manage all aspects of a project (documents, data, schedules, personnel, etc).

MP215 A Streamlined Risk Assessment Approach for Remediation of Inustrial Facilities T. Biksey, WSP Environment & Energy, Director Risk Assessment, EHS Support Corporation, Director Risk Assessment. The objective of the risk assessment process is to provide the risk manager with the necessary information to develop and evaluate remedial alternatives for corrective action at a site that are protective of human health and the environment with a reasonable foreseeable land use (e.g., continued commercial or industrial activity). The basis for an acceptable potential risk can include incorporating engineering and institutional controls as part of the development of remedial activities. For example, institutional controls can be implemented for the restricted use of groundwater as a potable resource, or soil management operational plans can be used for current and future exposures that may occur due to soil disturbance activities in the paved areas (e.g., utility maintenance) or from excavation activities (e.g., new building construction). A streamline risk assessment framework was developed for application to an industrial facility that has the components of a baseline risk assessment, including current and future land use as an operating facility with commercial off-site uses, and a future hypothetical unrestricted residential use of the site. However, because the focus is continued industrial activity, the streamline risk assessment framework focuses on those potentially complete exposure pathways that will exist within the current and reasonable foreseeable land use. It is recognized that additional investigations and risk assessment may be necessary for future redevelopment of the site to meet unrestricted future use. A key focus of the framework is the selection of constituents of potential concern (COPCs). The COPCs are evaluated as potential risk-drivers based on the current and reasonable foreseeable land use. If the COPC is detected at a concentration greater than the risk-based screening criteria, but is not part of a complete exposure pathway associated with a reasonable foreseeable land use (groundwater used that is restricted as a potable resource), then the COPC is not evaluated further in the risk assessment process. The purpose of this streamline framework is to limit unnecessary sampling, analysis, and evaluation based on reasonable foresseable landuse, and to ensure that realistic remediation goals for human health and environmental risk-reduction are established.

MP216 Best Practices Document for Application of Geostatistics to Sediment Assessment and Remediation J. Schofield, CSC, CSC, Senior Environmental Scientist; P. Goovaerts, CSC, BioMedware, Inc; J.W. Kern, Kern Statistical Services, Inc. To support successful remedial projects, a rigorous approach is needed to accurately characterize sediment contamination, estimate sediment volumes, and evaluate achievement of clean up goals. For a number of historical projects such as the Hudson river, prediction of contaminated sediment volumes has been low biased which can result in projects being over budget, past schedule and ineffective, with no choice but to leave contamination behind. Geostatistical tools, originally developed for the mining industry, are being increasingly applied in sediment site characterization and proving useful to support many aspects of remedial projects. One benefit of geostatistics is that it provides a measure of the uncertainty of model estimates whereas with other methods decision makers are blind to the confidence bounds around the estimates, which might be very large. Although the geostatistical methods have been used in mining for decades and are being applied to a variety of new fields, several challenges arise during application. Geostatistics have not been widely applied to sediment projects, few publications on the effectiveness for these types of projects are available, and specific expertise is not common. Standard practices have not been developed and, as is the case with many statistical tools, proper use of geostatistical tools is critical to the accuracy of results. To address these challenges, a best practices document for application of geostatistics to sediment projects is being developed by the US Environmental Protection Agency. The document will detail critical processes (e.g., data distribution evaluation) for proper application of geostatistical tools. Because different stages of a project require different levels of rigor, the document will provide guidelines for selection of the most appropriate tool for each step. The guidance also will detail reporting and documentation requirements to facilitate reproducibility of model results. The availability of a best practices document will facilitate use of the best available tools to support remedial decision making and result in more accurate contamination characterization and volume estimates. The tools would be applied according to best practices while contributing to the creation of a pool of expertise that is currently lacking in the field.

MP217 CHIPs – Industrial Process Hazard Assessments for Potential Chemical Releases L. Barber, C. Hard, C. Rudisill, SRC, Inc.; T. Miller, J. Rhodes, R. Garret, Dept of Defense; J. Tunkel, SRC, Inc. The Dept of Defense performs contingency assessment activities on chemical hazards utilizing a suite of database-driven tools. The Chemical Hazard of Industrial Processes (CHIPs) database contains information on industrial processes that use or produce commercial chemical substances. In its original form, the CHIPs reference database was designed to aid in the analysis of the

commercial chemical substance production and infrastructure. This presentation provides an overview of the methodology that was developed for a new CHIPs product, Industrial Process Hazard Sheets (CHIPs-IPHS), that were designed to communicate the hazards associated with the large scale release of chemicals from facilities where they are manufactured, used, or stored. The CHIPs-IPHS methodology was developed to assess both the potential health (toxicological) and physical hazards for all chemical substances that are present at a facility. The challenge in developing the CHIP-IPHS methodology was to define the perspective required to adequately categorize hazards for liquids, solids, gases, and solutions associated with the full variety of industrial processes, including chemical-based manufacturing and mechanical-based processes that use chemical substances, as well as non-manufacturing facilities where they are present. CHIPs analyses are based primarily on data collected from public domain resources including quality compilations such as SRC's Environmental Fate Database (EFDB) and commercial subscription services. To account for the likelihood that a health or physical hazard may be encountered, a probability score is defined by assessing volume on site, volatility, and the potential for chemical release within the scope of each process. Preliminary health and physical scores are then obtained using bright-line criteria to address a chemical's toxicity and flammability or instability, respectively. Pairing these two sets of scores in a matrix reveals an initial hazard for toxicity and physical hazards (high, moderate, low, or negligible) that incorporates the uncertainties noted during the assessment. The resulting hazard for each chemical is the higher of these two values, and the overall process hazard is obtained from the chemical with the highest level of concern. Examples of the decision logic used in CHIPS-IPHS, as well as the results of industrial processes scored under this methodology, will be provided.

MP218 Ecological Disinfestation: Evaluation of Substrates to Filter Zoospores of *Phytophthora nicotianae* from Water E. Nyberg, Clemson Univ, Institute of Environmental Toxicology; I. Meadows, S.N. Jeffers, Clemson Univ, Entomology, Soils, and Plant Sciences; S.A. White, Clemson Univ, Horticulture, Clemson Univ, Clemson Institute of Environmental Horticulture. Developing an ecologically-based remediation system to remove propagules of plant pathogens, particularly species of Phytophthora, from water at ornamental plant nurseries has the potential to reduce the need for agrichemical applications and, therefore, should decrease pesticide residues entering the environment. Focusing on irrigation water as a point-source of pathogen inoculum, the goal of this project was to evaluate and characterize the effectiveness of five substrates (sand, crushed brick, calcined clay, Kaldnes medium, and polyethylene beads) to filter zoospores of *Phytophthora nicotianae* from water. The physical filtration capability of each substrate was examined by pumping a zoospore suspension (10 zoospores/ml) through PVC columns (5 cm in diameter); six replicate columns were filled with each substrate, and each substrate was tested at six depths: 0, 5, 10, 20, 40, and 60 cm. Influent and effluent samples of suspension were collected from each column. Zoospore densities were quantified by filtering 200-ml aliquots through polycarbonate membranes (47 mm in diameter, 3-µm pores) and allowing colonies to grow on PARPH-V8 selective medium. Sand was the most effective substrate for removing zoospores; no zoospores were detected in water passed through 40 and 60 cm of sand. The other four substrates were less effective at physically filtering zoospores. Zoospore densities in effluent were reduced significantly by clay and crushed brick, but zoospores were not completely eliminated at any depth tested. The effect of adding a biological component to each substrate will be examined using runoff water from an ornamental plant nursery. Runoff will be continuously pumped through columns until a natural microbial film is established within each substrate. Zoospore removal will be tested before and after microbial growth develops to evaluate biological filtration efficiency. Sand, crushed brick, and calcined clay will be examined at a 10-cm depth and Kaldnes medium and polyethylene beads will be examined at a 60-cm depth, based on results from the physical filtration experiment. In the future, selected substrates will be evaluated for removal of pathogen propagules in the field using subsurface-flow constructed wetlands at a production nursery. If effective, use of constructed wetlands at nurseries could provide an ecological alternative to pathogen mitigation by reducing reliance on agrichemicals and should encourage use of recycled water.

MP220 RME: Exploring the Upper Bounds of Upper-bound Exposure Parameters in Deterministic Human Health Risk Assessments D. Chin, P. Anderson, B. Magee, ARCADIS. United States Environmental Protection Agency (USEPA) human health risk assessment guidance defines a reasonable maximum exposure (RME) scenario as "the highest exposure that is reasonably expected to occur at a site," provided that both quantitative data and professional judgment indicate that the exposure does not exceed the range of possible exposures. High end exposure parameters, chosen "to be conservative" without regard for the core purpose of the RME, result in unrealistic estimates of risk that contribute little to the evaluation of a site. Three considerations concerning the development of realistic RME scenarios are presented here. First, USEPA guidance does not support choosing more than one or two high end exposure parameters for a single RME scenario, particularly if the scenario involves more than one exposure pathway. Next, specific exposure parameters developed for an RME scenario should not be confused with those developed for bounding estimates of risk. Finally, the ability of a site to sustain the chronic high end contact rates used in an RME scenario is an appropriate and necessary consideration for a meaningful human health risk assessment. Examples based on recent, real-world risk assessments will be provided to demonstrate each consideration.

MP221 The Chemical Footprint: An Emerging Indicator of Environmental Performance K. Hitchcock, ChemRisk, Associate Health Scientist; J. Panko, P. Scott, ChemRisk. Currently, companies report ecological, carbon, and water footprints to communicate their environmental performance to the public. However, a measure of the impact of the chemicals contained in a product or used in its manufacture, the chemical footprint, will likely become increasingly common in the coming years. This footprint provides manufacturers with a comprehensive evaluation of the chemicals used and produced for a given consumer or industrial product. The chemical footprint includes an inventory of the chemicals as well as an evaluation of its positive and negative environmental characteristics. Characteristics of a chemical that may be evaluated include its identification as a known carcinogen, its persistence, its bioaccumulation potential, its mobility, and its exposure potential. Armed with this knowledge, companies are able to identify areas for improvement and safeguard against current and future regulatory compliance issues. Using a popular shampoo as an example, it is clear to see how a product-level chemical footprint, with a narrow scope, can be evaluated and communicated to the consumer. However, it is also easy to see how it can be extended to the entire manufacturing process for a more complete picture. The chemical footprint represents a new measurement of environmental performance that evaluates chemical properties, such as intrinsic hazards and volume used, which are not typically accounted for by other measures of environmental performance.

MP222 The First International Environmental Decision by The World Court on Paper Mill Impacts T. Deardorff, Exponent, Senior Managing Scientist; C. Menzie, J. Ma, J. Salatas, T. Wickwire, M. McArdle, Exponent; D. Pryke, Alliance for Environmental Technology. The World Court in The Hague, a court that adjudicates disputes between nations, recently ruled on a landmark environmental dispute between Uruguay and Argentina regarding the construction of a world-class pulp mill on Uruguayan side of the Uruguay River. There were two primary Argentine challenges against the development in Uruguay. The first challenge alleged that the Orion mill was not a state-of-the-art mill because it did not use best available technology (BAT) and would not be among the most environmentally efficient in the world. We compared the actual performance of the mill with international new source performance standards and other state-of-the-art, modern and recently commissioned mills in the world to demonstrate that the mill met these world class standards. Argentina's second challenge was that the mill would adversely impact the adjacent aquatic environment because the mill did not use tertiary treatment and, thus, could not obtain world class standards for nitrogen and phosphorus releases, citing a recent and massive bloom of cyanobacteria in the adjacent river as evidence of their assertion. We demonstrated, using satellite imagery of the river before and after the bloom, that the origins of the bloom were not associated with mill activities. In a 13-4 decision, the World Court ruled that there was "no conclusive evidence in the record to show that Uruguay has not acted with the requisite degree of due diligence or that the discharges of effluent from the Orion (Botnia) mill have had deleterious effects or caused harm to living resources or to the quality of the water or the ecological balance of the river since it started its operations in November 2007." The court went on to say that the Court's judgment vindicated Uruguay's assurances that, based on a comprehensive environmental impact analysis and strict monitoring of the mill's discharges, it was environmentally sound in all respects with no risk of harm to the

river or its surroundings. The court's decision on the environmental issues represented the first definitive decision in a case involving international environmental law.

MP223 Use of Aquatic Macrophyte Combinations to Mitigate Aqueous Concentrations and Effects of Permethrin and Nitrogen R.E. Lizotte, USDA Agricultural Research Service, National Sedimentation Laboratory, USDA-ARS National Sedimentation Lab, Water Quality and Ecology Research Unit, USDA-ARS National Sedimentation Lab, Water Quality and Ecological Processes Unit; M.T. Moore, USDA-ARS, National Sedimentation Laboratory, USDA-ARS National Sedimentation Laboratory, National Sedimentation Laboratory. Aquatic vegetation occurring in wetland habitats can be managed to mitigate agricultural contaminants exiting row-crop fields during storm events. Most such vegetation occurs as a mixture of different species and there is a need to better understand how multiple species can be managed to improve mitigation efficiency. In this study, combinations of two aquatic macrophytes, parrot feather (*Myriophyllum aquaticum*) and cattail (*Typha latifolia*), were used to assess mitigation of aqueous concentrations and effects on permethrin and nitrogen. Using hydraulically connected wetland microcosms (~50 L) in series, both species were tested singly (upstream microcosms *Myriophyllum* only, M; *Typha* only, T) and in combination (upstream to downstream *Myriophyllum* into *Myriophyllum*, MM; *Typha* into *Myriophyllum*, TM) to examine the influence of varying species along a linear hydraulic flow path. Upstream microcosms were dosed with a mixture of permethrin and nitrogen (as ammonium nitrate) simulating agricultural runoff. Aqueous concentrations of permethrin, NH4-N, and NO3-N were measured at 0 h (pre-treatment) through 8 h and again at 24, 48, 72, 96, and 168 h. Effects were assessed using *Hyalella azteca* 48 h aqueous laboratory bioassays at 0, 4, 24, and 48 h. Results showed permethrin was rapidly removed from the water column within 24 h. Mean permethrin half-lives (t1/2) ranged from 3-7 h with TM having a significantly ($p < 0.05$) longer t1/2 (6.8 h) than other treatments. Permethrin t1/2 was correlated ($r = -0.5256$, $p < 0.05$) with overall macrophyte biomass. Nitrogen as NH4-N and NO3-N steadily decreased over the 168 h study periods. Mean nitrogen t1/2 ranged from 59-238 h and 72-150 h for NH4-N and NO3-N, respectively, with T most rapid and M the least. Nitrogen t1/2 was also correlated (NH4-N: $r = -0.8649$, $p < 0.01$; NO3-N: $r = -0.7859$, $p < 0.01$) with overall macrophyte biomass. Effects of permethrin and nitrogen mixture toxicity occurred within 4 h and were mitigated within 24 h. Using the toxic unit model approach, the primary source of observed toxicity was permethrin. Despite apparent differences by aquatic macrophyte type, observed differences were due to overall differences in macrophyte biomass. As a result, overall macrophyte biomass appears to be the most important constituent in mitigating permethrin and nitrogen.

MP224 Using a Multiple Line of Evidence Approach for Determining a Remedial Footprint for Sediment M. Pattanayek, B. DeShields, ARCADIS. Sediment is composed of a complex matrix of soils, sand, organic matter, or minerals that accumulate on the bottom of a water body, which makes data interpretation difficult. Measured concentrations of chemicals in sediment do not address toxic effects or distinguish the bioavailable fraction from the bound fraction (which is what is measured in the laboratory results). To determine "impacted" locations from and ecological risk perspective, sediment quality assessments are often supported by other lines of evidence (LOEs) such as toxicity tests/bioassays and benthic community analyses. None of the individual LOEs are considered sufficient for assessing sediment quality impacts resulting from potentially toxic chemicals. A given LOE may overestimate or underestimate risk to a benthic community and may not address causality of specific chemicals. For remedial decision-making, sediment quality assessment (bioassay, benthic community, etc.) measures are often combined into a multiple line of evidence (MLOE) triad to integrate exposure and effects. We applied an MLOE approach at an estuarine site in California to categorize locations as "impacted" or "unimpacted" and estimate the remedial footprint for a mudflat area subject to metals and polychlorinated biphenyl (PCB) contaminated runoff from an adjacent upland site. The MLOE approach used for assessing the intertidal mudflat area was similar to the California Sediment Quality Objectives (SQO) triad approach but also included other LOEs such as identification of risk drivers based on an ecological risk assessment, hotspot analyses, and best professional judgment to provide a more robust assessment of sediment quality. Sediment conditions were categorized as "impacted" for a location if more than one LOE (other than chemical concentration) indicated potential concern, or based on best professional judgment. If only one LOE was present without any other supporting evidence, risk drivers were considered and best professional judgment was used to determine if the location could be categorized as "unimpacted." Using the MLOE approach, impacted sediment was delineated horizontally. Vertical delineation was also conducted; however, only limited LOEs were applicable. The MLOE approach used for the impacted mudflat was also compared to the SQO triad approach.

MP225 Using Statistical and Bioavailability Analyses to Identify Benthic Organism Risk Drivers A.B. Francisco, M.K. Butcher, M.B. Certo, J.J. Gravenmier, ARCADIS. Identification of risk drivers for benthic organism exposure to impacted sediment is frequently complicated by complex constituent of potential concern (COPC) mixtures. We present a methodology using toxicity tests, statistical analyses, and bioavailability assessments of associated sediment analytical data to narrow down an initial list of 33 COPCs to two likely risk drivers. We identified 33 initial COPCs by comparing sediment analytical chemistry data to conservative screening values. We then identified potential risk drivers by performing a ranked regression analysis of *Eohaustorius estuarius* 10-day acute toxicity test results against sediment analytical data. In our regression analysis, we evaluated bulk concentrations of metal COPCs, bulk and organic carbon normalized concentrations of non-polar organic COPCs, and sulfide and total organic carbon concentrations. The ranked regression analysis identified five distinct COPCs whose correlations were statistically significant at a p-value of 0.05. We then identified the likely risk drivers by qualitatively and quantitatively evaluating bioavailability. Qualitative evaluations of sediment chemistry indicated that divalent metal COPCs identified in the regression analysis (i.e., copper and lead) were unlikely to be risk drivers due to anoxic conditions and high sulfide concentrations (up to 17,200 mg/kg). These conditions would likely result in divalent metals binding with available sulfides to create insoluble metal-sulfide complexes that are largely not bioavailable and unlikely to cause toxicity. We also conducted quantitative bioavailability evaluations following United States Environmental Protection Agency equilibrium partitioning sediment benchmark (ESB) guidance. Quantitative evaluations indicated that DDT and metabolites (DDTr), chlordane, and endosulfan and metabolites exceeded their respective ESBs. Further evaluation of statistical trends and analytical data indicated that endosulfan and metabolites toxicity correlation and ESB exceedances were an artifact of elevated detection limits resulting from elevated concentrations of DDTr and chlordane. Therefore, we identified DDTr and chlordane as likely drivers of benthic toxicity, and are now able to more effectively make future risk management decisions.

MP226 Environmental Sustainability Innovations and Coastal Infrastructure Design T.J. Fredette, US Army Corps of Engineers; B.C. Suedel, US Army Engineer Research and Development Center, CEERD-EP-R, US Army Engineer Research and Development Center, Environmental Laboratory, Waterways Experiment Station EP-R; C.J. Banks, US Army Engineer Research and Development Center, CEERD-EP-R, US Army Engineer Research and Development Center, Research Biologist; S. Brasfield, US Army Engineer Research and Development Center, Environmental Laboratory. Since the advent of the National Environmental Policy Act (1969), design of coastal structures such as breakwaters, jetties, and seawalls in the United States have focused on balancing engineering and environmental goals, with great emphasis being given to minimizing unacceptable adverse environmental impacts. More recently, the concept of environmental sustainability has begun to influence the way in which planners and designers approach projects. In such instances, designers have sought ways to move beyond the somewhat narrow minimize-impact focus to incorporate features into projects with the explicit intent of improving the environmental compatibility of the infrastructure. In 2009, the US Army Corps of Engineers (USACE) began an initiative to identify examples and opportunities where application of this concept has already been employed or might be possible. Through these investigations, a number of specific projects were identified that include (1) the creation of tern nesting habitat on Great Lakes breakwaters, (2) the notching of Missouri River rock chevrons to create a more diverse pool and island habitat, (3) the placement of pea gravel aprons at the base of breakwaters to provide fish spawning habitat and decrease wave energy, and (4) the creation of spurs off of a shoreline revetment to develop habitat complexity. The USACE investigation also identified a wide range of potential ideas that could be incorporated into designs in marine, lacustrine, and riverine environments. These included the incorporation of specifically

designed reef modules into structures in place of normal construction materials, the addition of tide pool elements into seawalls or breakwaters, creation of marine mammal haul-out shelves, and others. Ongoing work consists of identifying other existing sites or potential pilot projects where evaluation of benefits can be documented.

MP227 Estimating Time-to-Compliance for Remediation Options Based on Monitored Natural Attenuation S. Selden, P.E. Goodrum, Environmental Resource Management. Reliable estimates of time-to-compliance are needed to evaluate monitored natural attenuation as a viable remediation option. Most often, simple kinetic models (e.g., first-order "exponential decay") are developed to predict the rate of change in concentrations over time and/or space. These models are mathematically convenient and supported by regulatory guidance and convention. However, too often model selection is viewed as purely a goodness-of-fit exercise without considering the conceptual site model or the strengths and limitations of alternative approaches. A decision process is presented to encourage consideration of a broader range of models and exploratory data analysis steps. Examples with groundwater data are provided to illustrate how the decision process can guide in the selection of an appropriate model given site conditions, including (1) assumption that concentrations approach background rather than zero; (2) influence of non-detects on parametric and non-parametric methods; (3) corrections for data transformation bias; (4) influence of potential outliers; and (5) determination of representativeness of historical data. While the decision process is illustrated for investigations involving compliance monitoring for groundwater, the approaches are generally applicable to time series analysis for a wide range of exposure media and remedial action objectives.

MP228 Evaluating CO_2 Emission from Automobiles Through Employimg Environmental Housekeeping Book Method and Trip Demand Estimation Model N. Kojima, Osaka Univ; S. Yao, Osaka Univ; K. Nakazawa, Osaka Univ, Graduate School of Engineering; A. Tokai, Osaka Univ. We have been developing new risk evaluation method named 'Risk Durability Method'. This method includes the view point of risk-risk tradeoff and value of information analysis. We have tried to evaluate the risk durability which includes risk tradeoff and Value Of Information (VOI) viewpoints through automobile industry environmental system as a case study. This method includes the policy or development trend of industry in scenario making level, so at that time, Risk Durability Method is depend on development of science technology. However, in order to manage several risk tradeoff in certain level, consumers who enjoyed technology should consider various convenience in their life and environmental burden. To understand the consumer's needs to automobiles under the environmental constraints, we employ the environmental housekeeping book method. In this study, we applied this method to public citizen and estimated the amount of CO_2 emission from car exhaust gas we could cut. Preliminary survey of environmental housekeeping book method on car usage was conducted to environmental volunteers who lives in Suita city, Osaka, Japan in January 2011. We collected 72 samples out of 189 questionnaires distributed to potential interest groups. The questionnaire of environmental housekeeping book consists of one week diary form and some relevant questions on everyday car usage and life activities. Through this survey, we found that some of respondents are willing to change the way of car usage by checking their everyday life activities through this environmental housekeeping method. As one of the potential operational variables, for example, they tried to walk or use bicycle instead of cars to commute and buy groceries. In this sense, the frequency and period of using cars could be controlled. They also chose options of public transportation, bicycle, walking, and a rental car instead of their own automobiles. These results can be integrated with the trip demand estimation model which we applied to Kinki region including Osaka, Japan. Finally we estimated the amount of potential reduction of CO_2 emission and some other environmental loads from automobiles, and discussed their tradeoffs.

MP229 Exposure Assessment for Antimicrobial Copper Use in Building Materials M. Velleux, HDR|HydroQual; A. Redman, Hydroqual; P. Paquin, R. Santore, HDR|HydroQual. Copper releases from antimicrobial agents used in building materials such as algae-resistant shingles and treated wood may pose risks to aquatic and terrestrial life. Exposure assessments for antimicrobial copper in urban areas are complicated because copper-containing building materials may be present in roofs, decks, fences, and utility poles that are installed in both densely clustered and widely dispersed locations. To address the need for a more refined exposure assessment approach, the TREX (Two-dimensional Runoff Erosion and Export) watershed model was used to estimate antimicrobial copper exposures in surface water, soil, and sediment from building materials in a simulated urbanized setting. TREX differs from other runoff models in that it has the capability to represent the land surface with a very high level of spatial detail. A 21.4 km2 watershed was used as the urban setting and was simulated at a 90-m resolution with 2,558 grid cells. The stream network within the watershed was 23 km in length and was represented by 258 grid cells. Each cell can be uniquely characterized with respect to land surface elevations, soil properties, rainfall-runoff, chemical release rates, and other properties. Copper release rates from building materials were determined based on surface area and rainfall rates. Benchmark effects levels for copper in surface water were determined using the Biotic Ligand Model (BLM) and regional water quality conditions. Benchmarks for copper in soil and sediment were determined using experimentally-derived toxicity endpoints and site-specific soil chemistry as well as equilibrium sediment guidelines. Simulations were performed for a 10-year period with 772 storms defined using 15-minute rainfall data. Simulated copper exposures from algae-resistant shingles were relatively low and did not exceed effects levels in any media. Simulated copper exposures for treated wood were larger than those for shingles. Exposures in soil and sediment did not exceed benchmarks. Treated wood copper exposures exceeded water quality benchmarks twice during the 10-year simulation period. Given the conservative nature of the assessment, these results suggest that potential risks posed by releases of antimicrobial copper used in building products are low.

MP230 Hexabromocyclododecane (HBCDD) – A Brominated Flame Retardant of Very High Concern in REACH Regulation A.A. Jensen, Nordic Institute of Product Sustainability, Environmental Chemistry and Toxicology; A. Bergman, Stockholm Univ. Hexabromocyclododecane (HBCDD or HBCD) is used mainly as a flame retardant in polystyrene-based insulation products and in textile products. It has a complex chemistry, and of particular concern is the capacity of this lipophilic and persistent organic pollutant to accumulate in the food chain, leading to progressively increasing levels in human tissues and in wildlife. The extent of HBCDD accumulation in the environment, in wildlife and humans correlates directly with its ever-more prevalent use. Despite this alarming trend, only limited toxicological information is available to assess its long-term implications for health or the environment. Nevertheless, HBCDD continues to be used and that despite the availability of alternatives. The European Chemicals Agency did in 2008 identify HBCDD as 1 of 14 substances of "Very High Concern", and in September 2010 HBCDD was added to REACH's Authorization List. In February 2011HBCDD was selected to be phased out in 3-5 years by EU REACH Regulation. In October 2010 a committee under the Stockholm Convention has assessed the risks from HBCDD and concluded that HBCDD fulfills the criteria of a persistent organic pollutant (POP), and the committee recommended a global ban of HBCDD use. This presentation provides a succinct up-to date overview of HBCDD's properties and discusses the risks associated with its prevalence in our homes and immediate environment. HBCDD was also included in the "San Antonio Statement on Brominated and Chlorinated Flame Retardants" signed by 245 scientists from 22 countries in September 2010.

MP231 Lab Scale Demonstration of an Electrode Enhanced Cap to Encourage Hydrocarbon Degradation F. Yan, The Univ of Texas at Austin. Capping is typically used to control contaminant release from the underlying sediments. However, the presence of conventional sediment caps will eliminate or slow natural degradation processes that might otherwise occur at the surface sediment. The objective of this study was to explore the potential of a novel reactive capping method-electrode enhanced cap for the remediation of contaminated sediment. Carbon cloth electrodes were placed in thin sand capping layer to remediate PAH contaminated sediments in a laboratory microcosm. A small voltage, i.e., 2V, was applied to create an oxidative environment in favor of PAH degradation at the cap-sediment interface. Oxidation and Reduction Potential (ORP) profiles showed redox potential approximately 100 mV higher than in controls could be sustained at the cap-sediment interface. Redox sensitive species (i.e., oxygen, Fe(II), Mn(II) and S(II)) were quantified by voltammetric measurement. The profiles of redox sensitive species corresponded well with the ORP measurement. Porewater concentration of PAH was obtained by Solid Phase Micro Extraction (SPME), and it provided evidence of PAH degradation

under electrode enhanced caps. qPCR analysis for PAH degrading genes showed that PAH degrading bacteria were stimulated by the production of oxygen. No significant degradation of the low cost carbon cloth materials was observed during the course of the experiment. Potentially, this novel electro-reactive capping can provide an inexpensive and long term technique to manage the contaminated sediment.

MP232 Phytoremediation of Atrazine from Simulated Surface Water Runoff Using Switchgrass V.C. Albright, I.J. Murphy, J. Anderson, J.R. Coats, Iowa State Univ, Entomology. Atrazine is one of the most widely used herbicides in the agricultural industry today and, as a result, can commonly be found in many bodies of water in the Midwest. Atrazine and its metabolites have been shown to have many adverse effects on plants and animals within an ecosystem. Previous research has shown that switchgrass can take up and degrade atrazine into its less toxic metabolites. Greenhouse studies have shown that mature switchgrass plants take up atrazine and quickly metabolize it and dispose of it. The current research project has two objectives: (1) determine degradation of atrazine using radiolabeled ^{14}C-atrazine to allow for more sensitivity than the previous studies which used gas chromatography and (2) determine the possible exudation of atrazine metabolites from the switchgrass after uptake and degradation.

MP233 Scenario Analysis of Alternative Fuels of Automobile Based on the Concept of Risk–Durability Y. Higuchi, N. Wada, K. Mochizuki, A. Tokai, Osaka Univ, Division of Sustainable Energy and Environmental Engineering,_Graduate School of Engineering. We have been studying new risk evaluation method which includes two viewpoints, that is, Value Of Information and risk-risk tradeoff analysis. We named this new risk evaluation method "Risk Durability Method" and have conducted a case study regarding the fuel switch of automobiles. We focused on the environmental system of automobile industry and picked up cases of automobile use, because automobiles enable us to improve the mobility in everyday life activities. Followings are points of the argument of this research based on our analysis. The first point is the emission profiles of environmental load from automobiles through their life stages in connection with multiple risks. We estimated the emission profile of carbon dioxide (CO_2) and other types of environmental loads, and their tradeoffs. The second point is the risk profile of switching fuels of automobiles. Here, the risk profile means the tradeoff relationships between different kinds of risk indexes: health risk, ecological risk, global risk and resources conservation risk. We estimated these risks at the specific time cross-sections, and clarified the risk profile and their risk-risk tradeoffs. Margin of exposure is employed for human and ecological health effects, CO_2 is for global warming and Total Material Requirement is for resources conservation risk index. Then we examine risk tradeoffs using health, eco, resources, and low CO_2 risk indexes of two time cross-sections. In addition, we will examine the suitable scenario where we can control these four risks. Finally we discuss the results from the viewpoint of risk durability of the system of automobile including consumers and their usage.

MP234 Successful Application of Thin Layer Placement in Two Dynamic Urban Water Bodies with Heavy Human Disturbance J.A. Colton, King County Dept of Natural Resources, Water and Land Resources Division, King Cty. Dept of Nat. Resources, Water and Land Resources Division; J.H. Stern, King County, Dept of Natural Resources. King County has conducted sediment remediation at two different sites (Pier 53/55 and Duwamish Diagonal in Seattle, WA) where multiple remediation technologies were implemented. In 1992, a 3-foot sediment cap and 1-foot sand layer (thin layer placement) were placed on 4.5 acres, offshore of Piers 53 – 55 on Seattle's downtown waterfront. Long-term monitoring at this site included periodic sediment chemistry sampling by core and grab in the experimental thin layer placement (10-18 inches depth) and the 3-foot cap to study enhanced natural recovery (ENR), and monitoring for stability and benthic community composition over a 10 year monitoring program. In 2004, a 7-acre area of contaminated sediment at Duwamish Diagonal in Seattle's Lower Duwamish Waterway was remediated by mechanical dredging to an average depth of 5 feet and covered with an engineered cap. Post-cap monitoring indicated dredging residuals had accumulated in the immediately adjacent area and significantly increased polychlorinated biphenyls (PCB) concentrations in the surface sediments. A thin layer of clean sand (6-9 inches depth) was placed across 4 acres, over the highest PCB concentrations, to enhance natural attenuation and immediately reduce exposure. The remaining area was projected to naturally attenuate to pre-dredge concentrations within 2 to 3 years. Long-term monitoring at this site included surface sediment chemistry grab samples collected annually for at least 5 years across the areas covered by engineered cap and a thin layer of sand, as well as in the perimeter where natural remediation was expected. These two projects provide a unique opportunity to compare the performance of thin layer placements at different thicknesses to each other, and to two other remediation alternatives (i.e., engineered caps and monitored natural remediation). Although thin layer placements are intended to accelerate natural remediation processes, at both sites, the thin layer placements performed similarly to engineered caps, showing little to no signs of mixing by biota at the contaminated sediment/sand interface. The benthic community monitoring at Pier 53/55 also suggested the thin sand layer smothered the benthic community, as occurred with the engineered cap, and the recolonization rates were the same. Both the ENR and engineered capping technologies successfully isolated contaminants and remained stable throughout the long-term monitoring program. Monitored natural remediation recovered to pre-dredge chemistry faster than predicted.

MP235 Uncertainty Analysis of Environmental Industry System Focused on the Usage of DecaBDE K. Nakazawa, Osaka Univ, Graduate School of Engineering; A. Tokai, Osaka Univ. Chemical risk evaluation has been conducting to concentrate each chemical which we concern. As a result, these assessments were used for decision making for policy or/and self regulation for industries. However, there are two issues which we need to argue more. Firstly, the chemical risk evaluation need to shift to comprehensive risk assessment considering about the some kinds of uncertainty. It contains various risks derived from certain industrial products , because each chemical was usually used for many kinds of products. Namely, we need to add the view point of risk-risk tradeoffs between environmental risks in risk evaluation for substance and products. Secondly, risk evaluation has been conducting using the data which are available at that time. Therefore, the viewpoint of information sufficiency level for the purpose of risk reduction, in other words, Value Of Information (VOI) should be examined for the clarification of them. We tackled to construct the new risk evaluation method based on the concept 'Risk Durability Method' which includes risk tradeoff and VOI viewpoint, through case study. We have conducted the case study focused on one of brominated flame retardant, decabromodiphenyl ether and evaluated health risks for human health in two time cross-sections with the viewpoint of VOI. We applied substance flow analysis method to DecaBDE and clarify the profile of exposure pathway. Firstly, we carried out sensitivity analysis and clarify the high priority datasets for risk evaluation, then we discussed the variability and uncertainty of data regarding the estimated risk level. In this presentation, we will show the evaluated results of the uncertainty of decabromodiphenyl ether health risk. Through literature survey and delphi type expert questionnaire survey study, we identify the uncertain parameters. Then using software tool of uncertainty analysis, we evaluate it using three indexes of Expected Value of Perfect Information (EVPI), Expected Value of Sample Information (EVSI), and Expected Value Including Uncertainty (EVIU).

MP236 Zebrafish as an Alternative Model for the Quantitative Assessment of Chemical-induced Developmental Toxicity in Humans C.R. Fleming, Oak Ridge Institute for Science and Education; J.C. Lambert, United Stated Environmental Protection Agency, National Center for Environmental Assessment. There is increasing interest in the use of alternative animal models in place of traditional rodent bioassays for characterization of chemical toxicity. Benefits of the zebrafish model include their small size, low cost of maintenance, rapid breeding cycle, large number of offspring, and transparent early life stages. Several analyses have demonstrated the utility of zebrafish as a predictive screening tool for mammalian developmental toxicity and teratogenicity. However, for human health risk assessment purposes, alternative toxicity testing models should inform quantitative dose-response, not simply provide an identification of hazard. To begin to examine the feasibility of applying quantitative dose-response data from zebrafish embryonic bioassays to human health risk assessment of potential developmental toxicants, we identified dose-response datasets in zebrafish and rodents for several developmental toxicants with differing toxicokinetic properties. Zebrafish studies were excluded from our analysis if aqueous exposure concentrations were not accompanied by an estimate of the dose to embryos. Reported doses in the fish and rodent studies were adjusted to a common dose metric and effect levels were compared between species to determine if dose-response data from assays using zebrafish embryos

can be considered as predictive of human developmental toxicity as more conventional mammalian model species. Preliminary results based on developmental NOAELs and LOAELs for a subset of chemicals showed good concordance of the dose-response data between rodents and zebrafish, indicating that it may be feasible to design a zebrafish assay that could be used to inform human health risk assessment without the introduction of a high degree of uncertainty. Zebrafish assays with appropriate dosing methods are needed for a larger database of chemicals to verify these findings. If zebrafish can be validated as a model organism for human developmental toxicity, assessment data gaps could be filled in a time- and cost-efficient manner. Thus, this work could have a significant impact on human health risk assessment of chemicals which lack developmental data. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the USEPA.

MP237 Anniston AL PCB Site: 1. Relative Endpoint Sensitivity of *H. azteca*, *C. dilutus*, and Mussel (*L. siliquoidea*) Chronic Sediment Toxicity Tests J.K. Stanley, US Army Engineer Research and Development Center, Environmental Laboratory; N.E. Kemble, US Geological Survey, Biological Resources Division, Columbia Environmental. Research Center; J. Farrar, US Army Engineer Research and Development Center; J.L. Kunz, USGS; J.G. Sims, US Army Engineer Research and Development Center, Environmental Lab (EP-R); J.F. Williams, US Army Engineer Research and Development Center, Environmental Laboratory; P. Chappell, Badger Technical Services; J.A. Steevens, US Army Engineer Research and Development Center, Waterways Experiment Station; C.G. Ingersoll, USGS, Columbia Environmental Research Center; M.S. Greenberg, USEPA Environmental Response Team; S.R. Thoms, USEPA, Region 4, Superfund Division, Superfund Support Branch, USEPA, Region 4, Waste Division, Office of Technical Serv. Polychlorinated biphenyls (PCBs) in the Anniston, AL, USA area were released from the operations of the former Monsanto Corporation's PCB manufacturing plant resulting in spatially expansive sediment contamination by PCBs in Choccolocco Creek and its floodplain. An integrated, multi-agency research team was assembled to assess bioavailability and toxicity of PCBs in sediments collected from the site in August 2010. As part of this investigation, a total of 32 sediment samples were collected from selected locations within the study area to support chemical characterization and whole-sediment toxicity or bioaccumulation testing. Of these, up to 26 sediment samples were evaluated in chronic toxicity tests (up to 20 samples from the site and six samples from a reference area), based on the measured concentrations of total PCBs and total organic carbon (i.e., to provide a broad gradient of total PCB concentrations in sediment). *Hyalella azteca* (HA) 42-d, mussel (*Lampsilis siliquoidea*; LV) 28-d and *Chironomus dilutus* (CD) life-cycle testing was performed in basic accordance with ASTM and EPA guidance. While data analysis and interpretation are ongoing, initial results indicate that sensitivity of chronic endpoints based on organic carbon normalized sediment PCB concentrations for the three organisms used follow the pattern: (Least Sensitive) CD survival < HA survival = LV survival < LV weight = HA weight < CD 13-d AFDW = CD 13-d biomass = LV biomass < CD emergence = HA young per female < CD egg cases per replicate = CD eggs per replicate (Most Sensitive). These initial results will be supplemented with additional data including other endpoints assessed in order to fully assess relative endpoint sensitivity in PCB contaminated sediment exposures using field-collected sediments from this system.

MP238 Anniston AL PCB Site: 2. Inter-laboratory Chronic Sediment Toxicity Testing with Amphipods (*Hyalella azteca*) and Midge (*Chironomus dilutus*) N.E. Kemble, US Geological Survey, Columbia Environmental. Research Center, USGS – Biological Resources Division, Columbia Environmental. Research Center; C.G. Ingersoll, USGS, Columbia Environmental Research Center; J.L. Kunz, USGS; D.D. Farrar, J.K. Stanley, J.A. Steevens, USACE; D.M. MacDonald, MESL; M.S. Greenberg, USEPA Environmental Response Team; S. Thoms, USEPA. Polychlorinated biphenyls (PCBs) in the Anniston, AL, USA area were released from the operations of the former Monsanto Corporation's PCB manufacturing plant resulting in spatially expansive sediment contamination by PCBs in Choccolocco Creek and its floodplain. An integrated, multi-agency research team was assembled to assess bioavailability and toxicity of PCBs in sediments collected from the site in August 2010. As part of this investigation, a total of 32 sediment samples were collected from selected locations within the study area to support chemical characterization and whole-sediment toxicity or bioaccumulation testing. Given difficulty for one laboratory to concurrently test multiple sediment samples in chronic sediment toxicity tests with midge and amphipods, sediments were split between two toxicity testing laboratories (US Army Corp of Engineers, USACE) US Geological Survey; USGS). Initial inter-laboratory comparisons of the life-cycle midge and 42-d amphipod whole-sediment toxicity tests were conducted with six samples selected to represent a broad PCB gradient. Toxicity tests were conducted following ASTM and EPA guidance and overlying test water was selected to represent site conditions and was relatively similar at both laboratories. Both laboratories met ASTM and EPA test acceptability requirements for both species (control survival was >94%). Similar decreases in survival, growth, emergence, or reproduction of midge or amphipods was observed across the six sediments evaluated in inter-laboratory testing and across an additional six samples evaluated in intra-laboratory testing of midge by USGS or in intra-laboratory testing of amphipods by USACE. Normalizing responses of test organisms to control or reference sediment helped reduce inter-laboratory variability in reproduction endpoints for both species. However, growth of amphipods tended to be greater in sediments tested by the USGS compared to USACE. Results of this study indicate there will likely be minimal inter-laboratory bias in subsequent toxicity testing of site sediments with midge by the USGS and with amphipods by USACE.

MP239 Anniston AL PCB Site: 4. Solid Phase Micro Extraction (SPME) Fibers Predict Bioavailability and Bioaccumulation of PCB from Sediment J.A. Steevens, US Army Engineer Research & Development Center, Waterways Experiment Station; J. stanley, US Army ERDC; N. Kemble, USGS; D. Farrar, G. Lotufo, US Army ERDC; J. Kunz, USGS; J. Sims, J. Williams, P. Chappell, US Army ERDC; M. Greenberg, EPA; C. Ingersoll, USGS. Polychlorinated biphenyls (PCBs) in the Anniston, AL, USA area were released from the operations of the former Monsanto Corporation's PCB manufacturing plant resulting in spatially expansive sediment contamination by PCBs in Choccolocco Creek and its floodplain. An integrated, multi-agency research team was assembled to assess bioavailability and toxicity of PCBs in sediments collected from the site in August 2010. As part of this investigation, a total of 32 sediment samples were collected from selected locations within the study area to support chemical characterization and whole-sediment toxicity or bioaccumulation testing. The bioavailability and bioaccumulation of PCB from site sediments was investigated using passive solid phase micro extraction (SPME) samplers and the 28-day *Lumbriculus variegatus* whole-sediment bioaccumulation tests. Passive samplers were placed in laboratory toxicity and bioaccumulation test chambers for up to 28 days to measure the bioavailable pore water fraction of PCBs. Variability of the PCB concentrations in the pore water fraction, measured using the SPME was low between laboratories and among toxicity and bioaccumulation test chambers. The *L. variegatus* exposures were conducted for 28 days and tissues analyzed for total lipid and PCB congeners and homologs. A strong relationship was observed for SPME concentrations and lipid normalized PCB concentrations in oligochaetes (r2 = 0.99). Similarly, a strong relationship (r2 = 0.91) between lipid normalized PCB concentrations in tissue and organic carbon PCB concentrations in sediment was observed. In the overall assessment of toxicity and bioaccumulation at this site, these measures of bioavailability and bioaccumulation will provide strong evidence about the relative availability of PCB to aquatic organisms and potential for bioaccumulation in a food web risk assessment.

MP240 Anniston AL PCB Site: 5. Relationships Between Sediment Chemistry and Sediment Toxicity D.M. MacDonald, MESL; C.G. Ingersoll, USGS, Columbia Environmental Research Center; W.G. Brumbaugh, N.E. Kemble, J.L. Kunz, USGS; J. Steevens, J.K. Stanley, F. Daniel, USACE; S. Thoms, M.S. Greenberg, USEPA. The Anniston PCB Site is located in north eastern Alabama USA. Environmental concerns focus primarily on polychlorinated biphenyls (PCBs) released from 1935 to 1971 from production waste, spills, effluent discharges, releases from landfills, and storm water runoff. USEPA, Solutia/Pharmacia, and Dept of Interior are evaluating risks to ecological receptors associated with exposure to PCBs and other chemicals of potential concern (COPCs) in environmental media at the site. As part of this investigation, a total of 32 sediment samples were collected from the study area by Solutia/Pharmacia to support chemical characterization and whole-sediment toxicity and bioaccumulation testing needed to support a CERCLA RI/FS. Of these, up to 26 samples were selected for toxicity testing and 15 samples were selected for bioaccumulation testing, based on concentrations of total PCBs and total organic carbon (i.e., to provide a broad gradient of total PCB concentrations in

sediments tested). Two toxicity tests were conducted including life-cycle whole-sediment toxicity tests with the midge, *Chironomus dilutus* (Endpoints: survival, growth, biomass, emergence, and reproduction) and a 42-d whole-sediment toxicity tests with the amphipod, *Hyalella azteca* (Endpoints: survival, growth, biomass, and reproduction). Bioaccumulation of PCBs was evaluated in 28-d whole-sediment exposures with the oligochaete, *Lumbriculus variegatus*. The Dept of the Interior evaluated splits of samples in 28-d whole-sediment toxicity tests conducted with the mussel, *Lampsilis siliquoidea* (Endpoints: survival, growth, and biomass). Peepers and acid-volatile sulphide were used to estimate bioavailability of metals and solid-phase micro extraction (SPMEs) were used to estimate bioavailability of PCBs. Matching sediment-chemistry and sediment-toxicity data were then used to develop site-specific concentration-response models and toxicity thresholds for PCBs, other COPCs, or various COPC mixtures using both empirically based sediment quality guidelines (SQGs; e.g., probable effect concentrations) and mechanistically based SQGs (equilibrium partitioning). The reliability and predictive ability of site-specific toxicity thresholds for PCBs and other COPCs were then evaluated to identify the most reliable basis for assessing risks to sediment-dwelling organisms at the site.

MP241 Anniston PCB Site: 3. Inter-laboratory Comparison of SEM-AVS and Pore Water Metals Sampled by Peepers During Chronic Sediment Toxicity Testing W. Brumbaugh, US Geological Survey, Columbia Environmental Research Center; N.E. Kemble, US Geological Survey, Columbia Environmental. Research Center, USGS – Biological Resources Division, Columbia Environmental. Research Center; J.L. Kunz, USGS; C.G. Ingersoll, USGS, Columbia Environmental Research Center; J.K. Stanley, J. Farrar, J. Steevens, US Army Engineer Research and Development Center; D. MacDonald, MacDonald Environmental Sciences Ltd.; S. Toms, US Environmental Protection Agency; M.S. Greenberg, USEPA Environmental Response Team. As part of a multi-party investigation, 32 sediment samples from a contaminated site near Anniston, AL, USA, were evaluated to assess bioavailability and toxicity of PCBs and other chemicals. Splits of sediments were tested concurrently by both US Army Corp of Engineers (USACE) and US Geological Survey (USGS) laboratories, in each of two toxicity testing cycles. As one component of the investigation, we evaluated repeatability of a mini-peeper method (in situ) for pore water sampling, and of sediment SEM and AVS concentrations in samples from exposure chambers tested by each laboratory. A 2.9-ml peeper was inserted into each sediment on test day 14, then removed on day 21. Afterwards, sediment from each of the same test beakers was transferred to a 60-ml glass jar, sealed, and stored at 4 °C for analysis for SEM-AVS. The SEM-AVS values were in good agreement for paired samples obtained from toxicity tests conducted by each laboratory for both testing cycles. Peeper metal concentrations in paired samples obtained from the first test cycle also were in close agreement; however, results from the second testing cycle were more variable. As evidenced by procedural blanks, the primary cause for variability in peeper samples from the second test cycle was trace-level contamination introduced during the transfer of peeper contents. Overall, this study demonstrated that consistent measurements for SEM, AVS, and pore-water metals are attainable in sediments tested and sampled by independent laboratories. Because of potential chemical changes that can occur during chronic whole-sediment toxicity tests, we recommend this type of pore water sampling approach. However, the transfer of peeper liquid contents must be performed using ultra-pure reagents and ultra-trace protocols to ensure reliable results.

MP242 Evaluating the Read-Across Approach on CdTe Toxicity for CdTe Photovoltaics S.W. Kaczmar, SUNY Upstate Medical Univ, Public Health and Preventive Medicine. Cadmium telluride (CdTe) is a semiconductor compound used in CdTe photovoltaic (PV) cells, an important thin film PV technology that is expected to reach nearly 4 GW in annual production capacity by 2014. Because there is limited energy and water use during operation, PV poses few environmental impacts and risks compared with other energy generation methods. The principal environment, health, and safety (EHS) issue for CdTe PV is the potential introduction of cadmium (Cd) compounds into the environment. This has been evaluated on a life cycle basis (Fthenakis, 2004) with regard to raw material, manufacturing, use, and decommissioning stages and found to produce minimal environmental emissions (0.02 g Cd per GWh). In evaluating risk from these emissions, toxicological data is often read-across from the parent element (Cd) to the compound (CdTe), because of limited specific toxicological data on CdTe. However, recent toxicity studies indicate that this may not be appropriate. Zayed and Philippe (2009) evaluated acute inhalation and oral toxicities of CdTe in rats and found the median lethal concentration and dose to be orders of magnitude higher than that of Cd. Prior testing by Harris et al. (1994) showed no detectable effects of CdTe on male or female rat reproduction. Additional research on toxicity and ecotoxicity of CdTe is presented here, based on OECD, ASTM, and USEPA EHS test guidelines. CdTe was tested with bacterial reverse mutation assay (Ames test), and no mutagenic activity was found. This compares to positive mutagenicity results for Cd (Oberly et al., 1982). The bioavailability of CdTe was evaluated with a simulated gastric fluid (pH of 1.5) and yielded 11 mg of cadmium per g of cadmium telluride (~1%). This compares to a read-across value of 100% for cadmium chloride. Transformation and dissolution testing to evaluate aquatic toxicity yielded a concentration of Cd below the LOAEL of 18 ug/L. Acute toxicity was evaluated for Zebrafish over an exposure period of 96 hours at the limit of solubility for CdTe, and there was no toxic effect at aquatic saturation on fish. Overall, CdTe is differentiated from Cd, indicating that simple read-across from CdTe to Cd is not appropriate. Therefore, in addition to minimal life cycle environmental emissions, environmental risks from CdTe PV are minimized by differences in toxicity between CdTe and Cd.

TP001 Bisphenol A in Drinking Water and Its Source Waters for North America and Europe C.A. Staples, Assessment Technologies, Inc.; K.E. Clark, BEC Technologies, Inc.; G.M. Klecka, The Dow Chemical Company, Toxicology and Environmental Research Dept; S.S. Dimond, Sabic Innovative Plastics, Staff Toxicologist; N. Caspers, Currenta; S. Hentges, American Chemistry Council. A review of over 75 studies describing measurements of bisphenol A (BPA; also 4,4'-isopropylidine diphenol, CAS Registry No. 80-05-7) in finished drinking water and its source waters was conducted to characterize the concentration of BPA. BPA has been detected in a small fraction of drinking water and source water samples. The fraction of drinking water measurements reported as less than the detection limit is 95%, 54%, and 41%, for North America, Europe, and Asia, respectively. The highest measured concentrations in drinking water in North America, Europe, and Asia are: 0.099, 0.014, and 0.317 µg/L. The median and 95th percentile concentrations of BPA in Asian drinking water are 0.020 and 0.16 µg/L, while the median and 95th percentile concentrations in North America and Europe are limited by detection limits which range from 0.0002 to 5.1 µg/L. In surface water/source water, the median and 95th percentile detection limits are: < 1 and < 1 µg/L for North America, < 0.006 and < 5.1 µg/L for Europe, and the median concentration for Asia is < 0.0155 µg/L. In groundwater/source water the median and 95th percentile detection limits are < 1 and < 1 µg/L for North America, while for Europe the median detection limit is < 0.001 mg/L. The 90th percentile concentration is < 0.073 µg/L for Europe in groundwater/source water and is only an estimate since individual data points were not available for all studies. Oral reference doses (RfDs) for human exposure to BPA have been derived by several agencies, including USEPA, European Food Safety Authority, and Health Canada, and range from 16 to 50 µg/kg-body weight (bw)/day. The lowest RfD, 16 µg/kg-bw/d derived by Willhite et al. (2008), is based on no-observed adverse effect levels (NOAEL) of 5 mg/kg-bw/d identified for systemic toxicity in rats and mice and application of an uncertainty factor of 300. The USEPA provides a mean estimate of ingestion of drinking water of 0.61 L/d for children aged 1 to < 2 years and a body weight of 11.4 kg. Using the median and 95th percentile concentrations of BPA in drinking water in Asia of 0.020 and 0.16 µg/L, respectively, and assuming 100% absorption, the estimated median and 95th percentile intakes of BPA due to ingestion of drinking water for children aged 1 to < 2 years are 0.0010 and 0.0086 µg/kg-bw/d. These intakes represent less than 0.06% of the lowest RfD and relative margins of safety over the NOAEL of 580,000 or more.

TP002 Chemical and Biological Analysis of Multi-residue Endocrine Disrupters in Wastewater Treatment Plants: A Perspective of Drinking Water Pollution W. Lee, Univ of Texas-El Paso; R. De La Torre-Roche, A.C. Ortiz, T. Carrick, Univ of Texas at El Paso. Recent decades have brought an increasing concern of potential adverse human and ecological health effects resulting from emerging environmental endocrine disruptor compounds (EDCs), such as estrogens (17ß-estradiol, estrone, 17α-ethynylestradiol), bisphenol A (BPA), nonylphenol ethoxylates (NPEOS), and nonylphenol (NP). These chemicals are released directly to the environment after passing through wastewater treatment plants (WWTPs), which often are not designed to remove them in the effluent. The occurrence of the aforementioned compounds in surface water supplies is becoming of increasing concern worldwide, and has led to a growing awareness that animals, and perhaps human health and function in ecosystems might become negatively impacted by continued release of these compounds into the environment at low levels (ng L^{-1}). To determine the concentrations EDCs and the possible impact of WWTPs discharge, chemical and biological analyses were used. EDCs concentrations in wastewater were analyzed by Stir Bar Sorptive Extraction-Thermal Desorption-Mass Spectrometry. Simultaneously, the estrogenic activity was quantified by a chemiluminescent yeast assay which was developed to test water directly without concentration. EDCs concentration and estrogenic activity in the influent were lower in WWTPs in El Paso compared to the plants located in Mexico. Concentrations in effluent were 200% to 8000% higher in Mexico for the majority of the EDCs in study compared to the plants in El Paso. NP and NPEOS were the compounds with the higher concentration ranging from non-detected to 8,144 ng L^{-1} in influent. BPA levels in effluent water were below 581.6 ng L^{-1} and for estrogen the levels were below 65.2 ng L^{-1}. The removals of EDCs in WWTPs in El Paso were higher than 60% for the majority of the plants, and in Mexico lower than 60%. Estrogenic activity was removed 31% to 98% in WWTPs in El Paso. Insignificant removal of estrogenic activity was determined in plants from Mexico ranging from no removal to 86%. Based on our observation, the WWTPs with at least secondary treatment process were able to remove EDCs more effectively for the EDCs analyzed in this study.

TP003 Tracking Organics in the Santa Cruz River: Sources and Attenuation A. Kahl, Univ of Arizona, Dept of Chemical and Environmental Engineering; L. Abrell, Univ of Arizona, Arizona Laboratory for Emerging Contaminants, Univ of Arizona, Soil, Water and Environmental Science; B. Arnold, Univ of Arizona; S. Snyder, Univ of Arizona, Chemical and Environmental Engineering; D. Jones, Univ of Arizona. It is now widely appreciated that trace organic compounds can affect the finished quality of water that is served to the public for potable use. Chemical fate during infiltration and underground transport to points of recovery is therefore relevant to the quality of delivered water. As reclaimed water begins to play a more important role in our regional water resource portfolio, interventions including natural processes during infiltration and underground transport will assume additional importance. Here we will attempt to (i) measure the levels of trace organic contaminants in several locations along the Santa Cruz River that serve as drinking water sources for major metropolitan areas (including Tucson), and (ii) measure the degree to which infiltration and underground storage/transport processes contribute to overall attenuation.

TP004 USEPA/USGS Study of CECs in Source Water and Treated Drinking Water: Introduction and Quality Assurance/Quality Control S.T. Glassmeyer, USEPA, Office of Research and Development, USEPA, NERL/MCEARD/CERB; E.T. Furlong, US Geological Survey, National Water Quality Laboratory; D. Kolpin, US Geological Survey; A.L. Batt, USEPA Office of Research and Development, National Exposure Research Laboratory; B. Benson, USEPA, Region 8; S. Boone, USEPA, Office of Chemical Safety and Pollution Prevention; O. Conerly, USEPA, Office of Research and Development; M. Donohue, USEPA; H. Mash, USEPA, Office of Reasearch and Development; S. Pfaller, K. Schenck, J. Simmons, E. Varughese, S. Vesper, E. Villegas, M. Ware, USEPA, Office of Research and Development; V.S. Wilson, USEPA, ORD, NHEERL, TAD, Reproductive Toxicology Branch, USEPA, Office of Research and Development. Most studies of contaminants of emerging concern (CECs) are focused on a rather limited list of analytes (typically fewer than 20). While occurrence data in general is needed, information on the co-occurrence of compounds is particularly important to better assess the overall human and ecosystem exposure to these micro-pollutants. In 2010, the US Environmental Protection Agency (USEPA) and the US Geological Survey (USGS) began a joint study to measure more than 230 chemical and microbial CECs in the source water and treated drinking water of 20 drinking water treatment plants throughout the United States. This presentation serves as the introduction to a series of follow-up platform and poster presentations. In addition to the background information, this presentation will discuss the project's extensive quality assurance/ quality control samples including duplicate samples, laboratory fortified matrix samples (spikes) as well as inter-method comparisons.

TP005 USEPA/USGS Study of CECs in Source Water and Treated Drinking Water: Perfluorinated Compounds S. Boone, USEPA, Office of Chemical Safety and Pollution Prevention; T. Boone, C. Byrne, USEPA/OCSPP/OPP/BEAD/Environmental Chemistry Branch; B. Guan, Univ of New Orleans, Dept of Chemistry; C. Vigo, J. Ferrario, USEPA/OCSPP/OPP/BEAD/Environmental Chemistry Branch. Contaminates of emerging concern (CECs) are being found at trace levels (ppt) in domestic drinking water, and there is an increasing concern for the effects of their exposures to the United States population. The USEPA and USGS are performing a study of approximately 25 drinking water treatment facilities in the US for the detection of over 200 emerging chemical and microbiological contaminates. The source water for these facilities includes ground wells, reservoirs, and rivers. The contaminates of interest include: prescription and nonprescription pharmaceuticals and their metabolites, perfluorinated compounds, industrial chemicals, fragrances, polycyclic aromatic hydrocarbons, hormones, pesticides, detergent related chemicals, plant and animal sterols, phosphorus based flame retardants, nanomaterial, bacteria, fungi, protozoa, and viruses. The USEPA Environmental Chemistry Laboratory was tasked with the development of a methodology to detect seventeen perfluorinated compounds and the determination of their lowest concentration minimum reporting levels (LCMRLs). Using two extraction techniques (one for the source water/one for the drinking water), the LCMRLs (ng/L) for source/drinking waters for each compound were calculated from a low

of 0.035/0.052 ng/L for PFHxA to a high of 0.600/0.640 for PFOA for the carboxylic acids, and from a low of 0.034/0.033 ng/L for PFHxS to a high of 0.140/0.130 for PFOS for the sulfonates. Twelve water treatment facilities have been sampled to date, and of the twelve, all water samples had detectible levels from at least one PFC, and, in some, as many as 12 PFCs (9 carboxylic acids and 3 sulfonates). Of the 17 PFCs tested, the most prevalent PFCs measured were (in decreasing order): PFHxA, PFHpA, PFBS, PFBA, PFPeA, PFHxS, PFNA, PFOS, PFOA, PFDA, PFUnDA, and PFDoDA. The highest level of any PFC detected was PFBA (47 ng/L). The highest detection of PFOA and PFOS was 30 ng/L and 6 ng/L, respectively. In all but one case, the drinking waters had comparable levels to their source waters. For 5 source waters and 6 drinking waters (of the 12 facilities), the detectible levels of PFCs were all below 3 ng/L. The USEPA provisional health advisory for PFOA is 0.4 ppb (400 ng/L) and PFOS is 0.2 ppb (200 ng/L), and New Jersey has a health advisory for PFOA at 0.04 ppb (40 ng/L). None of the drinking water samples had detectible levels above any provisional health advisory in place at the current time.

TP006 USEPA/USGS Study of CECs in Source Water and Treated Drinking Water: UPLC-IT/Orb Detection of Selected Endocrine Disrupting and Analogous Compounds H. Mash, USEPA, Office of Reasearch and Development; K. Schenck, US Environmental Protection Agency, ORD/NRMRL/WSWRD/WQMB; L. Rosenblum, Shaw Environmental & Infrastructure, Science and Technology Division. Numerous organic contaminants, including pharmaceuticals, endocrine disrupting compounds, personal care products, etc. have been detected in both surface and ground waters. Release into the environment is primarily due to their introduction from anthropogenic discharges and wet-weather runoff. Their presence in both source and finished drinking waters has led to concerns over the potential human health risks that may be associated with some of these organic contaminants, such as reproductive impairment, increased incidences of cancer and development of anti-biotic-resistant bacteria. This research investigates the effectiveness of a variety of drinking water treatments employed by full-scale treatment facilities to remove/alter selected contaminants. Solid-phase extraction followed by ultra-high pressure liquid chromatography/Ion Trap-Orbitrap mass spectrometry (SPE-UPLC-IT/Orb) was used to identify a group of organic contaminants, which included endocrine disrupting compounds (e.g., E1, E2, EE2, and E3), a pesticide (atrazine) and personal care products (e.g., triclosan). Results indicate atrazine is nearly ubiquitous in source waters, and persistent through most of the drinking water treatments investigated. In general, the other compounds investigated have either not been detected in the source water, or if present, have not been detected post-treatment.

TP007 USEPA/USGS Study of CECs in Source Water and Treated Drinking Water: Assessment of Estrogenic Activity Using an In Vitro Bioassay, T47D-KBluc V.S. Wilson, USEPA, ORD, NHEERL, TAD, Reproductive Toxicology Branch, USEPA, Office of Research and Development; N. Wrench, USEPA, ORD, NHEERL, TAD; K. Schenck, USEPA, ORD, NRMRL; H. Mash, USEPA, Office of Reasearch and Development; L. Rosenblum, USEPA, ORD, NRMRL; S.T. Glassmeyer, USEPA, Office of Research and Development, USEPA, NERL/MCEARD/CERB. Scientists from the US Environmental Protection Agency (USEPA) and US Geological Survey (USGS) are collaborating on a research study to determine the presence of contaminants of emerging concern (CECs) in source and treated drinking waters collected from up to 30 drinking water treatment plants from across the United States. One study goal is developing tools that can be used with source waters and drinking water systems to evaluate the cumulative biological activity on critical endpoints. Our lab has developed an in vitro transcriptional activation assay, T47D-KBluc assay, which has been adapted for screening of environmental samples for estrogenic activity. These cells endogenously express both human ER alpha and beta and are stably integrated with an estrogen responsive promoter-luciferase reporter construct. This assay was confirmed by comparison to analytical chemistry to accurately predict estrogenic activity in water and effluent samples in a multi-lab collaborative study with the Global Water Research Coalition (GWRC). These assays have been successfully used to screen many types of samples including effluents from waste water treatment and cattle, dairy, swine and poultry operations. Further, with complex mixtures, it is important to understand how compounds with similar or different mechanisms of action would affect assay results. Several defined mixture studies have, therefore, also been conducted. These successes support the use of bioassays to evaluate estrogenic activity in the proposed study. The focus of this part of the study is detection of potential estrogen-mediated activity in extracts from source and treated drinking water. Water from plants using various treatment processes will be tested. In vitro results from the current study will be compared to chemical identification of endocrine active compounds. Initial testing of control and mock-up sample extracts have confirmed appropriate responses and provide a high degree of confidence that the application of the in vitro assay will be possible. The current successes in evaluating endocrine activity via the estrogen pathway indicate that bioassays targeting other pathways could be developed and used to evaluate water samples as well. Disclaimer: This abstract does not necessarily reflect USEPA policy

TP008 Life-Cycle Exposure of *Daphnia magna* to Environmentally Relative Mixtures of Pharmaceuticals D.N. Wolfe, S. Richards, Univ of Tennessee at Chattanooga; M. Hanson, Univ of Manitoba. Due to the global detection of pharmaceuticals in surface water, risk assessments require toxicity testing to be preformed to close knowledge gaps for effects assessment regarding impacts on aquatic food web dynamics. The widespread use of pharmaceuticals has resulted in mixture concentrations of mg/l in effluent and ug/L concentrations in surface water. Their potential toxicological effect on fresh water ecosystems remains largely unknown, especially as complex mixtures. Toxicity data on the effect of pharmaceuticals has expanded in the past decade, but has mainly focused on single, acute pharmaceutical exposures, not environmentally realistic mixtures. By determining the threshold of response for environmentally relavant mixtures, the risk that these compounds may pose to the environment will be determined more accurately. In 2008, thirteen pharmaceuticals were quantified in the Tennessee River, USA and its tributaries, ranging from 0.1757 to 0.0028 ug/l. Using the same ratios of individual compounds, but increased concentrations, the present study conducted chronic life cycle toxicity test on the cladoceran *Daphnia magna*. Tests were performed using 10x, 100x and 1000x the concentrations detected in the Tennessee River, resulting in a total concentration of 6.031, 60.31, and 603.1 ug/l of total pharmaceutical exposure, respectfully. Mortality, time to first brood, size and fecundity were use as endpoints of toxicity. Test solutions were renewed three times a week and neonate removed each day until the conclusion of the experiment. *D. magna* showed a statistically significant decrease in the number of neonate produced when exposed to 100x and 1000x ($p < 0.003$). When *D. magna* was exposed to the 10x concentration, no significant decrease in neonate production was observed. Neither time to first brood nor size was affected at 10x, 100x, or 1000x. Studies are on going to pinpoint the threshold of effects occurring between 10x and 100x. These data will provide risk assessors more accurate data when analyzing non-lethal effects of pharmaceutical mixtures on aquatic ecosystems.

TP009 Monitoring of Perchlorate in Diverse Foods and Its Estimated Dietary Exposure for Korea Populations J. Lee, Pusan National Univ, Dept of Civil and Environmental Engineering; S. Oh, Pusan National Univ; W. Sim, Pusan National Univ, Korea Testing & Research Institute; J. Oh, Pusan National Univ, Environmental Engineering. Perchlorate is considered as a new emerging pollutant because of its health concern and ubiquitously detection. Perchlorate has been found in food and the main exposure pathway of perchlorate is the ingestion. Therefore, determination of perchlorate in food is particularly important. In 2004, USFDA conducted a large survey to monitor the perchlorate levels in food samples. They analyzed 775 samples from 27 food groups suspected contamination. From 2005~2006, they analyzed perchlorate in American's favorite foods to estimate perchlorate dietary exposure amount for general populations. They reported that several foods were contaminated with perchlorate and the levels of perchlorate ranged from 0.15 to 92.4 ppb. However, there is no other large-scale study, globally. Therefore, we carried out a large-scale of monitoring on perchlorate level in Korean food to understand the level of perchlorate and to assess the exposure amount of perchlorate by ingestion for Korean people. Total 663 samples from 39 kind different food groups purchased from Korean market were analyzed and target sample groups were selected based on dietary habits of general and/or specific age population. The preparation of perchlorate in food samples was conducted by modified US FDA and EPA methods. The recoveries of perchlorate in food samples ranged from 77.1 to 118.3% (RSD 0.5~14.8%). Measurable amounts of perchlorate were detected in 411 samples. The mean concentration of the 6 types of food samples has the following trend (ppb): fruit & vegetables (7.92) > dairy (6.34) > processed product (3.52) > alcohol & beverage (1.91) > meat & egg (0.98) > fishes &

shellfishes (0.95). These levels of Korean food samples were similar or lower than other previous studies. The exposure dose of perchlorate was calculated with analyzed perchlorate levels in domestic food samples in this study. The calculated daily perchlorate dose to Korean adult was 0.04 μg/kg•day based on average concentration and 0.15 μg/kg•day based on maximum concentration, which was pretty low compared to RfD (0.7 μg/kg•day) value suggested by US NAS. This result indicates that the current perchlorate exposure to Korean people by domestic food consumption is safe. However, the daily perchlorate dose for Korean infants(0.14 μg/kg•day based on average concentration) was higher than adults due to high levels of perchlorate in dairy products, indicating management of perchlorate exposure in infants group needs to be considered.

TP010 Simultaneous Removal of Dimethyl Phthalate and Dissolved Organic Matter Using an Aminated Hypercrosslinked Resin C. Shuang, Y. Xue, A. Li, Nanjing Univ. Water contaminations caused by endocrine disrupting chemicals (EDCs) and dissolved organic matters (DOMs) threat humans' health. An aminated hypercrosslinked resin was designed for simultaneous removal of both EDCs and DOMs. The obtained resin (NDA-8) was prepared and characterized. It was found that the hydrophobic hypercrosslinked resin turned to hydrophilic after amination with the declined in contact angle from 131.3º to 72.7 º. The resin had a surface area of 580 m2/g and ion exchange capacity (IEC) of 2.35 mmol/g. The performance of NDA-8 was investigated for the adsorption of dimethyl phthalate (DMP) and tannic acid (TA) from aqueous solutions, which are respectively used as model compound for EDCs and DOMs. Activated carbon (F400D), anion exchange resin (D730) were also used in adsorption for comparison. The adsorption capacities of DMP onto NDA-8 and F400D were 370, 256 mg/g at 298 K, respectively, while the adsorption onto D730 could be negligible. The capacities of TA onto NDA-8, F400D and D730 were 331, 117, 526 mg/g at 298K, respectively. The results indicated that the uptake of DMF was contributed on adsorption and TA mainly attributed to anion exchange. Due to the combination of adsorption and anion exchange for NDA-8, the binary adsorption performed the high removal efficiencies (>90%) of both DMF and TA at both initial concentrations of 10 mg/L at 298K.

TP011 Sorption of Micropollutant Estrone to Magnetic Hypercrosslinked Resins M. Zhang, C. Shuang, Nanjing Univ, School of Envrionment; Q. Zhou, Nanjing Univ, School of Environment; A. Li, Nanjing Univ, School of Envrionment; J. Qiu, Shanghai Jiao Tong Univ, School of Life Sciences & Biotechnology. The hypercrosslinked magnetic polymer beads with different pore structures were obtained using suspension polymerization and hypercrosslinking reaction. The obtained resins could be easily and rapidly separated owing to their superparamagnetic characteristics. Moreover, they had abundant micropore and mesopore distribution with the large specific surface area of from 600 to 1200 m2/g. The investigation of estrone sorption on the resin showed that both the pore volume and the pore diameter were the main factors in the sorption and desorption of estrone removal.

TP012 Preparation of a Novel Magnetic Absorbent for the Removal of Tetracycline in the Aquatic Environment Q. Zhou, Nanjing Univ, School of Environment; J. Qiu, Shanghai Jiao Tong Univ, School of Life Sciences & Biotechnology; M. Zhang, Nanjing Univ; A. Li, Nanjing Univ, School of Envrionment. A novel magnetic absorbent was synthesized by membrane emulsification-suspension polymerization (MESP) method. The obtained magnetic polymer microspheres exhibited distinct superparamagnetic characteristics, resulting in easy and rapid separation properties in the applications. Moreover, the absorbent was well monodispersed with the low-micrometer diameter and ultra-large specific surface area (more than 1200 m2/g). These advantages of the magnetic absorbent leaded to the excellent adsorption characteristic for organic micropollutant removal. It was found that the magnetic absorbent had not only similar adsorption capacity and dynamic property to the commercial powder activated carbon (PAC) 1240AC, but also much better desorption behavior than PAC. Furthermore, the competitive adsorption investigation of tetracycline and natural organic matter (NOM) showed that the existence of NOM had little effect on the removal of tetracycline using the magnetic absorbent. This could be explained by its controllable pore structure, uniform particle and low-micrometer size.

TP013 The Influence of Life History on the Sublethal Effects of Sea Lamprey Parasitism on Lake Trout S. Smith, Michigan State Univ, Fisheries and Wildlife; C.A. Murphy, Michigan State Univ, Dept of Fisheries and Wildlife, Lyman Briggs College, Michigan State Univ, Lyman Briggs College; F. Goetz, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences; S. Sitar, Michigan Dept of Natural Resources, Marquette Fisheries Research Station; R. Bergstedt, USGS Great Lakes Science Center, Hammond Bay Biological. Station. Sea lamprey (*Petromyzon marinus*) invasion of the Great Lakes has been linked directly to lake trout (*Salvelinus namaycush*) population decline through the effect of parasitism mortality. Less well understood are the sublethal effects of sea lamprey parasitism on lake trout. This study aims to identify and quantify sublethal effects of parasitism, such as changes in hepatic gene expression, fecundity, and growth and to determine if life history can influence such effects. We examined the effects of parasitism on two different lake trout morphotypes: siscowet and lean. Siscowets are found in Lake Superior at depths greater than 100m and have higher weights, lipid levels, and sea lamprey wounding rates than leans. Leans are found in shallow water throughout the Great Lakes. Siscowet and lean lake trout (n=64) were subjected to sea lamprey parasitism for one to five days and analyzed for changes in blood hormones, pituitary gonadotropin mRNA, lipid levels, fecundity, and hepatic gene expression. Wild Lake Superior lake trout (n=58) were also collected and sampled similarly to determine the range of responses experienced by fish in the field. Preliminary results suggest that as the length of time of parasitism increases, the hepatosomatic index decreases linearly, with leans showing a more drastic reduction. Changes in hepatic gene expression in response to parasitism were also observed with significant differences between lean and siscowets. Future work plans to incorporate changes in life history specific sublethal effects (such as plasma sex steroids) into models to link to population-relevant endpoints such as changes in fecundity and growth. Current models that estimate spawning stock biomass per recruit do not take into account the likely decrease in reproductive ability due to sublethal sea lamprey wounding and may be underestimating the full effect of sea lamprey parasitism on specific lake trout populations.

TP014 Effects of Munitions and Breakdown Products on Activation of Peroxisomal Proliferator Activated Receptors and Their Heterodimer Retinoid X Receptor D.R. Johnson, K.B. Donohue, US Army Engineer Research and Development Center, Environmental Laboratory; C. Ang, Badger Testing Services; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division. Exposure to munitions compounds has been shown to alter energy stores and biomolecules in wildlife. For example, 2,6-dinitrotoluene (2,6-DNT) impacts the expression of genes that facilitate energy metabolism including both gluconeogenesis and lipid metabolism in northern bobwhite (Colinus virginianus). This appeared to occur by 2,6-DNT-mediated suppression of peroxisome proliferator activated receptor gamma (PPARg)-regulated genes. PPAR is a class of nuclear receptors (i.e., transcription factors) that, when bound by endogenous and xenobiotic ligands, activate the transcription of regulated genes. While primarily found in several different tissues and activated by different ligands, PPARs are generally involved in changes of lipid and glucose homeostasis and inflammation. When bound by ligands, PPAR nuclear receptors heterodimerize with the retinoid x receptor alpha (RXRa). The objective of this project was to determine the role of military munitions in PPAR-mediated gene activation. PPAR alpha and gamma activation by military munitions (0.1-10 mg/l) and their breakdown products after 24 h exposure were detected by cell-based nuclear receptor activation kits. Cells were also treated with positive controls (GW590735 for PPARa, rosiglitazone for PPARg, and 9-cis retinoic acid for RXRa), all of which activated their respective receptor-reporter system by 10-70 fold. No munitions significantly activated PPARa, but 2,4,6-TNT and respective breakdown products (e.g., 2-amino-4,4-dinitrotoluene, 4-amino-2,6-dinitrotoluene) downregulated PPARa by 40-60%. For PPARg, 2,4,6-trinitrotoluene (TNT) strongly activated the receptor in a dose dependent manner, with 6.8-fold induction by 10 mg TNT/l. The munition 2,4-DNT was a weak PPARg activator (65% increase) at 10 mg/l. In contrast, 2,6-DNT and 4-amino-2,6-DNT decreased PPARg activation by 50-60%. For RXRa, TNT and respective breakdown products at 10 mg/l decreased RXRa activation by 40-70%. Triazole munitions (e.g., RDX) and new insensitive munitions (e.g., dinitroanisole) did not activate either PPAR receptor. These data demonstrate the ability of munitions to regulate nuclear receptor activation, resulting in

the differential regulation of numerous genes involved in lipid and glucose homeostasis. Trends in PPAR activation can be seen based on commonalities in chemical structures. These data may provide insight into molecular initiation events that can be linked to adverse outcomes at increasing levels of biological organization.

TP015 Relationships of Fluorescence, Dissolved Oxygen, and Analytical Chemistry Measurements as Indicators of MC252 Oil in the Gulf of Mexico Water Column M. Johns, Exponet, Inc.; M.R. Edwards, Exponent; R. Atlas, Univ of Louisville; J. Harney, T. Thompson, Cardno Entrix. The Deepwater Horizon accident (April 20, 2010) was unique in that it originated from a water depth of approximately 1,500 m. The oil release continued until July 15, 2010 when the well was capped. Physical and chemical dispersion of the MC252 oil resulted in a cloud of fine droplets at approximately 1,100–1,300 m that generally moved in a southwesterly direction while larger droplets moved to the surface and formed a slick that moved toward the shoreline. Numerous vessels were equipped with conductivity, temperature and depth (CTD), dissolved oxygen, fluorometry, and deep water collection capabilities to evaluate and track the subsea dispersed oil. Field fluorometry measurements were collected throughout the water column from early May to December 2010 at approximately 2,000 locations, including before and after the well was capped. These measurements were used to track the location of the subsea dispersed oil in real time. Water chemistry samples were collected and analyzed to quantify the field measurements. This poster presents an evaluation of the associations between the fluorometry, dissolved oxygen, and analytical water chemistry results over that period of time and in all directions and distances about the wellhead, including a summary of the quantity of data collected from this effort. The large quantity of data evaluated indicated fluorescence is not consistently associated with a depression in dissolved oxygen, and a sharp change in either fluorescence or dissolved oxygen is not always associated with the presence of polycyclic aromatic hydrocarbons (PAHs).

TP016 Toward the Full Chemical Characterization of Dispersants Used for Oil Spills M. Azzam, Univ of Houston-Clear Lake; C.(. Zhang, Univ of Houston-Clear Lake, Univ of Houston-Clear Lake, Environmental Science. Dispersants are employed in oil spill control under the general assumption that the active ingredient (surfactants) will reduce the interfacial tension and promote the break-up of the oil slick into fine droplets. Limited data are available to the public from the MSDS sheets on the chemical characterization of commercial dispersants, since the exact compositions are commonly considered to be a trade secret. However, such information is critical for the fate and transport modeling of dispersed crude oil, development of clean-up strategies, and analyses of affected environmental and biological media. Our work attempted to perform non-targeted trace analyses of metals, volatile and semi-volatile organic compounds that may be of importance for the chemical and toxicological evaluation of dispersant use in oil spill scenarios. Four commercially available dispersants were analyzed for inorganic and organic components using an array of instruments including ICP, GC-MS, LC-MS-ESI coupled with UV-DAD and fluorescence detectors (FLD), and LC-MS with accurate molecular mass time-of-flight (TOF) detector. GC-MS analysis of methanol prepared aliquot shows light aliphatic alcohols, ethers and ketones (e.g., 2-butoxy ethanol, 2- and 3- hexanol, 2- and 3-hexanone), whereas hexane extracts show a range of saturated, unsaturated aliphatics and cyclic hydrocarbons (e.g., 1,2,3-trimethyldiaziridine, 1-hexene, 2,5-dihydro-3-methylfuran, cyclohexane, undecane). LC-UV-FLD with an Acclaim surfactant column (4.6×150 mm, dp = 5 µm, Dionex) in an isocratic mode (60/40 acetonitrile, H_2O in 0.1 M NH_4AcO) results in a group of pure and co-eluting dispersant components. When NH_4AcO was used as the modifier in both the negative and positive ionization modes, LC-MS reveals molecular ions of surfactant sorbitam laurate and ethoxylates. TOF further reveals molecular formulas for the major ions in the range of m/z 200 – 500 (e.g., m/z 289, 317, 345, 428, 472). Since many of these compounds are not described in the MSDS, the implications of our findings regarding the evaluation of contaminant fate, transport and toxicity to concerned groups (researchers, practitioners and policy makers) of Gulf oil spill will be discussed.

TP017 Measurement of Oil Dispersant Ingredients Dioctyl Sodium Sulfosuccinate (DOSS) and Dipropylene Glycol Monobutyl Ether (DPnB) in Seawater and Sediment M.J. Benotti, Battelle, Analytical and Environmental Chemistry; F. Pala, Battelle; J.R. Thorn, Battelle, Applied Research and Laboratory Operations. Dispersants such as the Corexit have been applied to oil spills for many years. This talk discusses the development and application of two analytical methods pertinent to studying the fate and transport of Corexit dispersants. The first method is used for sensitively measuring dioctyl sodium sulfosuccinate (DOSS; CAS# 577-11-7) in seawater and sediment, the primary surfactant in Corexit. Aqueous extraction employs solid phase extraction, and the sediment extraction employs accelerated solvent extraction. Analysis is conducted using liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) with negative mode eletrospray ionization. This method benefits from use of a deuterated surrogate standard (DOSS-d34) and a 13C-labeled internal standard (DOSS-13C4). Thus, method variability due to loss during extraction and/or ionization suppression/enhancement is mitigated. Method detection limits are in the low ng/L range for seawater samples and the low ng/g range (dry) for sediment. The second method is used for sensitively measuring dipropylene glycol monobutyl ether (DPnB; CAS# 29911-28-2) from seawater and sediment, another ingredient in Corexit. Aqueous extraction employs liquid-liquid extraction, and the sediment extraction employs use of a shaker table. Analysis is conducted using gas chromatography coupled with mass spectrometry (GC-MS) operated in selected ion monitoring mode. Method detection limits are less than 10 ng/L for seawater samples and less than 1 ng/g (dry) for sediment. Both approaches are calibrated against laboratory experiments studying the fate of Corexit following application. The partitioning of Corexit between water, sediment and biota will be discussed. Ultimately the use of both the DOSS and DPnB methods affords a more a more complete understanding of the ultimate fate of Corexit in the coastal and marine environment as compared to approaches focusing on a single ingredient.

TP018 Toward the Full Chemical Characterization of Dispersants Used for Oil Spills M. Azzam, Univ of Houston-ClearLake; C.(. Zhang, Univ of Houston-Clear Lake, Univ of Houston-Clear Lake, Environmental Science. Dispersants are employed in oil spill control under the general assumption that the active ingredient (surfactants) will reduce the interfacial tension and promote the break-up of the oil slick into fine droplets. Limited data are available to the public from the MSDS sheets on the chemical characterization of commercial dispersants, since the exact compositions are commonly considered to be a trade secret. However, such information is critical for the fate and transport modeling of dispersed crude oil, development of clean-up strategies, and analyses of affected environmental and biological media. Our work attempted to perform non-targeted trace analyses of metals, volatile and semi-volatile organic compounds that may be of importance for the chemical and toxicological evaluation of dispersant use in oil spill scenarios. Four commercially available dispersants were analyzed for inorganic and organic components using an array of instruments including ICP, GC-MS, LC-MS-ESI coupled with UV-DAD and fluorescence detectors (FLD), and LC-MS with accurate molecular mass time-of-flight (TOF) detector. GC-MS analysis of methanol prepared aliquot shows light aliphatic alcohols, ethers and ketones (e.g., 2-butoxy ethanol, 2- and 3- hexanol, 2- and 3-hexanone), whereas hexane extracts show a range of saturated, unsaturated aliphatics and cyclic hydrocarbons (e.g., 1,2,3-trimethyldiaziridine, 1-hexene, 2,5-dihydro-3-methylfuran, cyclohexane, undecane). LC-UV-FLD with an Acclaim surfactant column (4.6×150 mm, dp = 5 µm, Dionex) in an isocratic mode (60/40 acetonitrile, H2O in 0.1 M NH4AcO) results in a group of pure and co-eluting dispersant components. When NH4AcO was used as the modifier in both the negative and positive ionization modes, LC-MS reveals molecular ions of surfactant sorbitan laurate and ethoxylates. TOF further reveals molecular formulas for the major ions in the range of m/z 200 – 500 (e.g., m/z 289, 317, 345, 428, 472). Since many of these compounds are not described in the MSDS, the implications of our findings regarding the evaluation of contaminant fate, transport and toxicity to concerned groups (researchers, practitioners and policy makers) of Gulf oil spill will be discussed.

TP019 Simulation of DWH Oil/Gas Releases Including Dispersant Application, with Focus on Droplet Size Distributions Experimental Concept and Initial Results P.J. Brandvik, O. Johansen, F. Leirvik, P. Daling, SINTEF, Materials and Chemistry, Marine Environmental technology. During the initial phase of the Deep Water Horizon (DWH) incident oil and gas were released from two locations on the broken riser and one on the drill pipe. Later the riser was removed and oil and gas were released from a single location on top of the BOP. Subsea dispersant was injected into

the released oil and gas stream at varying locations. The t size and distribution of oil droplets is believed to affect such factors as the time required for oil to rise to the surface, the location where it surfaces, dissolution in the water column, and entrainment of the smallest droplets beneath deepwater density layers. There were no immediate deepwater in situ measurements of oil droplet sizes at the various release points, or at the location of subsea dispersant injection into the turbulent deep water release. The first focus area of this project is to simulate the release of oil and gas from a hypothetical subsea blowout in order to increase our knowledge regarding the droplet size and distribution of released oil. The second focus area is to study different application techniques for deep water dispersant application and their influence on droplet size and distribution. A Tower tank is established at SINTEF for this purpose. The tank is 6 meters high, 3 meters wide and holds 40m3 of natural sea water. The tank is equipped with an advanced system for releasing oil and gas, and monitoring oil droplet size distributions and oil concentrations in the released plume. The droplet size distributions are measured with three independant in-situ methods (laser particle sizer, particle visual microscope and a macro camera with a blue-laser focusing plane). Different methods are studied to inject dispersants into the hydrocarbon stream. Although the tower cannot reproduce the temperature and pressure conditions encountered in a deep water release, the experimental conditions will exceed bench scale tests by at least one order of magnitude. We will review the assumptions needed to mathematically scale these results to the conditions involved in a deepwater release. Our aim is to use the broad range of experimental conditions possible with this basin to provide more confident extrapolations to full scale conditions. The experimental concept of the tower basin and initial results with oil alone, oil/gas and with dispersant will be presented.

TP020 Distribution and Fate of PAH and Chemical Dispersants in the Water Column Following the Deepwater Horizon Oil Spill P. Boehm, Exponent, Environmental & EcoScience Group, Exponent, Environmental Group, Exponent, Inc., Environmental & EcoScience sGroup; L. Cook, Exponent, 1 Clock Tower Place; L. Royer, Exponent, Inc.; R. Barrick, Infinity Solutions. An assessment of the chemical distributions of key chemicals related to the MC252 oil spill in approximately 10,000 offshore water samples (>3 miles from shore) that comprise a 4-dimensional (area x depth x time) data set from several key water column zones are discussed in this presentation. These samples were taken during the release period (April 20 through July 15, 2010) and in the post-release period (July 15 through the end of December, 2010). Total polycyclic aromatic hydrocarbon (TPAH) concentrations and distributions of the chemical dispersant, Corexit 9500, using two chemical tracers (DPnB and DOSS) are discussed. TPAH were found with a geometric mean of less than 0.01 ppb concentrations ranging from not detected (ND) to 146 mg/L (parts per million), the latter sample collected directly from the riser plume at 1524m water depth. Eighty-five (85) percent of all samples were at Total PAH (TPAH) concentrations of < 0.1 ppb, essentially at or near background levels. The highest concentrations of PAH (i.e., >1ppb) were largely observed only during the release (May-July) and the higher concentrations close to wellhead. The highest concentrations observed in the surface waters (0-10 m), not at depth, likely due to re-entrainment from the surface. PAHs in subsurface water masses including the subsurface layer from 1100 to 1300 are rapidly attenuated; post-release concentrations quickly return to low (background) levels. Mean concentrations (exposures) were uniformly low despite rare and sporadic high concentrations. Within the 1100-1300 m depth range TPAH seldom exceeded 10ppb with the highest concentration of 23 ppb TPAH and a geometric mean value < 0.1 ppb. Deepwater concentrations of TPAH attenuated rapidly with distance from the release point (the wellhead) and were seen to reach < 1.0 ppb within 15-20 miles in all directions other than to the southwest, where a small number of samples exceeded 1ppb out to 40 miles. The detailed compositions of 2 through 5 ringed parent and alkylated PAHs) of TPAHs varied widely; the range of these compositions and the association with dissolved and droplet fractions will be discussed. Chemical dispersant concentration (DPnB) distributions generally mimic those of the TPAH in the water samples. The range during the release was from ND to < 1000 ppb with high concentrations rarely exceeding 10 ppb. DOSS concentrations during the release were similar to DPnB, but after the release the DOSS concentrations appeared to remain higher (< 10 ppb) for longer and over a wider range than did the DPnB. Explanations for this apparent decoupling of DPnB and DOSS tracers of the dispersant will be discussed.

TP021 Chemical Composition of Different Weathering Stages of the Macondo Oil, and Their Water Accommodated Fractions L. Faksness, SINTEF, Marine Environmental Technology; P.S. Daling, SINTEF,, Marine Environment Technology.; K. Almaas, SINTEF, Marine Environmental Technology. At the SETAC meeting in Pensacola in April 2011 initial results on the chemistry on laboratory weathered Macondo oil samples were shown. This presentation gives the detailed results on each of the laboratory generated weathered oil residues, which included quantification of more than 200 compounds (including volatiles, PAHs, saturates, and biomarkers). Furthermore, an inter-laboratory comparison between three laboratories is documented. The chemical composition of the water accommodated fractions (WAFs) from selected numbers of these weathered samples will be reported, as the chemical profile of the WAF is very unlike that of the parent oil due to different water solubilities of the various compounds. The Macondo oil is a light paraffinic crude oil, where e.g., 50-55 wt% will evaporate within 5 days on the sea surface. Preparation of WAF has been performed under controlled conditions following the guidelines established by the Chemical Response to Oil Spills: Ecological Research Forum (CROSERF). The CROSERF testing protocols were developed to standardize WAF preparation, laboratory exposures to aquatic organisms, and analytical chemistry measurements used to determine the acute toxicity of the water soluble components in the oil. The WAF is of special interest because such components dissolved from an oil slick or from the dispersed oil droplets beneath a slick are known to have a high bioavailability to marine organisms and therefore have a potential for causing acute toxic effects. Different weathering degrees have been used in preparing the WAFs to illustrate "snapshots" in the dynamic process of weathering and dissolution occurring during a spill situation: Fresh and artificially weathered oils from 150 °C+ (compounds with boiling point below 150 °C is topped off) to 275 °C+, where the 150°C+ residue is assumed to be similar to the surfacing oil, and the 275°C+ residue to approximately 3 to 5 days on sea. An oil-to-water ratio of 1 to 10000 (100 mg oil/L water), which is considered to be a realistic approach in an oil spill release after treatment of chemical dispersants, are used.

TP023 Applications of Using Hyperspectral Data for Oil Spill Monitoring and Assessment D. Faust, Texas Tech Univ/TIEHH, Dept of Environmental Toxicology; L. Cong, Texas Tech Univ, Dept of Electrical Engineering; P.N. Smith, Texas Tech Univ/ TIEHH, Environmental Toxicology; S. Cox, Texas Tech Univ, Dept of Environmental. Toxicolgy; B. Nutter, Texas Tech Univ, Dept of Electrical Engineering; D. Liang, Texas Tech Univ. Monitoring and assessment of oil spills has traditionally relied on visual observations made either in the field or via remotely sensed imagery. Recent advances in sensing technologies and computational capabilities offer new opportunities for developing reliable, quick and automated detection and mapping methods to better support response, recovery planning, and impact analysis. Following unintended releases of oil, degradation processes quickly and dramatically change the chemical composition of crude oil. Thus, its physical form, toxicity, and spectral image signature will also evolve. We hypothesized that spectral signatures of oils were unique and, in response to weathering, would change over time in a manner that would allow hyperspectral imaging to be used as an oil spill monitoring and assessment tool. Using a FieldSpec3 Max Spectrometer Field Spectroscopy Environmental Analysis system, we measured solar reflectance from fresh West Texas sour crude and weathered crude oil collected from the Gulf of Mexico at approximate thicknesses of 0, 0.5, 1, 2, 4, and 8 mm on the surface of sea water in a microcosm environment. Crude oils were exposed to environmental conditions, and hyperspectral solar reflectance was measured weekly for ten weeks. Solar reflectance was different among the various thicknesses and sources of oil. For the sour crude oil at thicknesses of 1, 2, 4, and 8 mm, the reflectance spectrum was relatively uniform throughout the complete wavelength range, which was quite different from the spectrum of seawater. Generally, there was less reflectance with increasing surface oil thickness. Spectrally, the 0.5 mm oil surface exhibited spectral features from both thick oil surfaces and seawater and thus can be considered a linear mixture of both thick oil surfaces and pure seawater. The hyperspectral signatures of the oils changed with time, likely due to weathering and degradation processes. Generally we found that the spectrum of oil surfaces became very similar to that of seawater following degradation processes. Thick surfaces were also observed to degrade slower than thin surfaces. Correlation of in-situ data collected in this study with hyperspectral aerial or satellite imagery has the potential to yield a powerful tool for long-term monitoring, assessment, and management of future oil spills.

TP025 PAHs from MC-252 in Whole Blood and RBCs from Live-captured Birds Using Ultra Performance Liquid Chromatography (UPLC): Method Development/Assessment C.R. Perkins, Univ of Connecticut, Center for Environemtnal Sciences and Engineering; A. Provatas, Univ of Connecticut, Center for Environmental Sciences and Engineering; W. Seegar, M. Yates, G. Doney, Earthspan; D. Evers, Biodiversity Research Institute. The explosion of the Deepwater Horizon oil platform on April 20, 2010 resulted in an unprecedented release of crude oil in the Gulf of Mexico. Much of the oil and the dispersants used impacted salt marshes and beaches around the Gulf, with numerous species of birds documented as being exposed. While the use of dispersants in an oil spill response involves tradeoffs between effects to the shoreline and effects to pelagic and deep-sea environments, relatively little is known on the effects that the oil-associated polycyclic aromatic hydrocarbons (PAHs) have upon the health of avian populations. Circulating blood-borne, parent PAHs can provide a direct link for exposure assessment and reconstruction since they are not as affected by differences in metabolism and excretion. There are a couple of challenges in analyzing whole blood and red blood cells (RBCs) from live-captured birds that make quantitation more difficult; minimal sample volume (0.1- 0.5 ml) can be obtained without being detrimental and the target analytes are less abundant by volume in circulating RBCs in contrast to whole blood. We developed a novel method for the analysis of 16 PAHs utilizing ultra-performance liquid chromatography coupled to photodiode array, fluorescence, and tandem mass spectrometry detectors. This rigorous method obtained good recoveries of standard reference material (60-95%), matrix spikes (60-95%), calibration verifications (90-95%), and surrogates (85%) while obtaining good sensitivity of at least 5ng/g for PAHs. This method was developed in support of an ongoing study examining uptake and exposure in migrating peregrine falcons and other birds. Funding for a portion of this study was provided by Peter Jenny and The Peregrine Fund.

TP026 Assessment of Water, Sediment, and Oyster PAH Concentrations and RNA and Protein Expression Following the Deepwater Horizon Oil Spill M. Dailey, J. Corrales, C. Thornton, Univ of Mississippi, Environmental Toxicology; H. Patterson, Univ of South Alabama, Marine Science; A. Boettcher, Univ of South Alabama, Biology; R. Carmichael, Dauphin Island Sea Lab; M. Slattery, Univ of Mississippi, Pharmacognosy and Environmental Toxicology; K.L. Willett, Univ of Mississippi, Environmental Toxicology Research Program, Univ of Mississippi, Dept of Environmental Toxicol. On April 20, 2010, BP's Deepwater Horizon oil rig exploded leaking over 200 million gallons of crude oil into the Gulf of Mexico for 100 days. Exposure to oil-associated polycyclic aromatic hydrocarbons (PAHs) in the water and sediment could severely impact the aquatic organisms inhabiting the Gulf of Mexico (i.e., developmental defects, reproductive effects, death, etc.). Therefore, water, sediment and oyster, *Crassostrea virginica*, samples were collected approximately bimonthly between May 26 and November 30, 2010 from three sites along the Alabama Gulf Coast, namely, two sites in Mobile Bay (Denton and Sand at 1 or 0.1 m above the bay floor) and one near Perdido Bay. Water, sediment, and oysters were extracted for quantification of 24 PAHs by GC/MS. A possible correlation between PAH exposure and biological processes was investigated by studying RNA and protein expression in oyster gill by qRT-PCR and bottom-up shotgun proteomics, respectively. In bottom-up proteomics, proteins were digested into peptides and analyzed by LC/MS. Expression of stress indicators (e.g., catalase, superoxide dismutase, 14-3-3 proteins, heat shock proteins, etc.) at the transcriptomic and/or proteomic levels were measured. The concentration range for total PAHs in water was 3.46-1240 ng/L. The highest water total PAH concentrations were observed on 6/28/10 for Sand (1 m), 8/4/10 for Sand (0.1 m), 7/21/10 for Denton (1 and 0.1 m), and 9/9/10 for Perdido sites. Quantification of sediment and oyster total PAH concentrations and RNA/protein expression will allow for both biomarker development and further understanding of the physiological consequences of exposure. Supported by the Northern Gulf Institute and NIUST NA07OAR4300494.

TP027 Selection of a Surrogate MC252 Oil as a Reference Material for Future Aquatic Toxicity Tests and Other Studies O. Pelz, BP, Gulf Coast Restoration Organization, BP GUlf Coast Restoration Organization, GCRO; J.S. Brown, Exponent Inc.; M. BenKinney, Exponent; P. Gardinali, Florida International Univ; C. Gong, BP; D.B. Grass, BP, GoM Thunder Horse PU; M. Huddleston, Cardno Entrix; G. Rand, Florida International Univ, Ecotoxicology & Risk Assessment; W. Stubblefield, Parametrix, Inc.; A.D. Ahnell, BP GUlf Coast Restoration Organization, Science, Technology, Environment & Regulatory Affairs. Many scientific studies are planned that involve Macondo (MC252) crude oil; however, demand may exceed supply of the available source oil, such that surrogate crude oils are necessary. This presentation describes the process and analytical results for selecting an appropriate surrogate for MC252 oil. The selection criteria for surrogate candidates were based on a.) geography and oil family (also platform/well ownership), b.) crude oil chemistry and composition, and c.) aquatic toxicity testing. Oil produced from the BP facilities at Horn Mountain and Marlin satisfied the first criterion. Environmental forensic methods were then applied to several samples of different petroleum streams from these facilities to determine hydrocarbon profiles (including total petroleum hydrocarbons (TPH), volatile hydrocarbons (BTEX), saturated hydrocarbons (SHC – alkanes), polycyclic aromatic hydrocarbons (PAH), alkylated PAH, and geochemical biomarkers (steranes and triterpanes)). Based on the chemistry results, the two closest surrogate oils were selected and as a final criterion, laboratory-based acute and chronic toxicity tests are conducted on water accommodated fractions (WAFs) of these oils and MC 252 oil to enable direct comparisons of the aquatic toxicological properties (LC50 and EC10 values).

TP028 Changes in Dissolved Hydrocarbon Content of Shallow Waters During and Shortly After the Deepwater Horizon Incident A. Ross, C. Stalvies, C. Stalvies, X. Qi, E. Crooke, D. Fuentes, S. Armand, A. Revill, A. Talukder, CSIRO. The Deepwater Horizon incident began on April 20th 2010 and oil was released into the Gulf of Mexico until July 15th 2010. Mixing between the hydrocarbons and seawater while rising vertically about 1,500 meters to the surface, and mixing of the surface slick and seawater resulted in dissolution of components susceptible to partitioning into the aqueous phase. Such compounds include benzene, toluene, ethylbenzene, xylenes, naphthalenes and polyaromatic hydrocarbons. This presentation focuses on the dissolved hydrocarbon compounds and oil droplets detected and measured in the surface waters of the Gulf of Mexico during and shortly after the release. Between the 5th of June and 14th of September 2010 we investigated the abundance and distribution of these compounds using a prototype 3 fluorimeter hydrocarbon sensor array tuned to detect the presence of dissolved petroleum hydrocarbons in waters 1-2 meters below the sea surface. The Chelsea Aquatracker, Contros and Trios flourimeters operated continuously while the survey vessel was underway. In total we surveyed over 8,998 linear nautical miles (~16,664line kilometers) and gathered over 2.2 million real time sensor data points. The survey area in the Northern Gulf of Mexico encompassed a large offshore geographic area from western Louisiana through to western Florida, including transits within a few miles of the Macondo well. These data are calibrated to 440 results from discrete near-surface water, and surface oil slick samples analyzed by gas chromatography mass spectrometry (GCMS). The technical details of the operation and geochemical calibration of this real time data stream are presented in accompanying posters. The results of this work will be presented to demonstrate the geographic distribution, and changes over time, of the dissolved hydrocarbon concentrations in surface waters the over the survey period. Associations of dissolved hydrocarbons and oil droplets with surface slicks will be illustrated, and presented with background data from baseline areas where no slick was ever detected.

TP030 Acute Toxicity of the Oil Dispersant, Corexit 9500A, on Aquatic Photosynthetic Organisms S. Johnson, RUTGERS Univ, Environmental Science; M. Gorbunov, RUTGERS Univ, Institute of Marine and Coastal Sciences. Dispersing oil is assumed to protect shorelines and aquatic organisms living within a few meters below the ocean's surface. Acute toxicity studies of the oil dispersant, Corexit 9500A, were evaluated using mysid shrimp, copepod, and fish. However information pertaining to the dispersant effects on the primary producers is lacking. The goal of this research was to assess the acute and chronic toxicity of Corexit 9500A on aquatic photosynthesis utilizing the fluorescence induction and relaxation technique. This fluorescence technique provides a comprehensive set of parameters that characterize the excitonic energy transfer in the light-harvesting antennae, the photochemistry in Photosystem II, and the electron transport to carbon fixation. The diatom, *Thalassiosira weissflogii*, (TW) and the zooxanthellae, *Symbiodinium* spp. (Zoox) were exposed to varying concentrations (.038 to 1.71 g/L) of Corexit 9500A. The mean 48hr EC_{50} for the dispersant was .57 g/L and 1.33 g/L for TW and Zoox, respectively. At these concentrations, no effect to the photosynthetic electron transport on photosystem II acceptor side was detected. However, a marked decline in the quantum efficiency

of photosystem II and the energy transfer efficiency in the photosynthetic light-harvesting antenna was observed. The analysis revealed that Corexit 9500A adversely affects the primary photosynthetic reactions. This information can be utilized to organize dispersants by potency.

TP031 The EPA Aquatic Life Benchmarks and Beyond: Improving Toxicity Assessments with Predictive Models and Empirical Data S.R. Thoms, USEPA, Region 4, Superfund Division, USEPA, Region 4, Waste Division, Office of Technical Serv, USEPA, Region 4, Superfund Division, Superfund Support Branch, USEPA, Region 4, Waste Division, Office of Technical Serv; A.C. Bejarano, Research Planning Inc., Research Planning Inc.; U. Kipka, Anchor QEA. Estimating the bioavailability and toxicity of mixtures of crude oil chemicals is critical in assessing the impact of an oil spill. The water-accommodated fraction (WAF) of the oil is often tested to estimate potential toxicity if oil were released to receiving waters. The Operational Science Advisory Team (OSAT) extracted WAF from three types of residual oil collected at four case study locations, one within each impacted State. OSAT used the toxic unit approach, derived from the EPA aquatic life benchmarks, to assess potential toxicity of PAH mixtures to aquatic organisms, where the sum of PAH toxic units that exceeded unity may indicate potential adverse effects. For certain WAF samples PAH toxic units exceeded unity. The lack of actual WAF toxicity testing and field-collected chemistry data for realistic exposures, where dilution would occur, created controversy among the OSAT with regard to interpretation and presentation of the data. Many assumptions went into the development of the EPA aquatic life benchmarks. The additive model of PAH toxicity on which benchmarks were based is only as good as the description of toxicity and bioavailability of each chemical. However, predictive models are also available and should be evaluated to better assess the toxicity of oil residues to aquatic fauna when empirical data is limited or unavailable. This work aims to assess the current capability of both single parameter, octanol-water partitioning linear free energy relationships (LFERs) and polyparameter LFERs (pp-LFER) to predict literature-derived 95% species protection levels (HC5). Assumptions made in the derivation of the EPA aquatic life benchmarks will be examined. A pp-LFER model for coal tar more or less predicted the partitioning of PAHs between residual oils and WAF, while the single-parameter LFER used to derive the EPA aquatic life benchmarks overestimated solubility. Implications of observed deviations in the literature toxicity information or the WAF-derived bioavailability results from model assumptions will be discussed in terms of how model fits affect the strength and reliability of toxicity predictions.

TP032 The Interaction Effects of Natural Oil and Oil Dispersants with Delivery System on Embryos of *Palaemonetes pugio* J. Rayburn, Jacksonville State Univ, Dept of Biology. Grass shrimp (*Palaemonetes pugio*) are an important species from an ecological perspective because they serve as a link for energy transfer between trophic levels in the coastal food web. Grass shrimp are predators of meiofauna and small infaunal polychaetes, oligochaetes and nematodes and are consumed in large quantities by commercially important fishes and forage species. As part of the overall effort in determining the effects of hydrocarbon on estuarine environments in the Gulf of Mexico, this proposal would investigate the effects of oil and oil dispersant toxicity to grass shrimp (*Palaemonetes pugio*). The question investigated was to determine the acute toxicity of both the oil, the oil dispersants used and if there are synergistic effects between the two. The grass shrimp were collected and identified to species (*Palaemonetes pugio*), sexed, length, reproductive status, (state of embryos if present) and observations of parasites recorded. Ten females and 15 males were kept in glass aquaria (approximately 35 liters) at 20 ppt sea water (made with artificial sea salts). Grass shrimp were maintained in standard laboratory conditions, 12 hr light dark, 27 degrees C. The grass shrimp were feed high protein fish food. Gravid females were removed and ages of embryos were determined. Embryos were collected at tissue cap stage and 3 days prior to hatch. Embryos were placed in individual 24 well plates with 2 mls of test solution. Twenty-four wells (one plate) were used for controls and for each test concentration. Embryos were observed daily for mortality. Embryos were espoused to a concentration series of oil, oil dispersants and mixtures of the two to determine the LC50 using probit analysis. Toxic unit analysis was performed to quantify the interactions. This study further validates the use of grass shrimp embryos in assessing the impact of chemicals and mixtures in estuarine environments.

TP033 Development of a Rapid Method for the Analysis of Olafactory Compounds and Petroleum Hydrocarbons in Seafood Using SPME-GC-MS S. Genualdi, Environment Canada, Science And Technology Branch, Environment Canada; L. DeJager, T. Begley, FDA. During the aftermath of the Deepwater Horizon oil spill in April 2010, NOAA and the FDA revised the guidelines for re-opening closed seafood harvest areas. In order to improve the response time in the event of future oil spills, a rapid method using a 5975T transportable GC/MS is being developed for olafactory compounds indicative of petroleum taint. This would increase sample throughput and replace the currently required human sensory panel. The olafactory compounds used in this study consist of benzene, ethylbenzene, toluene, p-xylene, indan, tetralin, mesitylene, naphthalene, and 1-methyl naphthalene. Petroleum hydrocarbons were included as analytes of potential interest and consist of straight chain, branched, and cyclic alkanes. The analytical method using solid phase microextraction (SPME) gas chromatography – mass spectrometery (GC-MS) was first optimized using aqueous solutions. This method was further tested on seafood (finfish, shrimp, and mussels) obtained from local markets and also on seafood fortified with olafactory compounds, petroleum hydrocarbons and oil from the Deepwater Horizon Spill. This automated method significantly reduces analysis time while providing a transportable option to obtain quantitative results at concentrations < 50 ppb in the field in case of a future disaster.

TP034 Analysis of Polyaromatic Hydrocarbons (PAH) in Seafood Using HS-SPME-GC-MSD L.S. DeJager, T. Begley, Food and Drug Administration, Center for Food Safety and Applied Nutrition. Polyaromatic Hydrocarbons (PAHs) are a class of organic pollutants which are found in significant quantities in crude oil. In addition to the primary PAH structures, mono, di and tri alkyl substituted PAH moieties have been identified. PAHs contamination is a concern because some of these compounds have been shown to have significant gene toxicity. The recent Deep Water Horizon oil spill contaminated large areas of federal and state fishing waters. According to federal and state protocol, before the fisheries could be reopened seafood samples must pass sensory testing for taint and then pass chemical analysis for PAHs. Because of the low concentration of these analytes and the complexity of the tissue matrix, most analyses require pre-concentration and clean up prior to introduction onto analytical instrumentation. Classic extraction techniques, such as liquid-liquid extraction and solid phase extraction, are time-consuming and require significant quantities of solvents and consumable supplies. In order to reduce analysis time and decrease analysis costs it is desirable to develop an automated method for the analysis of PAHs and PAH homologs in seafood samples. Solid phase microextraction (SPME) is a sorptive extraction technique that can be used in conjunction with GC-MS to provide automated sample preparation for volatile and semi-volatile analytes. This technique has been used for the analysis of low molecular weight PAHs in seafood, but has not been applied to the higher molecular weight (and less volatile) PAH moieties. A SPME-GC-MS method for the determination of 16 PAHs and 40 alkyl substituted PAH compounds in finfish, oysters and shrimp has been developed. Parameters optimized include fiber coating, extraction time, extraction temperature, sample size and sample composition. Significant carryover of high molecular weight PAHs was problematic, but this was overcome by using a 7µm PDMS fiber and a high injection port temperature. Using a 3 hour extraction time, we achieved limits of detection of less than 10 ppb in seafood which are lower than the concentrations outlined in the reopening protocols. This method will provide an important analytical tool for rapid response in the event of another oil spill.

TP035 Natural Oil and Gas Occurrences in the Mississippi Canyon Protraction Area: Geochemistry and Origin of Naturally Occurring Hydrocarbons in Sediments A. Kornacki, Weatherford , BP GCRO, 1315 West Brooklake; P.D. Carragher, BP GUlf Coast Restoration Organization, Science, Technology, Environmental and Regulatory Affairs. Sediments near natural petroleum seeps contain mixtures of fresh oil, biodegraded oil, thermal and/or microbial natural gas, and recent organic matter (ROM). We applied quantitative methods to separate the relative contribution of these components in >100 deepwater sediment samples pre-dating the DWH incident, and present a model integrating the data and relevant processes. Deepwater Gulf of Mexico (GOM) sediments generally contain small amounts of organic matter -- the debris from the marine and terrestrial biospheres: e.g., algal or plant material. Turbidity currents transport waxy plant material into the deepwater GOM. This type of ROM consists largely

of C_{23}-C_{31} n-alkanes with an odd carbon-number preference, typically increasing in concentrations to a peak at C_{29}. Crude oil is different: n-alkanes lighter than C_{20} are more abundant than C_{20+} n-alkanes; C_{23}-C_{31} n-alkane concentrations decrease with increasing C number, and do not exhibit an odd carbon-number preference. Fingerprinting the oil in seeps is challenging because ROM also contains some biomarkers present in crude oil. We used a geochemical parameter based on the abundance of n-alkanes lighter and heavier than C_{23} to estimate the relative amount of crude oil vs. ROM in seep samples. The LHAR (*L*ight to *H*eavy *A*lkane *R*atio) value is higher in seep samples enriched in oil than in seep samples enriched in ROM. A map of the Mississippi Canyon Protraction Area and vicinity shows the complexity of the oil seep system.

TP036 Natural Oil and Gas Seeps and Oil Slicks in the Mississippi Canyon Protraction Area: Remote Sensing by Satellite, Surface Monitoring and AUV Surveys C. Scherschel, BP, BP, 1315 West Brooklake; R. Frost, BP, Upstream Technology, 1315 West Brooklake. Satellite data has proven very useful in the detection of oil slicks at sea, both from naturally occurring oil seepage, and the variety of human activities that cause oil releases. Repeat satellite passes, often over a number of years, identify areas of persistent release that are clearly from natural seepage. In detail, this process requires quality control of the data set to ensure the correct weather conditions for interpretation are met. This poster presents preliminary results of a project to identify oil slicks of a natural origin in the vicinity of the Mississippi Canyon Protraction area. The time period covered is the period up to April 2010, predating the DWH Incident and the resulting oil slick. The linkage of these natural slicks to seabed features and the sub-seafloor geology will be shown. Autonomous Underwater Vehicles (AUVs) provide detailed and accurate data on the seafloor in deepwater environments. The physical features of the seabed can be mapped with resolutions of 1 meter or less over areas in the order of 100 km2. In addition, sub-bottom profiling provides data on the stratigraphy of near- seabed sediments. This presentation focuses on the identification of natural seeps on the seafloor, in both map and cross-sectional view, over a large area surrounding the Macondo well in block Mississippi Canyon 252. The poster will show the geological context for an area of prominent seep features, tracing the seeping hydrocarbons from their migration pathway through the sedimentary sequence up to the seabed and then to the water surface. This data provides the local context for the sediment sampling work that was reported by the OSAT in December 2010; and the sediment fingerprinting paper presented by Brown et. al. at the SETAC special session in April 2011. At selected sites, the AUV performed a more detailed photomosaic survey, examples of which will be presented in this poster.

TP037 Time Integrative Large Volume In Situ Water Extraction for Total and Dissolved Trace Organics B. Hepner, Aqualytical Services Incorporated; D. Mabe Jr., C.I.Agent Storm?Water Solutions. The standard grab sample water bottle has a volume of 1 liter or less. This is an insufficient volume for the analysis of many contaminants at the sub-microgram per liter concentrations necessary for assessing compliance with water quality guidelines. In principle, the level of detection could be improved by collecting a larger volume, time integrative sample. The difficult task in concentrating large volume samples is capturing the pollutants in both the particulate and dissolved phases without allowing significant break-through of the contaminants. In order to accomplish this, two different pollutant removal mechanisms must be employed. Pollutants bound to the particulate phase can be removed via a filtering system that physically removes all particulate matter. Those pollutants in the dissolved phase, however, must be extracted from the water utilizing a substance that sequesters them. In order to extract in situ large volumes of water while separating the pelagic sediments from the dissolved fraction, a two stage Luer locked disk system coupled to a small submersible pump was developed. The first stage disk used lofted glass depth filtration to quantitatively retain pelagic sediments for extraction and analysis. The second stage disk sequestered dissolved trace organics of interest, with solid phase extraction media. The small submersible pumping system would draw water slowly through the disks at 10-50 ml/min. providing a time integrative extraction event, representing days to weeks, and up to 100 liters of water. GC/MS/ LVI results from two studies will be presented using this submersible extraction system: An ultra low level PAH study, comparing its relative concentration in the pelagic sediments to its associated dissolved water concentration from a large volume extraction event of 50 to 100 liters. The second is a study of the water column off Dauphine Island, Alabama, which was continuously monitored using this extraction system for PAHs in the PPT level during the Horizon spill event. This provided three months of monitoring before and during the event, which will also be presented.

TP038 Productivity of Colonial Waterbirds and Seabirds Breeding in the Northern Gulf of Mexico Following the Deepwater Horizon Accident J.R. Wakefield, P. Reilly, Cardno Entrix. In 2011, BP undertook one of the largest efforts implemented to date to estimate productivity (fledglings produced per active nest) of colonial nesting waterbirds in the northern Gulf of Mexico. Ground and aerial surveys were used to gather productivity data at 40 nesting colonies. Thirty of these colonies, all in eastern Louisiana, were stratified into three categories based on the peak level of oiling recorded in surrounding habitat during the summer of 2010. (The 10 remaining colonies were located along north Texas shorelines, which were unaffected by the Deepwater Horizon accident.) Nest counts began April 15, 2011 and continued through July 1, 2011. Ground counts occurred every three days and aerial counts and photo-documentation occurred every 15 days. Focal species included brown pelican, great egret, black skimmer and laughing gull. Other species, such as royal tern, Caspian tern, least tern, sandwich tern, and American oystercatcher, were included as field conditions dictated. Species-specific data describing the productivity of individual colonies will be presented along with statistical evaluations of the effect of 2010 oiling on 2011 productivity. These data will be supplemented with data from the ongoing satellite tracking of brown pelicans and great egrets to present a detailed picture of birds in the northern Gulf of Mexico one year following the Deepwater Horizon incident.

TP039 Contamination Profiles of PCB Congeners, Chlorinated Pesticides and PBDEs in Sediment and Fish Samples from Coastal Waters Off Savannah, Georgia, USA B.M. Cassidy, Murray State Univ, Chemistry and Watershed Studies Institute; P. Chakraborty, J.P. Richardson, K.S. Sajwan, Savannah State Univ, Natural Sciences and Mathematics; B.G. Loganathan, Murray State Univ, Dept of Chemistry & Watershed Studies Institute. Classical persistent organic pollutants and emerging new organic pollutants are of great concern due their negative effects on environment, wildlife and human health. Estuaries and coastal marine environments are considered the most sensitive areas to the accumulation of these pollutants. Objective of this study was to understand the contamination status of classical and emerging pollutants in the coastal waters off Savannah, Georgia. PCB congeners, chlorinated pesticides and PBDEs were analyzed in sediment and various fish species samples collected from riverine (Vernon River, Harmon Canal) and coastal waters off Savannah, Georgia. Standard analytical procedures were followed to determine the concentrations of these contaminants. Results revealed that detectable levels of PCBs, pesticides and PBDEs were found in sediments and fish samples from this region. The results were compared with the earlier studies on these pollutants to discern temporal trends.

TP040 Distribution and Air–Sea Exchange of Current-use Pesticides (CUPs) from East Asia to the Arctic G. Zhong, Helmholtz-Zentrum Geesthacht, Yantai Institute of Coastal Zone Research, CAS; Z. Xie, Helmholtz-Zentrum Geesthacht, Helmholtz-Zentrum Geesthacht, Dept for Environmental Chemistry, Helmholtz-Zentrum Geesthacht, Institute of Coastal Research, Dept for Environmental Chemistry, GKSS Research Centre, Research Scientist; M. Cai, Polar Research Institute of China; A. Moeller, R. Sturm, Helmholtz-Zentrum Geesthacht; J. Tang, Yantai Institute of Coastal Zone Research, CAS; G. Zhang, Guangzhou Institute of Geochemistry, CAS; J. He, Polar Research Institute of China; R. Ebinghaus, Helmholtz-Zentrum Geesthacht. Surface seawater and boundary layer atmospheric samples collected on the ice-breaker *M/V Xuelong (Snow Dragon)* from the East China Sea to the high Arctic (33.23–84.5 °N) in July to September 2010 were analyzed for six current-use pesticides (CUPs) trifluralin, endosulfan, chlorothalonil, chlorpyrifos, dacthal and dicofol. Paritculate CUPs in both air and seawater is minor. All CUPs were not only detectable in all oceanic air, but also had levels as high as 100s pg/m^3 in Japan Sea. Gaseous CUPs basically decreased sharply from East Asia (36.6 and 45.1°N) to the north, following a relatively slow descent until it bottomed out at the Bering Sea (58.1-66.4°N), thereafter air CUPs more or less mounted up again in Chukchi Sea. The dissolved CUPs ranged widely from α-endosulfan, chlorpyrifos and dicofol in seawater were roughly consistent with their latitude trends in air. Trifluralin in seawater was relatively high at Japan Sea (35.2°N) and evenly distributed from 36.9 to 72.5°N, whereas

below detection limit in the highest latitudes in Chukchi Sea. In contrast with other CUPs, chlorothalonil and dacthal in Chukchi Sea were far more abundant than those in East Asia. The air-sea gas exchange flux of CUPs was generally dominated by net deposition.

TP041 The Global Distribution of Perfluorinated Compounds and Long-range Transport via Marine Water in the Arctic, Atlantic Ocean and Antarctic Coast Z. Zhao, Helmholtz-Zentrum Geesthacht, Dept for Environmental Chemistry; Z. Xie, Helmholtz-Zentrum Geesthacht, Helmholtz-Zentrum Geesthacht, Dept for Environmental Chemistry, Helmholtz-Zentrum Geesthacht, Institute of Coastal Research, Dept for Environmental Chemistry, GKSS Research Centre, Research Scientist; A. Moeller, Helmholtz-Zentrum Geesthacht; R. Sturm, Helmholtz-Zentrum Geesthacht, Max-Planck Str.1; R. Ebinghaus, Helmholtz-Zentrum Geesthacht. Since the ubiquitous occurrence and potential toxicity to human beings, the perfluorinated compounds (PFCs) have attracted more concerning in the recent years. In 2010, one of the PFCs, perfluorooctane sulfonate(PFOS) was added to Annex B of Stockholm Convention on Persisitent Organic Pollutants(POPs), which means the official ban in the whole world. However, the emission of some other PFCs from the manufactures and products are still potential threats to the environment and living creatures. Perfluorinated carboxylic acids(PFCAs) and perfluorinated sulfonates (PFSAs) are very soluble, and the PFOS reside in marine surface water recently was estimated similar to the estimated release amount. The persistent PFCs could be transported via ocean current to polar areas which results the occurrence in polar water and biota. In this study, the global distribution and long-range transport of PFCs were investigated in marine surface water. 24 PFCs were detected in 78 seawater samples from Antarctic, Atlantic and Arctic area collected in 2010-2011. The levels were compared to former studies to figure out the trend of PFCs release to the environment. The dynamics of long-range transport of PFCs were investigated and the fates of different compounds were predicted.

TP042 Regional Differences of Concentration and Chiral Signatures of DDTs and HCHs in the Yellow Sea S. Hong, Korea Ocean Research & Development Institute, Oil and POPs research group, Korea Ocean Research & Development Institute; W. Shim, U. Yim, Y. Jin, S. Ha, Korea Ocean Research and Development Institute; G. Han, Korea Ocean Research and Development Institute, Oil & POPs Research Group; N. Kannan, Korea Ocean Research and Development Institute. Yellow Sea is a semi-enclosed body of water bound by Chinese mainland to the west and Korean Peninsula to the east. Yellow Sea has been threatened by both land- and sea-based sources of pollution resulting from the extensive economic development in the coastal zone. DDTs and HCHs are some of major contaminants of concern in this region. To assess their contamination characteristics, we collected air, seawater, and sediment samples from coastal and offshore regions and conducted chemical analysis. Generally, China showed a relatively high level of DDTs and HCHs at most matrixes, which could be due to the massive production and extensive use of these chemicals in China in the past. In order to understand the chiral signature of DDT and HCH compounds in this water body, chiral analysis for o,p'-DDT and a-HCH was conducted. In the Yellow Sea, (+) o,p'-DDT was more abundant than (-) o,p'-DDT. The portion of the (+) enantiomer in the sediment is relatively enriched. Generally, the chiral signature of o,p'-DDT in air of the Yellow Sea was closer to that in China in winter compared to Korea. But, in summer, it resembled the Korean sources. This indicates clearly that the chiral signature of o,p'-DDT in the Yellow Sea is mainly influenced by the direction of the wind . On the other hand, a-HCH was racemic in most of samples.

TP043 Dietary Exposure of Juvenile Whitemouth Croaker to PBDEs: Uptake, Biotransformation and Depuration Kinectics M.C. Pieroni, J. Leonel, G. Fillmann, Universidade Federal do Rio Grande. Polibrominated Biphenyl Ethers (PBDEs) are flame retardants compounds widely used in plastics, textiles, furniture, electronics, automobiles, and many other materials. Although PBDE are persistent and resistant to degradation, earlier studies have established that some fish can debrominate certain PBDEs congeners. Carps, for example, readily debrominate BDE 99 to BDE 47 while salmon slowly debrominate BDE 99 to BDE 49. Therefore, this study aimed to understand the accumulation and depuration kinetics of PBDEs in the whitemouth croaker (Micropogonias furnieri), an important species in the Brazilian fishery industry, as well as its ability to debrominate both BDE 99 and BDE 153 to lighter congeners. Aproximately 60 juveniles of whitemouth croaker, divided in two 250 L tanks, were used for each exposition (BDE 99, BDE 153 and control). BDE 99 and BDE 153 were chosen due to its use in the pentaBDE technical mixture, which is inferred as the most used mixture in Brazil according to the environmental data. They were exposed to artificially contaminated food for 30 days (50ng/dia/peixe of PBDEs) followed by non-contaminated food for others 30 days. Sampling, for both control and contaminated tanks, occur on days 0, 1, 5, 10, 15 and 30 (contamination period) and on days 41 and 60 days (depuration period). After anaesthesia with benzocaine fish size and weight were recorded and blood were collected. Liver, muscle, guts, stomach and feces are sampled to determined PBDEs concentrations.

TP044 Microbial Transformations of Pollutants in Arctic Ecosystems C. Larose, S. Cecillon, T.M. Vogel, Ecole Centrale de Lyon, Environmental Microbial Genomics Group, Laboratoire Ampère. The Arctic environment is undergoing changes due to climate shifts, long-range transportation of contaminants and increased human activity. That the Arctic is polluted by industrial processes was recognized several decades ago, serving in part as a major impetus for funding Arctic research and highlighted the role of atmospheric transport in contaminating isolated environments with few local pollution sources. Once deposited, these contaminants can undergo a variety of transformations that are biotically and abiotically mediated before contaminating the food chain. Snowpacks and aquatic ecosystems are involved in contaminant cycling and may influence their fate in Arctic systems. Among the different pollutants, this work focuses on mercury as well as legacy and emerging persistent organic pollutants (POPs) in Arctic ecosystems, with emphasis on microbial transformations and metabolism. Snow and fjord water samples were collected at different spatial scales from an Arctic field site, Ny-Ålesund, Norway (79°N). Bacterial diversity and community structure were measured by ribosomal intergenic spacer analysis (RISA) and phylogenetic microarrays. Some identified functional genes involved in POP and mercury metabolism were measured by quantitative polymerase chain reaction analysis (qPCR) and results were linked to contaminant levels. This preliminary work will provide a better understanding of biotic contaminant degradation pathways in arctic environments.

TP045 Evaluation of EROD Activity as a Biomarker of PAHs Exposure in Estuarine Fish and Crustacean in Southern Brazil A. Machado, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas; I.F. Barcarolli, C.L. Paganini, T. Martins Lopes, S. Carvalho Rodrigues, Universidade Federal do Rio Grande; A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. EROD (7-ethoxyresorufin-*O*-deethylase) activity has been widely used as a biomarker of exposure to organic compounds, such as biphenyls, polychlorinated, and polycyclic aromatic hydrocarbons (PAHs). However, few studies focus the application of EROD data to predict environmental health. The aim of this study was to evaluate EROD activity as a biomarker of PAHs contamination in two species from different trophic levels, the fish *Micropogonias furnieri* and the blue crab *Callinectes sapidus*. Animals were collected seasonally in different sites of the Patos Lagoon estuary (Southern Brazil) with different levels of contamination. EROD activity and PAH concentrations were measured in fish liver and crab. To determine its suitability as a biomarker, EROD activity data was correlated with tissue PAH concentration, biotic and abiotic (water) parameters. The higher mean values of EROD activity (μmol resorufin.min^{-1}.mg protein^{-1}) were observed in winter for fish (245.0) and in autumn for crab (325.4), while the highest mean values of PAHs concentrations (ng.g^{-1} ww) were found in winter for both fish (173.8) and crab (361.6). Twenty-five aromatic compounds of different molecular weight, an indication of the number of aromatic rings, were identified in fish liver and crab hepatopancreas. For high molecular weight PAHs, linear regression analysis showed that fish liver concentrations higher than 28.22 ng.g^{-1} ww were strongly and positively correlated with tissue EROD activity. In the other hand, no correlation was observed for low molecular weight compounds and EROD activity in fish liver. Also, no significant correlation was observed in crab hepatopancreas for either high or low molecular weight PAHs. Significant correlations between EROD activity and abiotic parameters such as water temperature and pH were also observed. These findings suggest that these parameters influence the biotransformation of xenobiotics. Taken altogether, findings described in the present study suggest the potential suitability of EROD activity as a reliable biomarker of exposure to high molecular weight PAH exposure in estuarine fish in different seasons. [Supported by Brazilian CNPq (CT-Hidro) and CAPES (Ciências do Mar)].

TP046 Chronology of Chemical Loadings to Tidal Marshes in the Delaware River Estuary M.W. Schafer, Academy of Natural Sciences, Staff Scientist, Patrick Center for Environmental Research, Academy of Natural Sciences, Staff Scientist; D.J. Velinsky, Patrick Center for Environmental Research, Academy of Natural Sciences; J.T. Ashley, Philadelphia Univ; C. Sommerfield, College of Marine and Earth Studies, Univ of Delaware; R. Greene, Delaware Dept of Natural Resources and Environmental Control; T. Fikslin, Delaware River Basin Commission. During the early 20th century, there was a substantial loading of chemical contaminants, such as PCBs, PAHs and DDT throughout the Delaware River Estuary. Since the mid-to-late 1980s, inputs of various "emerging" chemicals, e.g., PBDEs, have also increased. However, since the early 1960's, there have been efforts to reduce chemical loadings, improve ecological conditions within the estuary and reduce the concentration of contaminants in finfish. Sediment cores were taken from ~30 tidal freshwater and estuarine marshes in the Delaware River Estuary to estimate historic loadings of chemical contaminants, nutrients and their potential ecosystem impacts. Chronologies were determined with ^{210}Pb and ^{137}Cs isotopes. A preliminary analysis suggests an average sediment accumulation rate (^{210}Pb) of 0.62 ± 0.24 cm/yr (12% RSD; n =22) with a range of 0.22 to 1.3 cm/yr. Sediment-bound PCBs and other organic contaminants increased in concentration starting in the late 1930s to mid-1950s. Many organic contaminants showed peak concentrations in the 1960s to 1970s. There were also river basin specific differences in contaminant concentrations presumably related to changes in watershed land use. PCB and other sediment contaminant inventories were highest in more urban watersheds. The benefits of coring and developing accurate sediment contaminant chronologies are key to reconstructing historic anthropogenic impacts on the environment. This information will be used to evaluate current environmental conditions and guide future restoration efforts.

TP047 Microplastics in Korean Beach: Spatial Distribution, Composition, and Associated Organic Contamination S. Hong, Korea Ocean Research & Development Institute, Oil and POPs research group, Korea Ocean Research & Development Institute; W. Shim, G. Han, K. Heo, S. Ha, Korea Ocean Research and Development Institute. Currently, marine debris is of global environmental concern. A large portion of marine debris consists of plastics. Plastic materials that were discarded, disposed or abandoned at sea are broken down to microplastics through natural weathering processes such as degradation under UV radiation and abrasion by wave action. Microplastics enter marine environment by other means such as sea transportation or in industrial accidents. The microplastics are capable of adsorbing organic contaminants from water column acting as a useful monitoring tool for marine pollution. In order to understand the contamination status and characteristics of microplastics pollution in Korea, we conducted a beach monitoring survey and subsequently chemical analysis. The density of plastic debris was high at the upper tidal zone. < 5mm size plastics were dominant. Plastic fragments and fibers less than 1mm were also abundantly observed. Interestingly, expended polystyrene (EPS) was the major microplastics of the beach. The average number of microplastics on the beach was 1300 EPS and 16 pellets per m2. This is primarily due to the extensive use of EPS buoy in the aquaculture in Korea. EPS distribution was more at the upper tidal zone than plastic pellets. Persistent organic contaminants such as PCBs, DDTs, and PAHs were detectable in both EPS and the pellet. The POPs concentration was relatively high in pellets on an individual basis (greater surface area and/or active adsorption site) but the overall contribution from EPS was greater due to its high density of availability in a typical Korean beach. In general, aged EPS and pellet accumulated more of chemical residues than fresh ones.

TP048 Sponges as Biomonitors of PHA Contamination in Rio de Janeiro, Brazil A. Wagener, Pontifícia Universidade Católica do Rio de Janeiro, Quimica; K. Tellini, Pontifícia Universidade Católica do Rio de Janeiro; A.H. Nudi, Pontifícia Universidade Católica do Rio de Janeiro, Chemistry; D. Batista, A. Scofield, C. Sette, N. Floriano, Pontifícia Universidade Católica do Rio de Janeiro. Filter feeder organisms have been used to monitor oil contamination in coastal and estuarine waters. The present study evaluates the potential of marine sponge *Hymeniacidon heliophila* as biomonitor of PAH contamination in Rio de Janeiro, Brazil. Samples (sponges and waters) were collected in August 2010 from three areas in the polluted Guanabara Bay as well as in one reference site (Itaipu). Additionally, *Perna perna* was sampled for compare with *H. heliophila* since the mussels are widely considered efficient biomonitors. The determination of 16 PAH (USEPA) and its alkylated homologues were obtained by GCMS. The results show high correlation between species for ∑ 16PAH *(r=0.68) and the inter-specific total mean concentration* did not vary significantly *(ANOVA; p< 0.05). The highest mean concentration of* ∑ 16PAHs in sponges was observed in the most polluted site (1428 ng g^{-1}; Praça XV), followed by Urca (348 ng g^{-1}). Benzo[*a*]pyrene concentration ranged from 10 ng g^{-1} (Itaipú and Marina) to 139 ng g^{-1} (Praça XV). Unexpectedly, sponges from the reference site showed higher concentration *of* ∑ 16PAHs (193 ng g^{-1}) when compared a marina site located inside the bay (Marina da Glória; 174 ng g^{-1}).This area recently became affected by discharge at tons of contaminated sediment from the Rio de Janeiro Harbor and, probably, the activity results in contamination of local ecosystems. As suspension feeders, these animals have high retention rates for particles from 0.2 to 50 µm and consequently can collect pollutants from both suspended and dissolved phases. *Hymeniacidon heliophila* has a response very similar to mussel *Perna perna* and their distributions from North Carolina (USA) to Santa Catarina (Brazil) make them a good alternative for biomonitoring programs in the coastal shallow waters of Western Atlantic. Financing by Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq)

TP049 Development and Evaluation of a Multimedia Environmental Fate Model for Phthalate Esters in a Marine Aquatic Food Web G. Zandpour, H. Lai, Simon Fraser Univ, Biological Sciences; M.G. Ikonomou, Dept of Fisheries and Oceans, Ocean Chemistry; F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment). Di-phthalate esters (DPEs) are widely used commercial chemicals. Their main application is as plasticizers. DPEs are high volume production substances that have been observed to be present in environmental media from many locations around the world. There is concern over the potential impacts of di-phthalate esters and their main metabolites, the mono-alkyl phthalate esters (MPEs), in wildlife and humans. This concern is partly caused by the lack of a quantitative understanding of the environmental fate of these chemicals in the environment. To improve the understanding of the relationship between the release of DPEs into environment and resulting concentrations of DPEs and MPEs in abiotic and biotic media, we developed and tested a multimedia environmental fate and food web model to describe the distribution and transformation of DPEs and MPEs in an aquatic ecosystem. To test the model, we conducted a field study of the distribution of DPEs and MPEs in a marine Inlet in Vancouver, Canada. In this presentation, we present the model, describe the field study and discuss the performance of the model. We demonstrate that the calculated sediment water partition coefficients (organic carbon normalized) are in good agreement with the corresponding independently measured values for both DPEs and MPEs. The only exception was dimethyl phthalate (DMP). Both model calculated and observed bioaccumulation factors of DPEs and MPE in fish and benthic invertebrate species are also presented. The model was applied to assess the combined loadings of DPEs into the Inlet and to assess the real-world half-life time of DPEs and MPEs in an aquatic environment. The multimedia mass balance environmental fate model in conjugation with a food web model provides a better understanding of the distribution and transformation of DPE in aquatic ecosystems. The model can be used in other aquatic environments, with their own system specific and chemical specific parameters. The model is expected to be useful for preliminary ecological risk assessment in order to predict exposure concentrations, internal body burdens and possible remediation targets.

TP050 Inputs of Antifouling Paint-derived Dichlorodiphenyltrichloroethanes (DDTs) to a Typical Mariculture Zone (South China) H. Yu, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences; H.f. Cheng, E.Y. Zeng, Guangzhou Institute of Geochemistry. Existing evidence indicated that dichlorodiphenyltrichloroethane (DDT)-containing antifouling paints were an important source of DDT residues to mariculture zones. However, the magnitude of the impact on aquafarming environment has remained largely unknown. In the present study, the concentrations of DDT and its metabolites (designated as DDXs) were determined in harbor sediment and antifouling paint samples collected from a typical mariculture zone in South China. Compositional and concentration correlation analyses implicated the DDT-containing antifouling paints for fishing boat maintenance as an important source of DDT in the mariculture zone. The annual emission of DDXs to the study region was estimated at 0.58 tons/yr. Furthermore, a comparison of the expected DDT loadings in pelagic fish and field measurements indicated that fish feed especially trash fish was a major

source of DDTs in the fish body. Nevertheless, the use of DDT-containing antifouling paints should be limited to prevent further deterioration in aqua-farming environment.

TP051 Accumulation and Depuration of Polycyclic Aromatic Hydrocarbons (PAHs) in Benthic Gastropods and Crabs: Field and Laboratory Studies Y. Goto, K. Uehara, H. Nakata, Kumamoto Univ. It has been reported that there are significant sources of PAHs in coastal regions of the Ariake Sea and Yatsushiro Sea, western Japan. High concentrations of PAHs were detected in sediments from both areas, at the levels of several tens of mg/kg dry wt. basis. However, little information is available on the contamination of PAHs in organisms. In this study, we have analyzed 17 PAHs in gastropods (*Nassarius festiva*) collected from four locations of the Ariake Sea and Yatsushiro Sea to understand the status of contamination of PAHs in those regions. PAHs were also analyzed in crabs (*Macrophthalmus japonicas*) to compare the residue levels of PAHs between benthic species. PAHs were detected in all samples analyzed in this study. High concentrations of PAHs were found in gastropods from the Omuta River (Ariake Sea) and Tanoura Bay (Yatsushiro Sea), at the average levels of 102 ng/g and 82.6 ng/g (wet wt.), respectively. The residue levels of PAHs in samples of both sites were more than one order of magnitude greater than those in other reference sites. Elevated concentrations of PAHs were also detected in crabs from Tanoura Bay. Fluoranthene and pyrene were dominant components among PAH congeners in both species. Interestingly, high molecular PAH congeners, benzo[*k*]fluoranthene, benzo[*a*]pyrene, and indeno[1,2,3-*cd*]pyrene were predominant in gastropods from Tanoura Bay, which is probably due to discharge of wastewater from a chemical factory producing carbon materials in this bay. In this study, depuration of PAHs was examined in gastropods and crabs to evaluate their potentials for degradation/metabolism of PAHs. The crabs and gastropods collected from Tanoura Bay were transplanted to water tanks containing unpolluted artificial seawater to depurate PAHs in their bodies. The concentrations of PAHs in transplanted crabs drastically decreased from 396 ng/g (wet wt.) to 10.2 ng/g during a four-week experiment in the artificial seawater tank. Significant correlations of PAHs concentrations were found between sediments and crabs. The decline of PAH residues was also observed in gastropods in an artificial seawater tank. These results suggest that organic particles in sediment may play an important role to accumulate/depurate PAHs in the benthic organisms.

TP052 Brain Region and Tissue Distribution and Patterns of Bioaccumulative Perfluoroalkyl Acids (PFAAs) in Highly Exposed East Greenland Polar Bears A. Greaves, Carleton Univ, Dept of Chemistry; R.J. Letcher, National Wildlife Research Center, Carleton Univ, Wildlife Toxicology Research Section, Ecotoxicology and Wildlife Health Division, Wildlife and Landscape Directorate, Science and Technology Branch, Environment Canada; C. Sonne, R. Dietz, National Environmental Research Institute, Aarhus Univ, Dept of Arctic Environment; E.W. Born, Greenland Institute of Natural Resource. Perfluorinated sulfonates (PFSAs) and carboxylic acids (PFCAs) of varying chain lengths are perfluoroalkyl acids (PFAAs), which have been shown to bioaccumulate in wildlife and humans. Accumulation of PFAAs in wildlife has been largely thought, and in some cases demonstrated (e.g., perfluorooctane sulfonate (PFOS)), to be protein-association driven, although transport, deposition and accumulation of PFAAs in the body is not well understood. Previous studies have largely assumed that the liver is the major repository of accumulated PFAAs, and thus distribution of these compounds in other areas of the body is virtually unknown. Without investigating other regions of the body, it is difficult to interpret the overall PFAA pharmacokinetics, and thus tissue-/compartment-specific exposure to PFAAs in wildlife. Polar bears (Ursus maritimus), being the apex predator in the Arctic marine ecosystem, are an ideal species for studying contaminants in the Arctic. This study focuses on the distribution and preferential accumulation of PFAAs in specific regions of the brain as well as tissues (e.g., liver, muscle and fat) and plasma in highly PFAA exposed East Greenland polar bears. One hypothesis that we tested was that PFAAs will accumulate specifically and preferentially in certain brain compartments. Brain regions, and other tissues from 19 East Greenland polar bears (13 males, 6 females) were analyzed for 4 PFSAs (C4, C6, C8, C10), 10 PFCAs (C6 – C15), and 13 precursor compounds. Brain samples were taken from eight different compartments: pons and medulla, cerebellum, frontal cortex, occipital cortex, temporal cortex, striatum, thalamus and hypothalamus. Some highlights of our findings showed that in the brain, PFOS was present at the highest levels (35.2 ng/g ww), followed by perfluorotridecanoic acid, PFTriA, (31.4 ng/g ww). Long-chain PFCAs (C10-C15) and PFOS were all significantly ($p < 0.05$) positively correlated with lipid content. Significant differences ($p < 0.05$) between compartments for long-chain PFCAs (C11-C14) were present, and positively correlated with extractable lipid content. Positive age correlations were found for PFSAs (C6, C8, C10), long-chain PFCAs (C10-C15), and FOSA. Until now, it has been believed that relative to protein-associated interactions, lipids play a more minor role in the distribution of PFAAs in the body; however, these results suggest that long-chain PFCA distribution is indeed influenced by lipid content in the brain.

TP053 Developmental Toxicity of Perfluorinated Phosphonic Acids in Mice K. Tatum-Gibbs, UNC-EPA, Post-doc; K. Das, B. Grey, C. Wolf, A. Watkins, B. Abbott, USEPA, Toxicity Assessment Division; M. Strynar, A. Lindstrom, USEPA, Human Exposure and Atmospheric Sciences Division; C. Lau, USEPA, Toxicity Assessment Division. Perfluorinated phosphonic acids (PFPAs) are a third member of the perfluoroalkyl acid (PFAA) family, and are structurally similar to the perfluoroalkyl sulfonates and perfluoroalkyl carboxylates. PFPAs are used primarily as a surfactant defoaming agent in pesticide production. Recently, these emerging chemicals have been detected in the environment, particularly in surface water as well as in effluent of wastewater treatment plants at concentrations ranging from pg/L to the low ng/L range. The presence of these chemicals in wastewater suggests human exposure; currently there is limited toxicological data concerning the potential health risks associated with exposure to this class of PFAAs. Previous studies from our laboratory have identified developmental toxicity associated with gestational exposure to perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA). The current study examines the potential adverse developmental effects of PFPA in the mouse. A mixture of PFPAs (Masurf-780) was given to timed-pregnant CD-1 mice by oral gavage daily on gestation days (GD) 1-17 at doses of 5, 10, 20, 30 or 40 mg/kg; controls received deionized water vehicle. At GD 17 (24 hours after the last treatment), mice from each dose group were subdivided and approximately half were sacrificed via decapitation for maternal and fetal examinations. PFPA did not alter maternal weight gains, but significantly increased maternal liver weights at term (GD-17) in a dose-dependent manner. PFPA did not influence the number of live fetuses or fetus weight observed at GD-17, except in the 40 mg/kg group where some mortality was observed. In contrast, fetal liver weights were significantly increased at doses greater than 5 mg/kg. Neonatal survival and growth were monitored through postnatal day 42 where significant changes were only seen in the highest dose group; whereas increased liver weight persisted in all dose groups. These results thus suggest that PFPA exposure during pregnancy did not compromise neonatal survival and postnatal growth to the extent seen with PFOS and PFOA, but the hepatic effects appeared to be common to all classes PFAAs. This abstract does not necessarily reflect USEPA policy.

TP054 Perfluorinated Phosphinates and Polyfluoroalkyl Phosphoric Acid Diesters in Sediments from the Great Lakes Region R. Guo, Univ of Toronto; E. Reiner, Ontario Ministry of the Environment, Univ of Toronto, Dept of Chemistry; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch; C. Marvin, Environment Canada; S. Mabury, Univ of Toronto; S. Bhavsar, Ontario Ministry of the Environment; G. Tomy, Fisheries and Oceans Canada; M. Simcik, Univ of Minnesota. Perfluorocarboxylic acids (PFCAs) and perfluorinated sulfonic acids (PFSAs) have been the focus of environmental research and monitoring studies of perfluorinated chemicals (PFCs) over the past decade. More recently, other PFCs have attracted attention, including the polyfluoroalkyl phosphoric acid diesters (diPAPs) and perfluorinated phosphinates (PFPis). Following method improvements to enhance extraction efficiencies, we examined sediments from Lake Ontario, one of the Laurentian Great Lakes, and Lake Simcoe in the more populated region of south-central Ontario, and sediments from remote lakes in or near the Great Lakes region, for the occurrence and deposition trends of diPAPs and PFPis. In the Lake Ontario and the Lake Simcoe cores, PFCAs and PFSAs, also included in the study, increased from down core to peak concentrations in surface sediments. PFOS was the dominant PFC (1-12 ng/g in Lake Ontario sediment core, 0.1-1.9ng/g in Lake Simcoe). For PFPis, 6:6PFPi was dominant in Lake Ontario and Lake Simcoe sediment cores with concentrations ranging from 0.03 to 0.5 and 0.3 to 1.3 ng/g, respectively. PFPi concentrations are higher in sediment from Lake Simcoe than those from the Lake Ontario sediment core, contrary to the PFCAs and PFSAs. The PFPis increased in both cores from the 1960s to recent slices. For the diPAPs, 6:2 diPAP was dominant in

both sediment cores, with concentrations ranging from 0.03 to 0.64 ng/g in the Lake Ontario core and 0.05 to 9.1 ng/g in the Lake Simcoe core. Similar to PFPis, concentrations of the diPAPs generally increase from down core peaking in recent or surface sediments. Sediment concentration trends and fluxes will be compared to those collected from more remote lakes in the region assess if these PFC compounds are subject to atmospheric transport processes.

TP055 6:2 FTOH Aerobic Biodegradation in Freshwater Sediment and Activated Sludge L. Zhao, Nankai Univ, MOE Key Laboratory of Pollution Processes and Environmental Criteria; P.W. Folsom, P.K. Cooper, B.W. Wolstenholme, E.I. du Pont de Nemours & Company, Inc; H. Sun, Nankai Univ, MOE Key Laboratory of Pollution Processes and Environmental Criteria; N. Wang, R.C. Buck, E.I. du Pont de Nemours & Company, Inc. The widespread detection of anthropogenic perfluoroalkyl sulfonates [PFSAs, F(CF2)nSO3–, n = 4 – 8] and perfluorocarboxylates [PFCAs, F(CF2)mCOO–, m = 4 – 12] in the environment has lead to investigations about their sources, fate, transport, and behaviors in different environmental matrices. Products containing long-chain PFSAs and PFCAs or potential precursors are being phased out and replaced with shorter-chain alternatives based on perfluorobutane sulfonate and carboxylate, 6:2 fluorotelomer alcohol [6-2 FTOH, F(CF2)6CH2CH2OH], and fluorinated ethers. Currently, limited information is available on the environmental fate and behaviors of these alternatives. With increased production of 6:2 FTOH-based materials, it is important to understand the fate and behaviors of 6-2 FTOH in relevant environmental matrices. The purpose of this study was to investigate 6:2 FTOH degradation kinetics, identify potential transformation products, and elucidate biotransformation pathways in freshwater sediment and activated sludge. The 6:2 FTOH and 14C-labeled [1,2-14C] 6:2 FTOH were dosed into the "semi-static system" of sediment or activated sludge to determine 6:2 FTOH partitioning behavior and biodegradation potential. The experimental details such as setup, sample processing, analytical methods will be discussed. The results indicate that 6:2 FTOH can be rapidly transformed (T1/2 28 days) with 5:3 acid and volatile intermediates such as 5:2 ketone [F(CF2)5C(O)CH3] and 5:2 sFTOH [F(CF2)5CH(OH)CH3] as the major transformation products at day 28. Proposed 6:2 FTOH biotransformation pathways in activated sludge and aerobic sediment systems will also be presented.

TP056 Challenges Associated with the Analysis of Fluorotelomer Sulfonates in Environmental Samples J.P. Benskin, AXYS Analytical Services Ltd; M.B. Woudneh, AXYS Analytical Services Ltd, R&D Chemist; J. Pape, Axys Analytical Services Ltd.; M. Ikonomou, Fisheries and Oceans Canada, Contaminant Sciences Section; R. Grace, Axys Analytical Services; J.R. Cosgrove, AXYS Analytical Services Ltd. In contrast to perfluorinated sulfonates (PFHxS, PFOS, etc.), which are widely reported in humans and wildlife, there are comparatively little data on the environmental occurrence of their polyfluorinated counterparts, the fluorotelomer sulfonates (FTSs). The few data available indicate the latter compounds can be major contaminants of groundwater near airports (up to tens of mg/L); consequently, there is an urgent need for analytical methods capable of accurately quantifying the distribution of FTSs in environmental samples. Here we report a new method for determination of 4:2, 6:2, and 8:2 FTSs in water and biosolid matrices. Despite the apparent structural similarities between FTSs and perfluorinated sulfonates, analysis of the former by 'traditional' methods (i.e., methods designed for PFOS and PFHxS) resulted in significant matrix enhancement (i.e., >200%) of FTS congeners. Attempts at reducing this enhancement by dilution or clean-up with activated carbon were largely unsuccessful; as a result, a stand-alone method for the extraction and analysis of FTSs was developed. Absence of matrix effects in real samples analyzed by this new method was confirmed by standard addition, and detection limits for each congener were in the low ng/L range for a 500mL water sample. These data highlight the need for isotope-labelled internal standards for fluorotelomer sulfonates, and the significant differences in ionization behavior which exist between perfluorinated and polyfluorinated sulfonates.

TP057 Perfluoroalkyl and Polyfluoroalkyl Substances (PFASs) in the Environment: A Review of Terminology and Hierarchy J. Conder, ENVIRON International Corporation; R. Buck, E. I. duPont de Nemours & Co., Inc., Chemicals & Fluoroproducts, DuPont, Chemicals & Fluoroproducts; J. Franklin, CLF-Chem Consulting; U. Berger, Stockholm Univ, Dept of Applied Environmental Science (ITM); I. Cousins, Stockholm Univ; P. de Voogt, Univ of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics; A.A. Jensen, Nordic Institute of Product Sustainability, Environmental Chemistry and Toxicology; K. Kannan, New York State Dept of Health, Wadsworth Center; S.A. Mabury, Univ of Toronto, Dept of Chemistry; S.v. Leeuwen, Institute for Environmental Studies, VU Univ. Perfluoroalkyl and polyfluoroalkyl substances (PFASs), including the perfluoroalkyl acids (PFAAs) perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA), have been detected in the environment, wildlife, and humans. Owing to the variety and complexity of PFASs, the terminology and acronyms presented in the historic scientific literature for these substances are inconsistent. This paper will present a condensed overview of descriptive terminology, names and acronyms, and organizational hierarchy for PFASs to promote a sound, unified lexicon for use by the global scientific community that is clear, specific and descriptive for individual substances and groups of substances. We will illustrate the nuances and recommended uses of the terms "perfluoroalkyl", "polyfluoroalkyl", "fluoropolymers", "perfluorinated", "fluorinated", "polyfluorinated", and other phraseologies as well as the acronym PFC for perfluorocarbons. We propose that environmental PFASs of interest are best understood by segregation into general families: 1) non-polymer perfluoroalkyl substances (e.g., PFAAs which include PFOS and PFOA); 2) non-polymer polyfluoroalkyl substances (e.g., fluorotelomer alcohols, FTOHs); and 3) fluorinated polymers. We describe recommended terminology for classes of substances as well as individual substances. This hierarchical structure not only provides a better understanding of chemical structure, similarities, differences and nomenclature, but also facilitates a better grasp of uses and origins (e.g., electrochemical fluorination versus fluorotelomer process).

TP058 Phosphorus Containing Organofluorine Surfactants in Indoor Residential Dust A.O. De Silva, Environment Canada, Water Science & Technology Directorate, Environment Canada, Water Science and Technology; C. Allard, Aquatic Ecosystem Protection Research Division, Water Science and Technology Directorate, Environment Canada, Canada; G. Webster, School of Population and Public Health, Univ of British Columbia, Canada. Indoor dust is an important route of human exposure to many persistent organic pollutants (POPs), including perfluorinated compounds (PFCs). Anionic emerging PFCs are of particular interest including polyfluorinated phosphoric diesters (diPAPs), perfluorophosphonates (PFPAs) and perfluorophosphinic acids (PFPIs). diPAPs are used in paper treatment products and were measured in wastewater sludge, human sera, and are metabolized to PFCAs in rodents. PFPAs and PFPIs are used as leveling and wetting agents in waxes and coatings, defoaming agents in pesticide formulations and are environmentally persistent. PFPAs and PFPIs were measured in surface waters from Canada and PFPIs were observed in human serum. To date, none of these compounds have been monitored in indoor dust in Canada or elsewhere. This study describes the development of analytical methodology to measure emerging PFCs in 100 indoor dust samples collected in 2007-08 from the homes of pregnant participants enrolled in the Vancouver-based Chemicals Health and Pregnancy study (CHirP). The method consists of solvent extraction followed by carbon SPE clean-up and analysis by LC-MSMS. Each dust sample was analyzed in duplicate using 0.1 g. The method was evaluated for accuracy via spike and recovery, matrix effects, and precision (n=4). Significant matrix effects were noted for 6:2/6:2 diPAP (50% matrix suppression) and C6 PFPA (150% matrix enhancement). C6 PFPA concentrations were internally corrected for matrix effects using a surrogate with a Cl subsitutent (Wellington Labs, Guelph, ON). C13-labeled F(CF2)CO2- or F(CF2)SO3- surrogates were used as a recovery standard for diPAP, PFPA, and PFPI analytes. Extraction recovery corresponded to 64% 6:2/6:2 diPAP, 88% 10:2/10:2 diPAP, 109% C6 PFHxPA, 42-47% PFOPA, 74% C6/C6 PFPI, 84% C6/C8 PFPI, and 89% C8/C8 PFPI. Precision was based on RSD of replicate (n=4) analysis of 2 samples. %RSD was < 10 for all analytes except for C6/C6 PFPI (RSD < 25%). Preliminary analysis indicated that the predominant PFC was 8:2/8:2 diPAP ranging from 2000 to 60,000 ng/g. Other diPAP congeners were observed in every sample. PFPAs were >LOD in < 50% of samples and ranged from 3 to 200 ng/g, mainly C6 PFPA. Both the C6/C6 (0.1 to 37 ng/g) and C6/C8 PFPI (0.5 to 52 ng/g) were measured in every sample. Widespread detection diPAPs and PFPIs indicate ubiquitous presence in indoor residential dust and potentially a significant source of exposure.

TP059 Use of Microarray Analyses to Characterize Impacts of Hypersaline Conditions on Pesticide Toxicity in Salmonids L.A. Maryoung,

Univ of California – Riverside, Environmental Science, Univ of California – Riverside; R. Lavado, Univ of California, Riverside, Environmental Science; E.P. Gallagher, P.L. Stapleton, T.K. Bammler, R. Beyer, F. Farin, Univ of Washington, Environmental and Occupational Health Sciences; D. Schlenk, Univ of California, Riverside, Environmental Science. Acclimation to hypersaline environments has been shown in previous studies to enhance the acute toxicity of thioether organophosphate and carbamate pesticides to salmonids. While acute toxicity is likely due to enhanced formation of anti-cholinesterase metabolites, chronic impacts are less clear. In the current study, juvenile coho salmon (*Oncorhynchus kisutch*) were exposed to varying levels of salinity (< 0.5‰, 8‰, 16‰, and 32‰) for one week and mRNA was collected from the livers, gills, and olfactory rosettes. Micrroarray hybridization was used to determine differences in gene expression in the various tissues for the different treatments. Using a two fold cutoff, it was found that 20 genes were differentially expressed in livers between all treatments, 26 in gills, and 51 in olfactory rosettes. Further analysis of the data is ongoing, with the next steps including GO analysis and target clustering, to better understand the mechanisms of how these pathways are impacted by pesticides and hypersaline acclimation. (NIEHS P30ES07033).

TP060 Exploring Impacts of Climate-induced Changes in Temperature and Salinity on Freshwater Gastropods J. Suski, Texas Tech Univ, Dept of Biological Sciences, , United States Environmental Protection Agency, Risk Assessment Division; C.J. Salice, Texas Tech Univ/TIEHH, Environmental Toxicology, Assistant Professor, Texas Tech Univ. Climate change predictions for some regions indicate more extreme climate fluctuations including changes in precipitation patterns and global temperature changes. Freshwater systems will be impacted by predicted climate changes and those that are dependent on rainfall for filling or are shallow may be particularly vulnerable. Although precipitation volume may not change, patterns in rainfall may severely limit available habitat as misting rain leaves little accumulation in ponds and extreme downpours can result in lower overall water retention rates. This is especially significant in arid or semi-arid regions where many freshwater systems are dependent on filling of ponds. Playas are small ephemeral wetlands in the Southern High Plains and provide critical habitat for a wide variety of terrestrial and aquatic organisms. Climate change predictions for the Southern High Plains in conjunction with high water demand will lead to increases in salinity and temperature within freshwater ponds and playa wetlands. Locally, gastropods comprise a large portion of the invertebrate biomass and are important prey species for many aquatic and terrestrial animals. Hence, understanding how temperature and salinity impact gastropods may provide insight into higher-level wetland effects. We exposed juveniles of field collected ramshorn snails (*Planorbella tenuis*) to a range of environmentally relevant salinities (250 – 4000 µS cm^{-1}) and temperatures (21 – 32°C) as these two stressors can and will co-occur. Exposure duration was 14-days. Results showed that somatic growth rates of juvenile snails were positively correlated with temperature regardless of salt stress. Additionally, there were no adverse effects of salt stress. However, there was a slight increase in mortality at higher temperatures. The lack of a deleterious effect of salt stress is in contrast to previous studies in which we demonstrated negative effects to salt exposures that were much longer in duration. Collectively, our data suggest that negative effects of salt may take a relatively long time to manifest and as yet, do not appear to be exacerbated by the range of temperatures we used here. Future efforts will extend the study duration to include fecundity and also potential impacts of increased salt and temperature to predator avoidance behaviors.

TP061 Benzotriazole UV Stabilizers in the Environment H. Nakata, Kumamoto Univ, Graduate School of Science and Technology, Kumamoto Univ, Dept of Environmental Science; S. Murata, R. Shinohara, H. Yanagimoto, N. Shikata, Kumamoto Univ; M. Watanabe, National Institute for Environmental Studies; T. Isobe, S. Tanabe, Ehime Univ; T. Kunisue, K. Kannan, Wadsworth Center, SUNY at Albany. Benzotriazole UV stabilizers (BUVSs) have been used for various industrial and consumer products. Recently, the occurrence and contamination of BUVSs have reported in the aquatic ecosystems, but little information is available on the source, pathway, and distribution of BUVSs in the environment. In this study, we investigated the concentrations, bioaccumulation, spatial distribution, temporal trends and source identification of BUVSs in the environment. BUVSs were detected in marine and terrestrial organisms, such as mussels, fish, mammals, birds, and human, which suggest a bioaccumulation of BUVSs through the food-chain. The bioconcentration factor (BCF) of UV-327 (CAS #: 3864-99-1) in marine mammals was 33,300, which was similar to that of legacy POPs, HCHs (hexachlorocyclohexane). BUVSs were detected in oysters and mussels collected from nine Asian countries (Cambodia, China, India, Indonesia, Japan, Korea, Malaysia, Philippines, Vietnam) and the US, indicating a widespread contamination of BUVSs in the Aisa-Pacific regions. Sediment core samples collected from Tokyo Bay were analyzed BUVSs. UV-326, UV-327, and UV-328 were detected, and the levels increased from the depth 5-10 cm to the top layers. Sediment dating data suggested that BUVSs has emerged in first of the 1970s in Japan, and the contamination has been continued during past 30 years. To determine the sources of BUVSs in the environment, influent, effluent and sludge samples collected from WWTPs and road dust were analyzed. BUVSs were detected in all samples analyzed, and UV-326 was the dominant compound in wastewater samples, followed by UV-328, and UV-327. This indicates the current usage of BUVSs in cosmetics and household materials. In road dust, significant correlations were obtained between BUVSs concentrations and traffic density. These results indicate that WWTPs and road dust may be a potential source of BUVSs in the aquatic ecosystems.

TP062 Does Anti-inflammatory Drugs Bioconcentrate in Wild Fish Bile? J. Brozinski, Abo Akademi Univ, Laboratory of Organic chemistry, ?bo Akademi Univ, Laboratory of Organic chemistry; M. Lahti, A. Oikari, Univ of Jyvaskyla, Dept of Biological and Environmental Sciences; L. Kronberg, Abo Akademi Univ, Laboratory of Organic chemistry. The usage of pharmaceuticals is increasing worldwide. For example, the anti-inflammatory drugs diclofenac (DCF), naproxen (NPX) and ibuprofen (IBF) has been found as micropollutants in river water downstream of the discharge point of wastewater treatment plants. We have exposed rainbow trout (*Oncorhynchus mykiss*) to DCF, NPX and IBF in aquaria at near environmental concentrations, and have determined the up-take and metabolism of the drugs by studying bile samples. The bile samples were analyzed with LC-MS/MS methods. The identification of the formed metabolites were based on the exact mass determinations by a time-of-flight mass analyzer (Q-TOF-MS) and on the studies of fragments and fragmentation patterns of the precursor ions by ion trap mass analyzer (IT-MS). The quantitative analyses were performed by triple quadrupole mass analyzer (QqQ-MS). The studied compounds and their metabolites, mainly acyl glucuronides, were found in the fish bile. Also it was evident that the fish bioaccumulated the compounds in the bile. The bioaccumulation factors were 500, 1200, and 61 000 for DCF, NPX and IBF, respectively. Currently, we are collecting bile samples from wild fish from a river/lake system, which is heavily loaded with treated municipal wastewater. The objective of the work is to find out whether also wild fish bioaccumulate and metabolize pharmaceuticals. Results of this study will be presented.

TP063 Levels of Legacy POPs and Emerging Contaminants in the Tonlé Sap Watershed, Central Cambodia S. Bayen, National Univ of Singapore, Dept of Civil and Environmental. Engineering; H. Zhang, National Univ of Singapore, Dept of Civil and Environmental Engineering, National Univ of Singapore; B. Tan, DSO National Laboratories; N. Steenkeste, FONDATION MERIEUX; M. Chou, Univ of Health Science, Faculty of Pharmacy; P. Lim, Ministry of Water Resources and Meteorology; B.C. Kelly, National Univ of Singapore, Dept of Civil and Environmental Engineering. Tonlé Sap lake, in central Cambodia, is the largest natural lake in Southeast Asia (~18,000 km^2 during southwest monsoon maxima). The lake supports a vibrant fishery which provides a large proportion of the nutritional requirement of the human population of the country. The objective of the present study was to investigate the occurrence and levels of organic contaminants in water, sediments and biota from this important watershed. Samples, including surface water (n= 18), sediments (n= 18), bivalves (n = 5 pools) and fish (n = 257, across several trophic levels, both muscle and liver), were collected in March 2011 at four locations on the lake. Filtered water samples were extracted using SPE. Accelerated Solvent Extraction (ASE) and sonication were used to extract filters, sediments and tissue samples. After cleanup, extracts were analyzed by gas chromatography – tandem mass spectrometry (GC-MS/MS). Target analytes included legacy persistent organic pollutants (POPs) but also emerging contaminants of concern, including several brominated flame retardants (BFRs) and synthetic musks. ^{13}C mass-labeled compounds were used for quantification (isotope dilution). QA/QC measures included procedural blank analyses, recovery tests and replicate analyses. Observed concentrations of the various contaminants in field collected samples were compiled and compared with levels from other locations in

Southeast Asia and elsewhere. The partitioning behaviour and distribution of the hydrophobic chemicals between particulate and dissolved fractions is presented and discussed. Eventually, the concentrations of contaminants in fish from different trophic levels will be compared to highlight the biomagnification mechanisms. This study provides the first comprehensive dataset for legacy POPs and emerging contaminants in this important Cambodian watershed.

TP064 Bioavailability and Uptake of Hexabromocyclododecane in an Aquatic Food Chain A.K. Karjalainen, Univ of Jyvaskyla, Dept of Biological and Environmental Science; S. Huhtala, Finnish Environment Institute; J. Karjalainen, T. Keskinen, Univ of Jyvaskyla; J.V. Kukkonen, M. Leppanen, K. Maenpaa, Univ of Eastern Finland; P. Sainio, M. Verta, Finnish Environment Institute. Hexabromocyclododecane (HBCD), a brominated aliphatic cyclic hydrocarbon, is currently a third most used additive brominated flame retardant (BFR) following tetrabromobisphenol A and polybrominated diphenylethers (PBDEs). The synthesized technical HBCD mixture contains mainly three stereoisomers termed γ-, β- and α-HBCD with the γ isomer being the predominant component. Technical HBCD enters the environment through emission during its production or flame retarded products and by leaching from consumer products. As a result of its physical and chemical properties and widespread use, it is now a ubiquitous contaminant in the environment and humans. Contrary to PBDEs, increase in environmental concentrations has not levelled off but seem to be increasing. HBCD has a high bioaccumulation potential and may disrupt endocrine function both in animals and humans. Bioisomerisation in aquatic food chain can occur leading to altered proportion of stereoisomers in animals compared to the technical product or the primary source for uptake such as sediment. The aim of this study was to investigate the bioavailability, trophic transfer and bioisomerisation of HBCD in a simplified aquatic food chain model. Bulk of Oligochaete worm *Lumbriculus variegatus* was firstly exposed to HBCD-spiked sediment at environmentally realistic concentration to yield information on the bioavailability potential of HBCD in sediment. Additionally sublethal endpoints and bioisomerisation were measured. Secondly, we measured the partition ratio of HBCD at steady state between artificial freshwater and polydimethylsiloxane (PDMS) fibre, and used it to plan appropriate exposure conditions for passive dosing of masses of *Chironomus* sp. 4th instar larvae with saturated PDMS silicone. The contaminated larvae were used as a relevant food source for ruffe (*Gymnocephalus cernuus*) at environmentally realistic concentrations. Subsequently, uptake kinetics, trophic transfer and bioisomerisation fate of HBCD in the simplified food chain model were measured. Liquid scintillation counting (LSC) and ultra performance liquid chromatography tandem mass spectrometry (UPLC-TQMS) was used for radiolabelled and non-labelled HBCD, respectively. This study yields new information for risk assessment of brominated flame retardants.

TP065 The Influence of Surface Charge on Gold Nanosphere Accumulation in a Simple Aquatic Food Chain A. Wray, Clemson Univ, Institute of Environmental Toxicology; S.J. Klaine, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX), Clemson Univ, Institute of Environmental Toxicology (ENTOX) Over the last two decades, nanotechnology has ascended to industrial prominence; a fact attributed to the seemingly limitless potential for enhancement, innovation and invention. With increasing ubiquity in the market the release of NPs into the environment, whether intentional or accidental, becomes inevitable. The goal of our research was to characterize the influence of particle properties on the uptake and distribution of gold nanospheres in a simulated aquatic food chain. Expanding on our previous investigation of size dependent uptake and elimination, this study focused on gold nanoparticles exhibiting different surface chemistries (anionic, cationic, and neutral) to shed light on the mechanism(s) through which these particles accumulate in *Selenastrum capricornutum* and *Daphnia magna.* In mammalian studies, both in vitro and in vivo, surface charge has been identified as a key component controlling GIT absorption of NPs thus we expected it to play a similar role in our aquatic organisms. Additionally, our gold nanoparticle stocks were incubated with natural organic matter, to examine a more environmentally relevant scenario of nanoparticle exposures to our model organisms. In all scenarios, the uptake and elimination rate constants were derived to predict how surface chemistry influences accumulation of particles and how the presence of biotic ligands can enhance or devalue these influences.

TP066 Bioaccumulation Modeling of Perfluorinated Compounds in an Aquatic Food Web J.P. Benskin, AXYS Analytical Services Ltd; M. Ikonomou, Fisheries and Oceans Canada, Contaminant Sciences Section; F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment), Simon Fraser Univ; M.B. Woudneh, AXYS Analytical Services Ltd, R&D Chemist; J.R. Cosgrove, AXYS Analytical Services Ltd. Among the many differences between perfluorinated compounds (PFCs) and legacy persistent organic pollutants (POPs) is the tendency for PFCs to accumulate in protein rich tissues, as opposed to lipids. Predicting the bioaccumulation of PFCs using models designed for legacy POPs is difficult, since these methods rely on lipid partition coefficients (e.g., Log Kow), which are difficult to measure for PFCs, and largely inappropriate for predicting PFC behavior in wildlife. New approaches which account for the "proteinophilic" nature of PFCs are necessary to accurately predict their disposition in biota. Here we report a comprehensive examination of PFCs in a marine food web from False Creek (FC) and Burrard Inlet (Vancouver, BC, Canada) and application of these data in developing a mass-balance bioaccumulation model for PFCs. Representative samples of sediment, sea water, and biota (algae, bivalves, fish, etc.) were collected and analyzed for a suite of PFCs, including perfluoroalkyl carboxylates, sulfonates, sulfonamides, sulfonamido acids, telomer sulfonates, and telomer acids, and isomer profiles. In water, the highest total PFC concentrations (tens of ng/L) were observed in the East Basin (FC), where PFOS was the dominant congener. PFC concentrations decreased rapidly moving into the Central/ North Harbour (FC) and Burrard Inlet, where perfluorooctanoate (PFOA) and perfluorohexanoate (PFHxA) were the major PFCs. Isomer profiles of PFOA were exclusively linear, indicating contributions predominantly from a telomer manufacturing source. The utilization of protein partition coefficients and field data for model development is discussed.

TP067 Perfluorochemicals in Soil and Produce from Home Gardens C. Huset, K. Souther, MN Dept of Health, Organic Chemistry Unit. Ground and drinking water in Washington County, Minnesota have been monitored for perfluorochemicals (PFCs) since 2004. Several waste disposal sites located in Washington County were used by 3M to dispose of manufacturing wastes in the 1950s-1970s were determined to be the source for these PFCs in the ground and drinking water. While exposure to PFCs through drinking water has been reduced by changes in water source, or drinking water treatment, there are other exposure routes related to the contaminated drinking water that may still affect residents in these contaminated areas. There is potential for produce grown in gardens from these contaminated areas to accumulate PFCs through irrigation with contaminated water. There is also potential for uptake from soil with historic PFC contamination (arising from historical irrigation with PFC-containing water). The goals for this study are to determine the extent to which the garden soil is contaminated with PFCs and to determine the uptake of PFCs into fruits and vegetables grown on these sites. Twenty home gardens in the communities with PFC contamination as well as four control sites (sites located outside the contaminated area, with no known PFC contamination) were sampled for soil as well as produce collected throughout the growing season. 278 produce samples were collected, including 43 tomatoes, 23 peppers, 16 cucumber, 16 squash, 16 beans, 16 peas as well as onions, carrots, corn, berries and herbs. The PFCs of interest, PFBA, PFPeA, PFHxA, PFOA, PFBS, PFHxS, PFOS were analyzed in soil and produce using LC/MS/MS after homogenization and extraction. Quantitation limits, which vary depending on analyte and produce type, range from 0.05 ng/g to 0.15 ng/g. Data presented will compare soil, produce and water concentrations from the various sites.

TP068 Analysis of Bisphenol A in a Leafy Vegetable Using an Isotope Dilution Technique, Liquid-Liquid Extraction, and GC-Tandem MS Analysis J. Lu, J. Wu, Univ of Florida/IFAS-IRREC, Soil and Water Science; P. Stoffella, Univ of Florida/IFAS-IRREC, Horticulture; P. Wilson, Univ of Florida, IFAS, IRREC- Soil & Water Science. An isotope dilution method was developed for determination of bisphenol A (BPA) in leafy vegetables by gas chromatography with tandem mass spectrometry (MS/MS). The internal standard (IS) C13 labeled BPA (ring-13C12) and the surrogate 17α-ethinylestradiol (17α-EE2) were added at the beginning of the extraction. The matrix was homogenized and extracted ultrasonically using acetone. Effective elimination of impurities from the extract was obtained with a clean-up procedure involving liquid-liquid extraction by acetonitrile (ACN) saturated hexane to remove most of the chlorophyll, which can lead to the failure of subsequent derivation. The ACN extract was

subject to an unspecific acid hydrolysis procedure to release the conjugated BPA as free BPA. The silylating derivatization process was performed with trimethylchlorosilane (TMCS) and pyridine. Multiple reaction monitoring (MRM) mode was performed since BPA and the IS co-eluted at 13.3min. The precursor ions for BPA and internal standard were m/z 357 and m/z 369, respectively. The excitation amplitude voltage for BPA was 0.7 V while that for the IS was 0.8 V. Instrument limit of detection (LOD) and limit of quantification (LOQ) were 1.8 μg/L and 6.0 μg/L, respectively, based on 1 μL injections of 1 mg/L BPA standard solution. The BPA concentrations in lettuce samples ranged from 6.6 μg/kg fresh weight to 150.0 μg/kg fresh weight. Hexane clean-up is an essential step for this analysis method. The results illustrate a useful, alternative method for analysis of BPA content in leafy vegetables.

TP069 Uptake and Biotransformation of 17β-trenbolone by the Common Bean Plant (*Phaseolus vulgaris*) B.R. Blackwell, Texas Tech Univ/TIEHH, Environmental Toxicology, Texas Tech Univ, Environmental Toxicology; A. Karnjanapiboonwong, Texas Tech Univ/TIEHH, Environmental Toxicology, Missouri Univ of Science and Technology, Civil, Architectural and Environmental Engineering; T. Anderson, P.N. Smith, Texas Tech Univ/TIEHH, Environmental Toxicology. Manure from livestock feeding operations is commonly applied to agricultural fields as an alternative to chemical fertilizers. Trenbolone acetate is an anabolic growth promoter frequently utilized in beef cattle feeding operations. Metabolites of trenbolone acetate can be present in manure and subsequently applied to fields, however, the fate of trenbolone after application to agricultural fields is not fully understood. The objective of this study was to investigate uptake and biotransformation of the trenbolone acetate metabolite 17β-trenbolone (17β-TbOH) using the common bean plant (*Phaseolus vulgaris*). Vegetated (n=20) and control sands (n=16) were amended with 17β-TbOH at a level of 1 μg/g of sand once per week for a total of 4 weeks. Plants and controls were collected each week and separated into sand, above-ground plant portion, below-ground plant portion, and analyzed for 17β-TbOH, 17α-trenbolone, and trendione (TbO). Low levels of 17β-TbOH were taken up into the roots of plants and, to a much lesser extent, transported throughout the plant. Extensive transformation to the metabolite TbO occurred in plants and in vegetated sands while minimal TbO was detected in control sands. After four weeks, maximum concentrations of total trenbolone in fresh plant tissues were 38.5 μg/g in roots and 0.290 μg/g in leaves. These results demonstrate 17β-TbOH can be taken up into plants and transformed to various trenbolone metabolites.

TP070 Pharmaceuticals in Sewage Sludge Compost and Their Uptake from Fertilized Soil by Food Plants L. Nei, Tallinn Univ of Technology Tartu College, Dept of Environmental Protection; M. Lillenberg, Estonian Univ of Life Sciences; E. Haiba, Tallinn Univ of Technology, Tartu College; K. Kipper, K. Herodes, Tartu Univ, Institute of Chemistry. The potentially hazardous organic compounds that may be present in sewage and sewage sludge number in the thousands. Fortunately, the concentrations of toxic organic chemicals are usually low and for most of them their plant bioaccumulation factors are small. Still, compounds with strong sorption and recalcitrant to degradation remain in surface soils and have the potential to subsequently be uptaken by plants. However, very limited information is currently available. Previous research has focused primarily on plant uptake of veterinary pharmaceuticals that are associated with animal waste, that is, manures, and demonstrated their potential to accumulate in plants. Humans may be exposed to residues of drugs in the environment by a number of routes including the consumption of crops that have accumulated substances from fertilized soils. As the compost made from sewage sludge contains detectable amounts of pharmaceutical residues, there was a need to determine the significance of uptake into plants from soil under "real" conditions as a potential migration route for pharmaceuticals in the environment. Therefore, the current study was conducted to determine the potential for tetracyclines, fluoroquinolones and sulfonamides to be taken up by food plants from soil fertilized with sewage sludge or its compost. The results of this work clearly show that pharmaceuticals are able to accumulate in plants. This phenomenon remarkably depends on the nature and concentration of pharmaceuticals and the soil type. Before using the sewage sludge compost as a fertilizer, it should be carefully tested against the content of different pharmaceuticals. The content of pharmaceuticals in the compost made from sewage sludge may easily lead to the elevated concentrations in food plants, if the compost is used as a fertilizer. This work should be continued by the development of novel and more efficient sewage sludge treatment technologies, leading to intelligent solutions of environmental problems related to sewage sludge exploitation.

TP071 Effects of Feeding Rate and Loading Density on Bioaccumulation of PCBs in Oligochaete *Lumbriculus variegatus* N. Billa, Environmental Protection Agency; T. Lahren, US Environmental Protection Agency, Mid-Continent Ecology Division; T.L. Highland, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; J.R. Hockett, US Environemtal Protection Agency, ORD; D. Hoff, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; D.R. Mount, US Environmental Protection Agency, ORD; T.J. Norberg-King, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; L.P. Burkhard, USEPA, Mid-Continent Ecology Division. Sediment tests with aquatic organisms can provide valuable information about potential toxicity and the bioavailability of polychlorinated biphenyls (PCBs) to the organisms. The US-Environmental Protection Agency 28-day *Lumbriculus variegatus* bioaccumulation test for sediments when successfully performed often has poor growth of the *L. variegatus*.Potential causes of poor growth include poor nutritional quality of the sediment, sublethal toxicity effects, and/or too much competition for the available food in the sediment (i.e., too many organisms for the available food). The test, as currently configured, has conditions of no feeding and a loading rate of organisms in the test chambers of no less than a ratio of 50:1 of organic carbon to organism dry weight (USEPA, Test Method 100.3). The objectives here are to investigate the effects of loading density and feeding on the growth of the *L. variegatus* and their subsequent impacts on the bioaccumulation of PCBs by the organisms. A preliminary test was performed with 2 loading densities, 100:1 and 25:1 (ratio of organic carbon to organism dry weight) and 3 feeding rates (0, 2, 4 times feeding per week) using a Hudson River (HR) sediment contaminated with PCBs at 2.6 ppm along with our standard control sediment (West Bearskin). Results of the preliminary study demonstrated that PCBs residues were influenced by feeding and loading rates. Growth of the organisms increased with increase feeding rate suggesting more available nutrition from external food provided. A significant difference (Tukey honestly significant difference, α = 5%) in the growth of the organisms was observed with low loading (100:1). No significant difference in the growth was observed with high loading (25:1). These results suggest limited food availability per organism in high loading treatments. PCB residues declined with increasing feeding rate and residues increased with increased loading. Growth of the organisms with feeding in combination with loading rates was inversely related to the bioaccumulation of PCB residues. Following this study, we performed another 28-day exposure with no feeding and four different loading densities based on the organic content of the sediment samples of WBS and HR sediments. The end points of the test were biomass, lipid content and PCB concentrations in the tissue. Further, analyses and interpretations of the test results will be presented. This abstract does not necessarily reflect USEPA policy.

TP072 Bioavailability of Heavy Metals in Two Earthworm Species and its Relationship to Extractable and Labile Metals in Soils Y. Liu, Univ of California, Riverside, Environmental Sciences Dept, UC-Riverside, Environmental Sciences; D. Parker, Univ of California, Environmental Sciences Dept. The bioavailabile pool of Cd and Zn to the earthworms *Eisenia fetida* (*E. fetida*) and *L. terrestris* (*L. terrestris*) in soils was investigated using stable isotopic dilution (SID) technique and chemical extraction methods. Ten soils used for earthworm culturing were from three sources with variety of soil properties. The soils were extracted by five chemical solutions and the amount of extractable Cd and Zn followed the order: EDTA>1M CaCl2>DTPA>0.05M Ca(NO3)2 >0.01M Ca(NO3)2. In each extraction, the fraction of extractable-Cd was significantly higher than the extractable Zn. SID technique was used to get Cd, Zn labile pool (E-value) in soils. It was showed in average the fraction of labile Cd (44.7%) is significantly higher than that of Zn (25.4%), which indicated Cd is more mobile in soil compared to Zn. The labile pool of Cd and Zn was found to be independent with soil pH, total organic carbon and clay content. It was observed the accumulated Cd and Zn in two earthworms were highly correlated with heavy metals labile pool (p

TP073 Impact of Solar Drying on PAHs and NPEs Removal in Sewage Sludge N.A. Perendeci, Univ of Akdeniz, Dept Environmental Eng.; M. Barret, N. Delgenes, M. Pype, Laboratoire de Biotechnologie

de l'Environnement, INRA; V. Yilmaz, Univ of Akdeniz, Dept Environmental Eng.; H. Carrere, D. Patureau, Laboratoire de Biotechnologie de l'Environnement, INRA. Occurrence of priority and emerging organic contaminants in the aquatic environment is now indeniable. Sewage treatment plants (STPs) play a main role in their environmental dissemination, because it is a point of convergence of various type of water containing a variety of compounds present at low level. According to the extensive use of biological processes in urban WWTPs, many studies focused on the efficiency of biological treatments and the influence of the operating parameters associated to these systems to remove these contaminants. If it was demonstrated that their removal is related to their biodegradability, sorption is one of the main mechanisms that drive their fate in STP, particularly the hydrophobic ones. Indeed many studies focussed on the occurrence of contaminants in sludge. However, agricultural land application of sewage sludge from WWTP is one of the common ways for their disposal: the presence of such contaminants may thus limit their use on agricultural lands. Various sludge processes are used to stabilize the sludge before spreading. If anaerobic digestion and composting have received considerable attention for their impact on contaminants removal, other processes like solar drying have received little. In this study the effects of solar drying on nonylphenol polyethoxylates (NPEs), nonylphenol (NP) and 13 PAHs removal present in sewage sludge was evaluated. For this purpose, sewage sludge taken from two Turkish WWTPs (Hurma and Lara) was solar dried in controlled prototype greenhouse. NPEs, NP and PAH concentrations were monitored during the solar drying. Samples were extracted using accelerated solvent extractor at 120°C and 100 bar with hexane/acetone. NPEs, NP and PAHs analysis were carried out using reverse phase-HPLC coupled to fluorecence detector. NPEs, NP and PAHs were measured in the two sewage sludge samples at level commonly found in other European sludge. During the 120 hours solar drying of the two sludge samples, the NP concentration decreased sharply whereas only for Hurma, the NP2EO and NP1EO concentrations increased. The total PAH concentration in the sludge was 469.018 $\mu g/kg_{TS}$ and 303.527 $\mu g/kg_{TS}$ for respectively, Hurma and Lara. During the solar drying, all the PAHs concentrations fell down with 55 and 50 % removal for respectively, Hurma and Lara. As no biological activity was measured during the process, these contaminant removals are probably linked to volatilization, sequestration or photodegradation.

TP074 Occurrence and Contribution to Global Contamination by Organohalogens and Trace Elements from India M. Subramanian, G. Devanathan, N. Ha, Ehime Univ, Center for Marine Environmental Studies (CMES); A. Eguchi, Ehime Univ, Center for Marine Environmental Studies; K. Nomiyama, T. Itai, Ehime Univ, Center for Marine Environmental Studies (CMES); T. Isobe, Ehime Univ, Senior Research Fellow Center (SRFC); S. Takahashi, S. Tanabe, Ehime Univ, Center for Marine Environmental Studies (CMES). India is now confronting the huge problem of e-waste, both locally generated and internationally imported, posing a serious threat to human health and the environment. Our decades-long studies on samples of air, soil, fish, and also human hair, blood and milk collected from Mumbai, Bangalore, Chennai, Kolkata, Chidambaram, Parangipettai, Karaikudi and Sivakasi in India confirm the presence of polybrominated diphenyl ethers (PBDEs), hexachlorocyclododecanes (HBCDs), dioxins and related chemicals (DRCs), polychlorinated biphenyls (PCBs) and heavy metals in the Indian environment, at considerable levels. It has been noticed that the e-waste recycling activities in Bangalore and Chennai create elevated levels of PBDEs in the ambient air, which had also reflected in the soil from the same locations. Higher levels of HBCDs and brominated and mixed halogenated dioxins and furans were found in the soils from e-waste recycling areas than in non e-waste soils. Further, the scalp hair samples of the recycling workers contained higher levels of PBDEs and also PCBs and HBCDs indicating e-waste recycling activities in India as a source for human exposure to these contaminants. Fish collected from Mumbai, Chennai, Karaikudi and Sivakasi had considerable levels of PCBs, PBDEs and HBCDs, the levels of PCBs being higher than PBDEs and HBCDs. In addition, HBCDs were lower than PBDEs. A recent work from our center showed the presence of not only PBDEs and PCBs but also their metabolites, OH-PCBs, OH-PBDEs and MeO-PBDEs in serum of e-waste workers and general population in India indicating possible metabolism of these toxic chemicals in the animal bodies and/or the environment. Another interesting finding is the detection of increasing levels of PBDEs in Indian mothers' milk of the year 2009 than those gathered during 2006, revealing that e-waste related chemicals are increasing even in the general population of India, while the chemicals like PCBs are decreasing. Apart from organic chemicals, some trace elements were higher in the air and consequently in the hair of the workers at the e-waste recycling sites than the control site. Higher Hazard Quotient values (HQ>1) observed for certain metals in the soil from the recycling areas, especially for children, who are highly susceptible, is of serious concern.

TP075 Organohalogen Contaminants of Emerging Concern in Predatory Birds from Coastal South Carolina, USA J.L. Reiner, National Institute of Standards and Technology, Environmental Health Sciences, NIST, Analytical Chemistry Division; S. Rossman, Michigan State Univ, Dept of Zoology; P. Ostrom, Michigan State Univ; S. Hughes, K. Bargnesi, J. Elliott, The Avian Conservation Center and Center for Birds of Prey; J. Yordy, National Institute of Standards and Technology, Hollings Marine Laboratory, Medical Univ of South Carolina, Marine Biomedicine and Environmental Sciences Program. As a result of being top predators, birds of prey are susceptible to bioaccumulating countless environmental contaminants. Since recent environmental surveys have shown the widespread occurrence of polybrominated diphenyl ethers (PBDEs) and perfluorinated compounds (PFCs) in the aquatic and terrestrial environment, the levels of these contaminants, in addition to legacy persistent organic pollutants (POPs), were measured in birds of prey livers from the coastal region of South Carolina (USA). The 26 birds included in the study comprised 10 species (red-tailed hawks, red-shouldered hawks, barred owls, great horned owls, eastern screech owls, Mississippi kites, turkey vultures, one black vulture, one osprey and one American kestrel), spanned 2 to 3 tropic levels (as determined by stable isotope analysis), exhibited a wide range of body conditions and utilized a diversity of habitats (rural or urban; terrestrial or marine), allowing for an assessment of the factors that influence PBDE and PFC exposure in predatory birds within this region. Despite their status of newly emerging contaminants, _PFCs (95% CI, 75.9 ng/g wet mass to 168 ng/g wet mass) were within the same order of magnitude as legacy contaminant levels (_PCBs 95% CI, 34.4 ng/g wet mass to 302 ng/g wet mass). In comparison, _PBDEs (95%CI, 5.45 ng/g wet mass to 47.5 ng/g wet mass) were amongst the highest lipid-normalized levels reported for these compounds in wildlife to-date (maximum, 200 µg/g lipid). This presentation will discuss the implications of this exposure as well as relationships between exposure and feeding ecology, body condition, and proximity to human populations.

TP076 Challenges in the Application of Mercury Environmental Quality Standards for Biota D. Vignati, Irsa-Cnr, IRSA-CNR, UOS Brugherio; M.S. Bank, Harvard Univ, School of Public Health, Dept of Environmental Health, Harvard School of Public Health, Dept of Environmental Health. Environmental Quality Standards (EQS) for Hg in natural waters are among the lowest for all trace elements (in the range of ng L^{-1}). Quantifying total Hg at such low levels is extremely difficult because of the contamination risks associated with sampling and sample handling prior to analytical measurements. Furthermore, the actual chemical species of concern is methylmercury (MeHg) whose routine quantification in monitoring programs is still far to come. EQS based total Hg concentration in biota (prey tissue) offer an attractive alternative to water-based standards for the protection of top predators against Hg secondary poisoning. Levels in biota are much higher (mg kg^{-1}) than in water and measuring Hg in biota would automatically account for important confounding factors regulating Hg bioavailability. However, this second type of EQS generically refers to 'biota' without further specification for the trophic level or for any preferred taxonomic group. The current EU standard for biota (0.020 mg kg^{-1}) would result in a quasi-total non-compliance if applied to fish; while application to filter-feeders (e.g., *Dreissena polymorpha*) or benthic organisms (e.g., chironomids and oligochates) would yield a much less worrying picture. This contribution will examine the current problems and possible solutions to facilitate switching the Hg regulation from the traditional water-based EQS to the more ecologically relevant biota-based ones.

TP077 Mercury in Perch from the Scandinavian Region – Spatial and Temporal Trends A. Miller, Naturhistoriska Riksmuseet; S. Danielsson, J. Hedman, A. Bignert, Naturhistoriska Riksmuseet, Dept of Contaminant Research; M. Verta; E. Fjeld; S. Rognerud; P. Porvari. To investigate trends in bioavailable mercury within the Scandinavian aquatic environment, mercury concentrations in European perch (Perca fluviatilis), a freshwater cyprinid, were collated from national monitoring programs within Norway,

Sweden and Finland to form a single database (n=6779). The perch came from reference lakes with no known local contaminant sources. Mercury concentrations were weight adjusted to 300, 200 and 100 g perch body weight. Geographical patterns and changes in mercury concentration in perch over time were examined. No statistically significant geographical trends were seen; however a comparison in mercury concentrations in perch pre- and post-1995 show a non-statistical geographical pattern, with increasing mercury concentrations seen in Norway and eastern Finland. The average mercury concentration in perch (adjusted to 300 g) was 500 ng/g ww, and did not differ significantly between countries. This implies that about half of the perch weighing 300 g caught in Scandinavia between 1968 – 2005 exceeded the current maximum allowable concentration of mercury in fish for human consumption in the EU of 500 ng/g ww. When mercury concentrations in perch taken from the most recent 10 years of data (1996 – 2005) were compared to the data set as a whole (1968 – 2005), it indicated that concentrations have been increasing in this latest period. Despite large reductions in mercury use and production in all three countries, mercury levels in perch continue to be higher in Scandinavia than other European areas. It has been suggested that background mercury concentrations in Scandinavia are generally higher than the rest of Europe, and this may need to be taken into account when considering mercury concentrations in fish for human consumption from this area.

TP078 Quantitation of Organophosphate Insecticides in Drinking Water Using Automated Online Sample Preparation and a 3-D Ion Trap J. Beck, M. Blackburn, J. Wang, M. PrietoConaway, Thermo Fisher Scientific. Organophosphates are irreversible acetylcholinesterase inhibitors and as such are highly toxic. Due to the toxicity of organophosphates and other effects such as delayed learning rates in children, an increased risk of Alzheimer's, and chronic fatigue symptoms it is essential to be able to detect even low levels of these compounds. This presentation will demonstrate the use of automated online sample preparation coupled with a 3-D iontrap mass spectrometer, performing full scan MS2, for the detection of organophosphates in drinking water. Calibration curves were generated from 1mL or 4mL injections of standards spike into HPLC grade water with no further preparation. Quantitation was based on the post acquisition extraction of multiple fragments, where possible, for each compound from the full scan MS2 data. Detection limits in the parts per trillion were achieved for most of the organophosphates analyzed. Several local water sources were also analyzed for the presence of organophosphate using the previously described method.

TP079 Screening for Pharmaceuticals and Personal Care Products in Drinking Water Using a 3-D Iontrap and Automated Online Sample Preparation J. Wang, M. Blackburn, J. Beck, M. PrietoConaway, Thermo Fisher Scientific. Pharmaceuticals and personal care products (PPCP) consist of human and veterinary drugs, consumer products such as sun-screens, nutritional products, and personal hygiene products. These compounds enter the environment through a variety of sources including wastewater effluent, landfill leachate, industrial effluent, and animal feed lots. Environmental impact of these compounds remains unclear. However, in 2007 the EPA released method 1694 addressing the analysis of these compounds. This method utilizes solid phase extraction (SPE) followed by LCMSMS monitoring a single transition. We will demonstrate an automated online sample preparation that eliminates the need for the laborious SPE method described in EPA method 1694. In addition, we will show automated quantitative and qualitative data processing using 3-D iontrap full scan data for quantitation and data dependent (DD) full scan MS2 spectra for confirmation of PPCPs. Standards were spiked into HPLC grade water and 1mL injections were analyzed with no additional preparation. The PPCPs were detected down to levels as low as 10ppt in spiked standards. Several sources of drinking water were analyzed and caffeine was quantitated in bottled beverages. Calibration, quantitation, and confirmation of PPCPs detected was simultaneously achieved applying an automated quan/qual software package designed for routine analysis in production laboratories.

TP080 A Protocol for Measuring In Vivo Biotransformation Rates of Hydrophobic Substances in Fish J. Lo, Simon Fraser Univ, Biological Sciences, Simon Fraser Univ, Dept of Biological Sciences, Simon Fraser Univ, M.E.T. (Master of Environmental Toxicology) studen; C.J. Kennedy, Simon Fraser Univ, Dept of Biological Sciences; S.V. Otton, Simon Fraser Univ; M.M. Moore, Simon Fraser Univ, Biological Sciences Dept; F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment), Simon Fraser Univ. It is well recognized that biotransformation is an important process controlling the degree to which chemicals can bioaccumulate in biota. However, there are no standardized methods to measure biotransformation rates and methods for the assessment of biotransformation rates are at an early stage of development, largely because of the lack of good quality data on biotransformation rates that could be used to develop or test biotransformation rate assessment methods. In this paper, we propose a methodology for the empirical determination of biotransformation rates and test this methodology in bioaccumulation studies in rainbow trout (*Oncorhynchus mykiss*) involving fifteen chemicals, including metabolizable chemicals of very high Kow. We report biotransformation rates in the liver, intestinal tract, carcass and the whole organism basis to test the ability of in vitro biotransformation assays to assess in vivo biotransformation rates. Results show that non-metabolizable PCB and chlorobenzene congeners have lower elimination rate constants compared with test compounds with comparable hydrophobic properties. We conclude that this study presents a promising method for determining empirical in-vivo metabolic biotransformation rates in fish. Results from this study should also help in the extrapolation of in vitro to in vivo biotransformation rate constants.

TP081 A Sensitivity Analysis Approach to Bioaccumulation and Biomagnification in Aquatic Food Webs D.E. Powell, Dow Corning Corporation, Health & Environmental Sciences, Dow Corning Corporation, Health & Environmental Sciences (C03101); F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment), Simon Fraser Univ; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, Environment Canada, National Water Research Institute; R.M. Seston, K.B. Woodburn, Dow Corning Corporation, Health & Environmental Sciences. The potential of a chemical substance to accumulate in aquatic organisms and to increase in concentration with increasing trophic level is a criterion used to classify substances as being bioaccumulative in the environment. For aquatic organisms, bioaccumulation factors (BAFs) describe the accumulation of contaminants by living organisms relative to the amount stored in the water compartment. Similarly, biota-sediment accumulation factors (BSAFs) describe the accumulation of contaminants by living organisms relative to the amount stored in the sediment compartment. Biomagnification factors (BMFs) describe the increase in concentration of a substance in living organisms that are separated by a single trophic level step on a food chain. Because of biomagnification processes, individual BAF or BSAF values are dependent upon trophic level position of the organism under consideration. Consequently, trophic magnification factors (TMFs), which describe the increase in concentration of a substance in living organisms that occupy successively higher trophic levels within a food web, are used to assess bioaccumulation and biomagnification of chemicals in the environment. This presentation will show how these field metrics for assessment of bioaccumulation and biomagnification (i.e., BAF, BSAF, BMF, and TMF) are interrelated. We will also use actual field data and a model food web to evaluate various approaches that may be used to calculate bioaccumulation and biomagnification metrics from measured concentrations, normalized concentrations (for example, to lipid content), concentration ratios, and reference materials that are known to bioaccumulate and biomagnify (for example, polychlorinated biphenyls). Several factors may directly affect the relationship between trophic position and the bioaccumulation and biomagnification of contaminants in aquatic ecosystems. Therefore, the evaluation will include an assessment of the sensitivity of the different approaches to parameters such as trophic level, nitrogen-15 enrichment factors (used to estimate relative trophic level position), food-chain outliers, unbalanced designs, omnivorous feeding, and lipid content.

TP082 Application of Fish In Vitro Metabolism Assay for Assessing Bioaccumulation Potential A. Adekola, Maxxam Analytics, Graduate student in Masters in Environmental Toxicology; C.V. Eickhoff, Maxxam Analytics, Ecotoxicology. Currently, bioaccumulation potential is assessed in silico using models such as BCFBAF or in vivo using the OECD 305 test. Inherent metabolic potential is one of the most important factors affecting the bioaccumulation of chemicals in aquatic organisms. The ILSI HESI Bioaccumulation Group has developed a combined approach for estimating the biotransformation rates of potentially bioaccumulative chemicals using an in

vitro fish S9 metabolism assay and a predictive model (Cowan-Ellsberry et al., 2008). We evaluated the in vitro method by incubating environmentally relevant chemicals such as pyrene, 4-nonylphenol, fluroxypyr methyl heptyl ester, methoxychlor and a synthetic pyrethroid with the S9 fraction isolated from rainbow trout strains. When statistically significant, clearance rates obtained from the in vitro assay were extrapolated to whole fish biotransformation rates (kmet) and used to refine BCF computer model predictions based on log Kow, molecular weight and structure alone. The BCF values estimated from this combined approach are similar to the in vivo BCF values found in literature for pyrene (Carlson et al. 1979, Ogata et al. 1984, Jonsson et al. 2004) and 4-nonylphenol (Ekelund et al. 1990, Ahel et al. 1993, Snyder et al. 2001) . This study shows that the combined in vitro and in silico approach can be effective for predicting BCF values. However, the metabolic potential of chemicals represented by the kmet value can also be used to assess bioaccumulation potential in relative terms. Funding was provided by the European Commission JRC/IHCP/In Vitro Toxicology Unit – ECVAM, Contract #CCR.IHCP.C434207.X0 and by the European Chemical Industry Council Long-range Research Initiative (CEFIC-LRI), Contract #LRI-ECO6.2-ILSIHESI-0804.

TP083 Empirical Evidence and Ecological Support for a Strong Water Column Tie in Hudson River Benthic Fish E. Lamoureux, J. Connolly, D. Chiavelli, Anchor QEA, LLC. A significant source of uncertainty in bioaccumulation modeling is the relative proportion of contaminants derived from the water column and the "bioavailable" sediment. Bioaccumulation models typically deal with this issue by incorporating the results of invertebrate surveys and fish gut content analyses to characterize the proportion of invertebrate water column feeders and benthic detritivores that forage fish consume. Polychlorinated biphenyl (PCB) body burdens in water column and benthic invertebrates are then respectively modeled as resulting from exposure to contaminants associated with water column particulates, or with bulk sediments averaged over a depth typically in the range of 2 to 15 cm. However, this approach is at odds with research demonstrating that benthic invertebrate growth and habitat selection is strongly correlated with the availability of fresh organic material. Because the bioavailable sediments typically have an average age of multiple years, the organic matter is mostly refractory in nature. The contaminants associated with this material generally have relatively low bioavailability because a major fraction is resistantly sorbed; a significant body of literature supports the notion that resistant sorption of contaminants limits their bioavailability and that the level of resistance increases with the length of time the contaminant has been associated with the sediments. Based on this research, contaminant body burdens in benthic invertebrates should be more strongly tied to fresh organic matter recently derived from the water column than to bulk sediment organic matter. This idea is supported by the spatial patterns of PCB concentrations in Hudson River invertebrates and fish: benthic fish tissue and benthic invertebrate PCB patterns track water column PCB patterns, decreasing by a factor of less than 2 moving from upstream to downstream, whereas surface sediment PCBs decrease by almost a factor of 10. Thus, the empirical evidence is that Hudson River benthic fish PCB exposure is more strongly linked to water column particulate PCB concentrations than to the bulk sediment PCB concentrations, and that relying solely on a bulk sediment PCB exposure to model PCB concentrations in benthic invertebrates may be inaccurate. Efforts to model bioaccumulation in the Hudson indicate that sediment sources to benthic invertebrates cannot be ignored, but that water column sources must be accounted for as well.

TP084 Modeling Bioconcentration Factor (BCF) of Many Organic Compounds in Fishes D.T. Kuo, Univ of Delaware, Dept of Civil and Environmental Engineering; D.M. Di Toro, Univ of Delaware, Dept of Civil Engineering. Fishes occupy an important ecological role in aquatic environments. They are also a significant source of our dietary intake. As a result, the prediction of bioconcentration factor (BCF) of current or new organic compounds in fish has been of great interest to the public, regulatory agents, and scientists. BCF is measured by chronically exposing individual fish to test chemical under well-controlled laboratory conditions. It can be an important component of models that assess the likelihood of a chemical to bioaccumulate in fish in their natural habitat. Despite the improvement and standardization of the BCF methodology and the accumulation of BCF measurements for many chemicals and fish species over the years, researchers have constructed prediction models based on very different conceptualization of the bioaccumulation processes and mechanism. Furthermore, most current models contain model coefficients that are determined 'after-the-fact' via regression and/or correction schemes. We have re-analyzed bioconcentration data by considering only chemical partitioning with or without biodegradation/biotransformation kinetics. The predictive performance of our BCF model was comparable to those of the others. Our analysis and model results suggest that: (1) fish BCFs data can be predicted without explicit after-the-fact fitting of the model parameters, and (2) future model improvement should be approached by improving our predictive capabilities in chemical partitioning and biodegradation kinetics, and (3) elaborate parameter estimation schemes may be unnecessary.

TP085 Moving Bioaccumulation Assessments to the Next Level: Progress Made and Challenges Ahead C.E. Cowan-Ellsberry, CE2 Consulting, LLC, Central Product Safety, CE2 Consulting; M. Bernhard, Procter & Gamble; M. Bonnell, Environment Canada, New Substances Division, Environment Canada, Science and Risk Assessment Directorate; J. Domoradzki, Dow Corning Corporation, Senior Toxicology Specialist; M.R. Embry, ILSI Health and Environmental Sciences Institute , ILSI Health & Environmental Sciences Institute (HESI), Senior Scientific Program Manager; S. Erhardt, Michigan State Univ, TERC; M. Halder, European Commission, Joint Research Centre, ECVAM; J.W. Nichols, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; H. Segner, Univ of Bern, Centre for Fish + Wildlife Health. Since 2005, the HESI Bioaccumulation Project Committee has helped to advance the science of bioaccumulation ('B') in several areas: developing in vitro methods as part of weight of evidence approaches to 'B' assessment; publishing peer reviewed papers on the state of 'B' science; advancing models to better screen organic chemicals for 'B'; and funding research in basic fish physiology to better understand ADME processes. In addition, the HESI committee has collaborated with SETAC and others to sponsor workshops bringing together academia, industry and regulatory authorities to discuss and advance 'B' science. In February 2011, a workshop was held to highlight recent and ongoing research efforts funded by HESI and others, to demonstrate progress that has been made in the bioaccumulation field, to identify key gaps in current 'B' knowledge, and to discuss obstacles that hinder implementation of this recent progress into regulatory assessments. The ultimate goal of this workshop was to provide guidance to the HESI 'B' Project Committee to further develop the research program and move the science of bioaccumulation forward. Participants included 65 academic, industry and regulatory scientists from 14 countries on 4 continents. The workshop included introductory presentations of the current research, breakout sessions to discuss the research and identify needed work, and finally an assimilation session where the key leanings and next steps were captured. For the discussions, the participants focused on four areas of bioaccumulation research: in silico, in vitro, in vivo and field. In addition to the focus on the research and science, one session discussed the forming weight of evidence for bioaccumulation and obstacles for regulatory acceptance of new methods. The participants emphasized the importance of the recent and on-going research but recommended that the committee seek to move from a linear tiered approach to a network linked approach with cross-cutting focus areas. These cross-cutting focus areas included: 1) Improve overall data access; 2) Bridge in silico – in vitro – in vivo – field information; 3) Develop benchmarks for the available bioaccumulation methodologies; 4) Address issues related to uncertainty; and 5) Engage in a continued regulatory dialog. This presentation will focus on describing the outcomes of the workshop and the follow-on activities.

TP086 Bioamplification as a Non-steady State Bioaccumulation Mechanism for Persistent Organic Pollutants (POPs) in Fish and Wildlife J.M. Daley, Univ of Windsor, Great Lakes Institute of Environmental Research; K.G. Drouillard, Univ of Windsor, Great Lakes Institute for Environmental Research. Persistent organic pollutant (POP) bioaccumulation models have been generally formulated to predict two main processes, bioconcentration and biomagnification under a steady-state framework. A third bioaccumulation process that can mediate chemical potential in an organism is bioamplification. Bioamplification occurs when an organism loses body weight and chemical partitioning capacity at a faster rate than it can eliminate contaminants. It is explicitly a non-steady state process that arises from sudden changes in steady state to non-steady state conditions or from perturbations of the non-steady state trajectory. Although bioamplification is not generally recognized as a bioaccumulation process independent of biomagnification, the consequences of bioamplification can be important.

Bioamplification generally occurs under specific life history stages when an organism experiences major bioenergetic bottlenecks. Examples of bioamplification in a wide variety of species including bird and fish embryos during egg development, overwintering yellow perch, larval Chinook salmon, amphibians during tadpole-frog metamorphosis and emergent aquatic insects will be presented. These examples will demonstrate that bioamplification is a general bioaccumulation process that contributes to enhanced chemical fugacities of POPs in a wide variety of animal species.

TP087 Challenges in Evaluating Biomagnification in Terrestrial Food Webs: A Study with Perfluorinated Compounds C. Mueller, ETH Zurich, Institute for Chemical- and Bioengineering, Swiss Federal Laboratories for Materials Science and Technology, Laboratory for Analytical Chemistry; A.O. De Silva, Environment Canada, Water Science & Technology Directorate, Environment Canada, Water Science and Technology; X. Wang, Environment Canada, Aquatic Ecosystem Protection Research Division; A.D. Morris, Univ of Guelph, Environmental Biology, Environment Canada, Environment Canda, graduate student; M. Gamberg, Gamberg Consulting; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, Environment Canada, National Water Research Institute. Assessing biomagnification of organic contaminants is a difficult task due to the need to understand properties of the chemicals and characteristics of the food web. It is even more complex for perfluorinated compounds (PFCs), e.g., perfluorinated carboxylates and sulfonates because their mechanism of accumulation seems to differ from classic lipophilic chemicals. PFCs are considered proteinophilic and accumulate mainly in protein rich compartments such as liver and blood. Little is known about PFC bioaccumulation in terrestrial organisms. Therefore, we investigated biomagnification of PFCs in a terrestrial food web in two areas in the Canadian Arctic. This food web included vegetation (plants and lichens), barren ground caribou and wolves. There are certain advantages in studying such remote food webs: The lichen-caribou-wolf food web has been well studied and it is relatively simple as caribou feed mostly on lichen and wolves living near caribou herds almost exclusively feed on them. Therefore, it is potentially easier to assess diet-consumer relationships than for complex aquatic food webs. PFCs were measured for all species (with muscle, kidney and liver for caribou and wolves) along with stable isotope ratios (d13C and d15N in muscle) to assess biomagnification (BMF) and trophic magnification factors (TMF). To determine BMFs and TMFs for PFCs two alternate calculation methods were tested: (i) calculation on the basis of the liver concentration or (ii) calculation on the basis of a theoretical whole body concentration. Both approaches have advantages but also carry potential errors: (i) is simple to calculate but may overestimate factors due to higher concentrations in caribou and wolf liver and ignores that different tissues may have different accumulation behavior. (ii) may represent more realistic factors but also carry higher uncertainty due to necessary estimations of unknown body fractions. Utilizing the TMF approach to terrestrial food webs has additional challenges which apply not only to PFCs but also other persistent, bioaccumulative organics. Especially seasonal variation in d13C and d15N in vegetation in temperate and arctic climates as well dietary variation in herbivores may alter TMFs. Selection of the species used to calculate trophic levels and of the appropriate trophic enrichment factor are therefore important factors which need further study in terrestrial food webs.

TP088 Effect of Different Extraction Procedures for the Determination of Aqueous Analyte Concentrations on the Result of Fish Bioconcentration Studies C. Schlechtriem, Fraunhofer IME, Oekotoxikologie; L. Boehm, R. Duering, Institute of Soil Science and Soil Conservation, Justus Liebig Univ Giessen. Measured bioconcentration factors (BCF) and n-octanol-water partition coefficients (Kow) of hydrophobic organic chemicals (HOC) show a curvilinear relationship up to log KOW 5-6. BCF values of more lipophilic substances tend to level of or decline (hydrophobicity cutoff). Debated reasons are steric effects, but also measurement artefacts. Jonker and van der Heijden (2007; Environ Sci Technol 41:7363) suggested that the overestimation of bioavailable aqueous HOC by the presence of non-bioavailable HOC bound to dissolved organic matter, might lead to an underestimation of the true uptake. This was supported by the determination of freely dissolved aqueous concentrations by solid-phase microextraction (SPME). The suitability of SPME to measure highly hydrophobic substances is described in the literature. However, the standard method for sample preparation in BCF-tests according to OECD TG 305 is liquid-liquid-extraction (LLE). The aim of this study was to investigate the potential of SPME with regard to the determination of aqueous analyte concentrations in fish BCF studies with special reference to different contents of organic matter (OM). Water with different concentrations of organic matter was spiked with four test substances (log KOW >5) and analyzed at equilibrium conditions. Analysis of samples with SPME was compared to conventional sample preparation with LLE. With SPME, the detection of freely dissolved analyte concentrations is possible, as is the determination of sorption. Extraction of samples with LLE yields total analyte concentrations. Results show, that the freely dissolved concentration of highly hydrophobic analytes (which corresponds to the bioavailable fraction) is significantly reduced due to sorption to OM – already beneath the permitted concentration of 2 mg L-1 TOC in the dilution water according to OECD TG 305. The results are compared with the outcome of a flow-through fish test on rainbow trout which was carried out to investigate the effect of different extraction procedures on the result of BCF studies carried out under realistic experimental conditions. The results show that SPME can give important information on the ratio between bound and freely dissolved compounds and help to estimate suitable TOC for highly lipophilic substances prior to a BCF study. However, SPME measurements should not replace LLE procedures to keep the results of BCF studies comparable.

TP089 Laboratory Biotransformation – A Link in Understanding Field Bioaccumulation? P. Leonards, Institute for Environmental Studies, VU Univ, Chemistry & Biology, VU Univ, Institute for Environmental Studies; S.v. Leeuwen, B.v. Hattum, VU Univ, Institute for Environmental Studies; F. Gobas, Simon Fraser Univ; H. Leslie, VU Univ, Institute for Environmental Studies. The current state of bioaccumulation science relies heavily on fish bioconcentration (BCF) testing according to international protocols in order to predict the level of bioaccumulation of chemicals in real organisms in food webs in the field. Biotransformation is a key metric in bioaccumulation. The presence of metabolic enzyme systems (CYP450 types), induction of enzyme systems (concentration-dependency), and metabolisation rates are important aspects that determine the overall biotransformation rate – and bioaccumulation – of a chemical. How similar is biotransformation in the laboratory and in the field? The test species in BCF studies often are kept at high temperature (about 25°C), while in the field situation temperatures can be much lower, resulting in lower metabolic rates and higher bioaccumulation. How easily can we use laboratory biotransformation rates to predict bioaccumulation in the field? We present here examples of how laboratory biotransformation of chemicals, with a wide range of K_{oa} and K_{ow}, are related to bioaccumulation and biomagnification in food chains, and to model biotransformation predictions. Laboratory biotransformation rates of the chemicals were studied using S9 rat liver incubation studies. From a pelagic and benthic food chain in the Western Scheldt estuary (The Netherlands) field derived biotransformation rates of the chemicals were estimated using relative concentrations compared to a persistent chemical (PCB153) in predator/prey interactions, including higher trophic organisms (piscivorous bird). The laboratory biotransformation rates were related to the estimated relative field rates and model predictions of biotransformation rates in fish. These biotransformation data were then examined in light of the trophic magnification factors (TMF) measured in this ecosystem. We concluded that the chemicals can be grouped in a persistent and a non-persistent group based on laboratory and field data. These data will be used to develop and test models that describe the relationship between in vitro biotransformation rate constants, in-vivo bioconcentration factors and in situ bioaccumulation in food-webs.

TP090 Patterns of Bioaccumulation of Lake Huron Lake Trout (*Salvelinus namaycush*) M. Ryder, D. Haffner, Univ of Windsor, GLIER. Steady state kinetics has been the primary assumption when describing the accumulation of organic contaminants, including super hydrophobic compounds (log Kow > 6). Recent studies have shown that not all chemicals achieve a steady state within an organism's lifetime. This study investigates the accumulation of polychlorinated biphenyls (PCB's) in lake trout (*Salvelinus namaycush*) from Lake Huron and tests the assumption these organisms achieve a steady state in their lifetime. Micro-extraction methods were used to extract both lipids and 24 individual PCB congeners from 36 lake trout. Whole body homogenates were used to provide a better representation of total body burdens. Fish ranged in ages from 3 to 11 years. Sums of the lipid normalized concentrations of the 24 congeners in the fish ranged from 610.7 to 2692.9 ng/g. Preliminary results indicate that compounds of high hydrophobicity (log Kow > 6.5) were less likely to achieve steady state than

low Kow compounds, and the super-hydrophobic chemicals continued to accumulate throughout the life time of these fish. These data suggests using a steady model can underestimate the level of contaminants present in the fish and therefore under predict the potential hazard associated with fish consumption guidelines.

TP091 The Suitability of Freshwater Amphipods as Test Organisms for Bioaccumulation Studies C. Schlechtriem, Fraunhofer IME, Oekotoxikologie; I. Goeritz, Fraunhofer IME; C. Schaefers, Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Dept of Ecotoxicology. The bioaccumulation of sediment-associated contaminants by benthic invertebrates can be assessed by using the bioaccumulation test TGD OECD 315. Endobenthic aquatic oligochaetes burrow in the sediment and are therefore exposed to contaminants via multiple uptake routes including direct dermal contact, ingestion of contaminated sediment particles, porewater, and overlying water. Therefore, the test endpoint is defined as a bioaccumulation factor (BAF). However, the ultimate decisive bioaccumulation-criterion as part of the REACH regulation (Annex XIII) is the bioconcentration factor (BCF) reflecting the uptake of a test substance from the contaminated surrounding medium. A suitable method to deduce BCFs from BAFs derived from OECD 315 studies is still missing leading to a limited value of this test from the regulatory point of view. The aim of this study was to investigate whether benthic amphipods can be used as alternative test organisms for bioaccumulation studies, providing the opportunity to explain bioaccumulation from water (bioconcentration) and food (biomagnification) separately. In a first approach, an algal based diet suitable to grow the freshwater amphipods *Hyalella azteca* and *Gammarus pulex* was identified using a simple filter feeding system. The selected dietary component was then enriched with a highly lipophilc test item (logP = 5) and applied in a feeding study on both species. In a further approach animals were exposed to a test item of moderate lipophilicity (logP = 3) via the water. Animals collected during the bioaccumulation studies were analysed for their tissue concentrations. Based on the kinetic study design the depuration and uptake rates for both test items were determined which were further used to calculate species specific BCFs or biomagnification factors (BMF). The results of all studies are presented and compared with BCF and BMF values obtained from fish bioaccumulation studies carried out according to the revised TGD OECD 305. The potential of freshwater amphipods as test organisms for bioaccumulation studies is discussed.

TP093 How Sources of Organic Matter Affect Mercury Concentrations in Stream Biota T. Jardine, Griffith Univ, Australian Rivers Institute; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology; J. Rasmussen, Univ of Lethbridge. Our understanding of the trophic transfer of mercury (Hg) through aquatic food webs has been advanced by including measures of stable isotopes of nitrogen ($\delta^{15}N$) and carbon ($\delta^{13}C$) to assess trophic position and carbon flow, respectively. Numerous studies of lakes have shown that Hg concentrations in food web organisms are positively related to their relative trophic position and that this Hg vs. $\delta^{15}N$ relationship can be used to contrast systems that have different biological, physical and chemical characteristics. In contrast to lakes, mercury biomagnification through riverine food webs is not well understood and is confounded by the dynamic nature of these systems and the complex reliance of these biota on in-stream or terrestrial carbon sources. Here we sampled two species of fish (blacknose dace, *Rhinichtyhs atratulus*; brook trout, *Salvelinus fontinalis*), several invertebrate taxa, periphyton and terrestrial producers of 60 temperate streams in New Brunswick, Canada. We used a gradient approach – a comparison of the strength of association between consumer isotope ratios and periphyton isotope ratios – across temperate streams that range in their pH to assess consumer reliance on terrestrial versus aquatic organic matter, and whether Hg concentrations in fish and their prey were related to these energy sources. Taxa varied in their use of terrestrial material, with grazing mayflies (Heptageniidae), predatory stoneflies (Perlidae), one species of water strider (*Metrobates hesperius*) and the fish blacknose dace (*Rhinichtyhs atratulus*) having strong connections to aquatic sources, while water striders (*Aquarius remigis*) and brook trout (*Salvelinus fontinalis*) showed a weak link to aquatic food sources. In addition, stream pH – known to affect Hg concentrations in lake biota – was a much better predictor of Hg in predatory invertebrates that relied mainly on aquatic carbon sources when compared to those that used terrestrial carbon. These results suggest that it is important to understand energy sources and flows in these food webs before examining the importance of water chemistry or other variables on Hg concentrations and fate in riverine food webs.

TP094 Biogeochemical Cycle of Mercury in Urban Streams A. Aragon-Jose, J. Bushey, Univ of Connecticut, Dept of Civil and Environmental Engineering; C. Perkins, Univ of Connecticut, Center for Environmental Sciences and Engineering; M. Mendes, Univ of Connecticut, Dept of Civil and Environmental Engineering; G. Ulatowsky, Univ of Connecticut, Center for Environmental Sciences and Engineering. Mercury (Hg) can easily bioaccumulate in the food chain representing a risk even at low levels due to its high toxicity. The presence of urban activities can substantially alter different mechanisms and processes of the Hg biogeochemical cycle. Urban watersheds are characterized by high imperviousness and some may even be impacted by combined sewer overflows, both being fundamental factors contributing to Hg loading, mobilization, and shifts in bioavailability in urban watersheds. Research is still needed to understand the fate and dynamics of Hg in urban streams. We are collecting stream water and suspended sediment samples in the North Park River watershed in Hartford, CT (USA) during baseflow and precipitation events to assess potential for loading, mobilization, and bioavailability of Hg. We also collect water samples at the Hartford's waste water treatment plant (WWTP) from the influent, effluent, and the wet-weather lagoon. Water samples are analyzed for total, dissolved, and particulate Hg and methyl Hg (MeHg); major ions (Cl^-, NO_3^-, SO_4^{2-}, and PO_4^{3-}); total suspended solids (TSS); and dissolved organic carbon (DOC). Our results show that both total and dissolved Hg concentrations increase in the streams during precipitation events, however the greatest portion of Hg is associated, and consequently transported, with suspended sediments, as evidenced by the high correlation coefficient (R^2 ~ 0.80) between TSS and total Hg. No significant correlation was observed between dissolved or total Hg and DOC for the stream samples. In the WWTP, concentrations of both Hg and DOC are higher than those from the streams, but no significant correlation between TSS and Hg was observed, indicating differences in the transport mechanisms, and possibly on Hg sources between the streams and the WWTP. Overall, effluent samples exhibit lower Hg concentrations than their corresponding influent samples showing that Hg is somehow removed during the water treatment process. Unfiltered MeHg stream samples exhibited a similar pattern than that of total Hg, that is, an initial increase in concentration up to a maximum followed by a decrease close to the starting point. Dissolved MeHg is mostly below our detection limit for the stream sites. MeHg concentrations are generally higher at the WWTP compared to the stream. Both the influent and the lagoon sites show a decrease in MeHg concentration, whereas the effluent samples increase over time.

TP095 Sulfur and Carbon Controls on Methylmercury in St. Louis River Estuary Sediment N. Johnson, B. Beck, Univ of Minnesota Duluth, Civil Engineering. Transformation of inorganic mercury to methylmercury represents a public health concern due to its bioaccumulative properties in fish and neurotoxicity in humans. Biological mercury methylation primarily occurs in anoxic environments and has been shown to be limited by organic carbon and sulfate in wetland and saltwater estuary sediments. The work presented here investigates the controls on methylation in the St Louis River system, a freshwater estuary potentially impacted by upstream mining. Surface water sulfate concentrations in the St. Louis River Estuary are impacted by both upstream mining and local urban sources and occur in a range that has been considered ideal for methyl mercury production (10-50 mg/L). Both in situ measurements and microcosm studies with sulfate amendments are being used to characterize biogeochemistry related to mercury methylation in different habitat zones of the St. Louis Estuary. Sediment phase methyl mercury was measured in the context of various biogeochemical parameters including byproducts of microbial metabolism (H2S, Mn(II) and Fe(II)), total organic carbon, sulfate, and sulfate reducing bacterial abundance (qPCR). Results from intact sediment cores show that surficial sediment from each of four habitat zones has the capacity to methylate mercury (47-157 pg/g) and observed differences are interpreted in light of simultaneous geochemical measurements. Higher methylmercury concentrations in relatively low-organic habitat near the estuary mouth suggest that rates of biological sulfate reduction alone may not be the limiting factor for methylation. Microcosms with controlled sulfate concentrations in the overlying water are presently being used to examine the extent to which changes in sulfate loads will affect sediment biogeochemistry and associated mercury methylation. Preliminary results from microcosms imply that both

sulfate and organic carbon play a role in limiting methylation in different habitats within the estuary. A simple model for sediment methylmercury is used to explain observations and tie results to upstream sulfur management objectives.

TP096 Methyl Mercury in Fish Tissue and the Water Column of the Upper Ohio River D. Langseth, C. Tuit, Gradient. In 2001, the US Environmental Protection Agency (USEPA) changed the mercury ambient water quality criteria related to human health protection to be based on fish tissue concentrations , rather than water column concentrations. In 2009, USEPA issued guidance on how to incorporate the fish tissue criteria into discharge permitting under the Clean Water Act. The 2009 USEPA guidance describes two fundamental approaches, one based on only fish tissue, without translation to water column or discharge criteria values, and a second that includes translation to water column and/or effluent concentration values. Under the second option, the 2009 USEPA guidance recommends translation between water column and fish tissue concentrations based on measured values of methylmercury in fish tissue and the water column, preferably filtered water sample concentrations, for the location of interest. The Ohio River River Valley Sanitation Commission (ORSANCO) has been collecting water column and fish tissue data from the Ohio River for several years, but until 2010 these samples were analyzed only for total mercury, and in water samples only for whole water samples. During 2010 and 2011, Gradient collected fish tissue and water column samples, both filtered and unfiltered, from the upper Ohio River. These samples were analysed for total and methyl mercury and provide some insight into mercury bioaccumulation in the Upper Ohio River.

TP097 Hormetic Responses in *Daphnia magna* Growth and Reproduction Upon Exposure to the Energetic Compounds TNT, RDX, and the New Tetrazole Energetic TAGMNT J.K. Stanley, US Army Engineer Research and Development Center, Environmental Laboratory; J.G. Sims, US Army Engineer Research and Development Center, Environmental Lab (EP-R); P. Chappell, Badger Technical Services; L.L. Escalon, US Army Engineer Research and Development Center, Environmental Laboratory; T. Habib, Badger Technical Services; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division; A.L. Russell, Badger Technical Services; A.J. Bednar, US Army Engineer Reseach and Development Center; M.A. Nascarella, Gradient. Currently, there is little information as to how munitions might cause effects when at low concentrations. A number of chemicals have been observed to cause a hormetic, or stimulatory, effect on animals exposed at low concentrations. The purpose of the present study was to identify the existence and the concentration range of hormetic responses observed for representatives of three different classes of energetic compounds. We used the model aquatic invertebrate *Daphnia magna* and assessed effects in 21-day growth and reproductive bioassays. The energetics assessed included hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX), trinitrotoluene (TNT), and a newly developed nitrogen-rich tetrazole energetic triaminoguanidinium 1-methyl-5-nitriminotetrazolate (TAGMNT). Observed hormetic responses included increases in *D. magna* reproduction at TNT concentrations ranging from 0.06 to 0.22 mg/L and increases in *D. magna* growth at TNT concentrations ranging from 0.004 to 0.97 mg/L. Apparent, yet non-significant, increases in *D. magna* reproduction and growth were observed at RDX concentrations ranging from 0.02 mg/L to 14 mg/L and in growth of *D. magna* exposed to TAGMNT at concentrations ranging from 0.0002 to 0.01 mg/L. Ongoing efforts to be presented include an assessment of the magnitude and width of stimulation and work to elucidate the mechanism of the observed hormetic responses in *D. magna* using gene microarrays.

TP098 Do Nanomaterials Used in Munition Formulations Alter the Fate of Energetic and Metal Munitions Constituents? J.K. Stanley, US Army Engineer Research and Development Center, Environmental Laboratory; A.J. Kennedy, US Army Engineer Research and Development Center; A.J. Bednar, US Army Engineer Reseach and Development Center; A. Poda, US Army Engineer Research and Development Center; J. Brame, Rice Univ. While the environmental implications of energetic compounds and metals of military concern have received study, little is known about how the bioavailability of these military relevant compounds will be affected by their interaction with Army performance-enhancing nanomaterials. The likelihood of such interactions in the environment is high as nanomaterials such as nano aluminum and carbon nanotubes (CNTs) are already used in energetic formulations as oxidizers and stabilizers, respectfully, and CNTs are also being investigated as components of battlefield obscurants. Such applications of nanomaterials are predicted to increase in the future. Additionally, unintended interactions between nanomaterial waste streams and contaminants of military concern (e.g., runoff from training ranges) are likely. The purpose of the present research was to determine the ability of nano aluminum oxide (Al2O3) and CNTs to bind to and remove the munition constituents RDX (cyclotrimethylenetrinitramine) and tungsten (W) from solution as a first step in determining the bioavailability implications of such interactions. Al2O3 size (11 – 1,500 nm) and CNT functionalization (hydroxylated) were varied to assess the effects of surface area and charge on this binding. Preliminary results from this ongoing work indicate significant reductions in aqueous RDX concentration in the presence of 100 mg/L nano Al2O3 and apparent, albeit nonsignificant, reductions in RDX concentration in the presence of 100 mg/L multi-walled CNTs. Additional research to be presented includes assessments of binding strength between munition constituents and nanomaterials via thermally programmed desorption and the ability of nano Al2O3 and carbon nanotubes to bind tungsten in solution. Bioavailability implications of such interactions will be directly measured using bioassays in upcoming years of this project. Consideration will be given to both bioavailability of the munition remaining in the water column and whether munition initially bound to nanomaterial is bioavailable following bio-uptake.

TP099 Determining Diffusion Kinetics of Lithium Bromide Tracer into Nitrocellulose as a Distinguishing-Model for Nitroglycerin and 2,4-Dinitrotoluene M. Simini, US Army Edgewood Chemical Biological Center, Environmental Toxicology, RDCB-DRT-E, E5641; R. Checkai, US Army Edgewood Chemical Biological Center; M. Minyard, US Army Defense Threat Reduction Agency; R.G. Kuperman, US Army Edgewood Chemical Biological Center, Environmental Toxicology; H.E. Allen, Univ of Delaware, Civil & Environmental Engineering Dept; D.M. Di Toro, Univ of Delaware, Dept of Civil Engineering. Development of effective technologies for predicting the fate and transport of munitions constituents (MC) at explosives-contaminated sites is needed to sustain operational training and testing ranges. Dissolution of MC from propellant particles is a major concern at these sites. The presence of the nitrocellulose (NC) matrix complicates modeling of MC release from propellant and into soil solution. In addition to the dissolution of the soluble components, the role of adsorption to NC, and desorption from NC, matrix swelling in the presence of water, and diffusion within the matrix, all need to be taken into account. No adsorption/desorption kinetic model of MC into the NC matrix currently exists. The present study investigated the diffusion kinetics of lithium bromide (LiBr) into the NC matrix, using LiBr as an inert tracer in order to distinguish diffusion from adsorption and desorption of the MCs nitroglycerin (NG) and 2,4-dinitrotoluene (2,4-DNT) on NC. Experiments were conducted in triplicate using NC (12.3% N) pre-moistened for 5 days to a previously determined saturation point. A LiBr solution was added to determine rates of Li and Br diffusion into the NC matirx. Replicated samples were extracted from the solution at timed intervals from 0 to 48h, and analyzed for Li and Br simultaneously by ion chromatography. Diffusion of LiBr from the NC matrix into aqueous solution was also investigated; for this, NC was pre-saturated with LiBr and its diffusion into clean ASTM Type I water was determined as a function of time. Most diffusion of LiBr occurred within the first few hours. The rates of diffusion of tracer will be used to determine the appropriate type of diffusion model, and to distinguish diffusion from adsorption/desorption kinetics of NG and 2,4-DNT. These studies were supported by project number ER-1688 of the Strategic Environmental Research and Development Program (SERDP).

TP100 A Kinetic Model for Munition Constituent Adsorption and Desorption A. Miglino, R. Gonzalez, K. Michelson, H. Allen, D.M. Di Toro, Univ of Delaware, Dept of Civil Engineering. Partially detonated explosives are a source of concern on military ranges due to the potential for off-site transport. A kinetically based adsorption-desorption model for munition constituents (MCs) will be presented to predict behavior of explosive and propellant compounds. The model incorporates diffusive transport into particles where the MC can partition into organic matter. Calibration of the model reproduces adsorption data. Based on laboratory batch test data, a portion of the MC is resistive in desorbing from soil. This portion is not accurately described by only diffusion and partitioning. The results of a

two component reversible/resistant model will be presented to explain this behavior.

TP101 Interference of Heavy Metals on Degradation of Nitroaromatic Compounds in Soil by Advanced Oxidation Processes E. Jho, J. Jung, Seoul National Univ, Dept of Civil and Environmental Engineering; K. Nam, Seoul National Univ, Dept of Civil and Environmental Engineering, Seoul National Univ, Dept of Civil and Environmental Engineering. Many firing ranges in Korea are contaminated with both nitroaromatic compounds (NACs) such as trinitrotoluene and heavy metals such as lead (Pb) and copper (Cu). Feasibility of advanced oxidation processes (AOPs) for remediation of combined NACs and heavy metal contamination is studied by performing lab-scale experiments. Specifically, Fenton reactions are used to degrade dinitrotoluene (DNT) in soil in the presence and the absence of Pb and Cu. In addition, a range of hydrogen peroxide (H_2O_2) concentrations will be investigated to study the effects of H_2O_2 on DNT degradation in soils. The changes in the concentrations of DNT, Pb, and Cu in soil and in aqueous phase during Fenton reactions will contribute to identifying the effect of heavy metals on the DNT sorption in soil, hence, DNT degradation during Fenton reactions as sorbed organic compounds are not easily desorbed and degraded by Fenton reactions. We hypothesize that more DNT to be degraded by Fenton reactions in the absence of Pb or Cu as Pb or Cu compete with DNT for sorption sites on soil particles. Thus, in the presence of Pb or Cu, more DNT will be available in aqueous phase for degradation by radicals produced by Fenton reactions. The findings will contribute to the advancement of Fenton reactions for remediation of soils contaminated with NACs and heavy metals.

TP102 Assessing Bio-uptake and Phytohydraulic Influence of Native Willow Trees in a Radioactively Contaminated Site K.G. Keil, W.T. Frederick, M.R. Masset, S.P. Buechi, US Army Corps of Engineers, Buffalo District. During the 1940's, the Linde Corporation in Tonawanda, New York separated uranium ores to support the Manhattan Project. Radioactively contaminated materials from Linde were placed in the northern portion of the Tonawanda Landfill, a municipal landfill approximately 1.5 miles away. This area of the landfill remains uncapped, pending final assessment and potential remediation by the Federal Government. Samples of surface and subsurface soils, surface water, sediment, and groundwater, as well as from vegetative portions of a stand of willow trees growing within this uncapped portion of the landfill were used to assess the potential for human and ecological impacts from the localized subsurface radioactive contamination. The tree-focused samples (soil and water within the root zone; roots, trunk, and leaves) were intended to characterize potential impacts that the black willow trees have on groundwater flow through the landfill (phytohydraulics), and whether or not plant uptake of radionuclides was occurring. The soil samples taken within the shallow root zone of the trees had slightly elevated radioactivity, although less than nearby soils. Concentrations of radionuclides in vegetative samples were comparable to unimpacted soils. Unfiltered surface and groundwater samples obtained from within the tree root zone had concentrations of uranium (the most soluble and mobile of the radionuclides) greater than proximal groundwater samples. The groundwater levels and dissolved uranium concentrations in groundwater along the northern edge of the landfill show that the boundary of the landfill material with the natural lake-clay promotes an upward groundwater flow through the contaminated soil. Coincident groundwater and surface water impacts indicate that drainage features near the northern fence receive groundwater discharge containing uranium that was solubilized along the flow path through the radioactive material. This impacted groundwater then partially discharges to the surface water features and flows downgradient towards an off-site creek. These results indicate that while bio-uptake of radionuclides is not occurring into the black willow trees, the trees may be drawing in uranium-contaminated water toward their root zone, thereby affecting the uranium distribution in groundwater and receiving surface water discharges.

TP103 Effects of Tungsten Chemical Species on Phosphate-dependent Pathways in a Bone Cell Line D.R. Johnson, US Army Engineer Research and Development Center, Environmental Laboratory; C. Ang, Badger Testing Services; A.J. Kennedy, US Army Engineer Research and Development Center. Tungsten (W) is a metal that has numerous civil and military applications due to its high strength and melting point. When W enters the environment, it is rapidly oxidized and speciated based on the environmental matrix it is embedded in. Bone is the long-term storage organ for W—and presumably W chemical species if present—when taken up by organisms. It is unknown what long-term effects W has in bone. Extensive polymerization of W to phosphate may deplete intracellular phosphate stores, disrupting phosphorylation reactions in cells. Furthermore, disruption of normal osteoblast function by W may impact bone formation (a phosphate-rich hydroxyapatite matrix) and biomechanics. Therefore, we evaluated the effects of W species on several phosphate-dependent intracellular functions, including energy cycling (ATP production), regulation of enzyme activity (protein tyrosine kinase [PTK]), and intracellular secondary messengers (cyclic adenosine monophosphate [cAMP]). hFOB 1.19 osteoblastic cells were exposed to vehicle control (water) or W chemical species (sodium tungstate, phosphotungstate [PW], poly tungstate [polyW], and tungstosilicic acid [TSA]) at 0-10,000 uM for 24 h at 37 degrees C. Cells were then lysed and analyzed for cell viability, ATP concentration, tyrosine kinase activity, and cAMP concentration. W species did not affect ATP concentrations except at the highest concentration. PW, polyW, and TSA, but not tungstate, significantly increased protein tyrosine kinase activity at 10,000 uM after 4 h exposure. Tungstate and PT increased cellular cAMP at ≥ 100 uM, while TSA decreased cellular cAMP at 10,000 uM. These data demonstrate that W chemical species generally only affect phosphate-dependent cell signaling and secondary messenger pathways in hFOB 1.19 cells. However, the W chemical species concentrations needed to affect these phosphate-dependent biochemical pathways greatly exceed the amount of W deposited in bone (100 uM W = 18 mg/kg), thus providing evidence that W chemical species will not affect osteoblastic cellular activity.

TP104 A Standardized Contact Transfer Method for Assessing Soil-to-Clothing Exposure to Chemical Agents R.T. Checkai, The Ohio State Univ, School of Environment and Natural Resources, US Army Edgewood Chemical Biological Center, Environmental Toxicology, US Army Edgewood Chemical Biological Ctr, Dept of Environmental Toxicology; M.V. Haley, C.T. Phillips, M. Simini, US Army Edgewood Chemical Biological Center, Environmental Toxicology. Exposure to chemical warfare agents (CWA) can present a potential Contact Hazard even when the CWA compounds are sorbed onto soil. Previous studies have investigated levels of CWA transferred from contaminated surfaces utilizing a malleable latex material (dental dam; DD) as transfer substrate; however DD is typically inconsistent in compositions, and not a reliable simulant for toxicological investigations. Measurements of CWA on standard Army Combat Uniform (ACU), plus toxicological effects of CWA on mammalian skin, have been reliably established for some CWA, and ongoing-testing continues for others. But the need still existed for a reliable transfer-exposure method for assessing the exposure potential for CWA sorbed onto soil. We have established a method for reliably determining Contact Transfer of CWA compounds from soil directly onto clothing, utilizing standard mass (x Gravity) as a standard force to produce a standard measure of exposure potential. We initially determined the effects of contact time and applied mass (DD); then in benchmark investigations, we established the efficacy of CWA extraction from ACU (and DD), and Contact Transfer of CWA from soil onto clothing (ACU). A 4"-diameter circular swatch of ACU material was selected, similar to surface areas that may contact soil at knee or elbow locations; standard contact was created by placing the ACU swatch directly onto the soil-surface one minute after CWA dissemination, then covering the swatch with a 4"-diameter Plexiglass disk to distribute force from a centrally-placed standard mass. Contact Transfer of CWA was determined by solvent extraction of swatches, with subsequent analyses by GC/GC-MS. Masses 0.250, 0.500, 1.000, 1.500 kg, resulted in significantly greater CWA transfer ($p \leq 0.05$) at ≥0.500kg compared to 0.250kg; therefore the 1-kg standard mass was selected for integration into the method. Although the quantities of soil-sorbed CWA that transferred increased as a function of contact time, the rate of transfer decreased dramatically after 1h; therefore 0.25h was selected for integration into the method. The quantities of chemical agents transferred from soil surfaces contaminated at operationally important levels from Soil-to-Clothing (ACU) are amounts that are within the range of concern for Soldiers. The standardized Contact Transfer Method provides reliable standard predictions of exposure potential, and in conjunction with toxicity data for predictions of Contact Hazard.

TP105 A Study of Mercury and Neurochemical Biomarkers Across Several Fish Species D. Nam, Univ of Michigan, Dept of Environmental Health Sciences; D. Adams, Fish & Wildlife Research Institute; D. Evers, Biodiversity Research Institute; J. Head, Univ of Michigan, Cooperative

Institute of Limnology and Ecosystem Research, Univ of Michigan, Cooperative Institute for Limnology and Ecosystem Research; M.J. Carvan, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences, Univ of Wisconsin-Milwaukee, Childrens Environmental Health Sciences Center; N. Basu, Univ of Michigan, Dept of Environmental Health Sciences, Univ of Michigan, Dept of Environmental Health. Mercury (Hg) is a potent neurotoxicant that impairs key physiological processes related to vertebrate behavior and reproduction. Recent studies in fish have also established that Hg is a neuroendocrine disruptor, though little is known about the subclinical effects and the underlying mechanisms. Here we present findings from a series of studies (in vitro, field work, laboratory bioassay) that aimed to assess Hg-associated neurochemical effects in several fish species as follows: 1) studies on wild fish (lemon shark, mako shark, seatrout, largemouth bass); 2) in vitro screening assays (lemon shark, mako shark, yellow perch, goldfish) on neurochemical receptors and enzymes underlying vertebrate reproduction; 3) studies on laboratory-exposed yellow perch. In the wild fish studies, mean brain Hg levels were: 0.145 ppm dry wt in lemon shark (n=28; South Florida), 1.69 ppm in mako shark (n=12; Atlantic coast), 0.577 ppm in seatrout (n=28; South Florida), and 0.069 ppm in South River fish (n=28; Virginia). Saturation binding curves were developed from each fish species to obtain Bmax (195 – 266 fmol/mg for mAChR, 236 – 3065 fmol/mg for NMDAR) and Kd (3.18 – 4.64 nM for mAChR, 28.9 – 368 nM for NMDAR). Based on inhibition constants (Ki) against $Hg^{2+}$and CH_3Hg^+, goldfish and yellow perch were the most sensitive to mAChR and NMDAR binding, respectively. When brain Hg was related to neurochemical enzymes (MAO, AChE) and receptors (mACh, NMDA), there were no Hg-associated neurochemical changes except in the mako shark where a negative correlation with NMDA glutamate receptors ($r = 0.496$; $p < 0.05$) was found. Mercury inhibited glutamate uptake in synaptosomes from seatrout and two shark species in a dose-dependent manner (IC50: 0.39–2.3 μM of Hg^{2+}; 0.15–2.1 μM of CH_3Hg^+). Via cell-free in vitro screening assays, we are assessing Hg-related impacts towards sex hormone receptors, neurotransmitter release and uptake mechanisms, and neurochemical receptors and enzymes that have critical roles in reproduction (e.g, dopamine and GABA systems) and neurobehavior (e.g., glutamate pathway). We will also report on neurochemical data from laboratory-exposed perch.

TP106 Comparing the Sensitivity of Wild Populations of *Carcinus maenas* from Two Estuaries of the NW Coast of Portugal to the Insecticide Fenitrothion A. Rodrigues, Univ of Porto – ICBAS & CIIMAR, ICBAS – Institute of Biomedical Sciences of Abel Salazar, Dept of Populations' Studies, Porto, Portugal; CIIMAR – Interdisciplinary Centre for Marine and Environmental Research, Laboratory of Ecotoxicology and Ecology, Porto, Portugal.; P. Oliveira, Univ of Porto, CIIMAR , CIIMAR – Interdisciplinary Centre for Marine and Environmental Research, Laboratory of Ecotoxicology and Ecology, Porto, Portugal.; L. Guilhermino, Univ of Porto, CIIMAR & ICBAS, Laboratory of Ecotoxicology, Univ of Porto, ICBAs & CIIMAR, Universidade do Porto; L. Guimaraes, Univ of Porto, CIIMAR & ICBAS. Sensitivity to fenitrothion of crab populations from the NW Portuguese estuaries of rivers Minho and Lima was assessed through laboratory exposure bioassays. Minho is a low impacted estuary, which has been used has reference in previous studies. Lima estuary receives inputs from urban and industrial sources, it has a harbour and a shipyard at its mouth, and field crops are located in its vicinity. Fenitrothion was selected as test substance because it is a widely used organophosphate insecticide (OP), with a well known mechanism of primary toxicity (acetylcholinesterase inhibition). In two bioassays running in parallel, crabs from the two populations were individually exposed to several concentrations of fenitrothion. In each bioassay, 10 crabs were used per treatment. Mortality was recorded at each 24h. After 7 days of exposure, surviving animals were sacrificed, the activity of target enzyme was determined and mechanisms of biotransformation and defence against toxicant insults were investigated. Overall, the results indicate that the population of Lima estuary is less sensitive to fenitrothion than the population of the Minho estuary, suggesting that crabs developing in the most contaminated estuary may have developed tolerance to pollution. This work was supported by funds from the Portuguese Foundation for the Science and Technology (FCT) and EU-FEDER funds through the Programme COMPETE (Project CRABTHEMES FCOMP-01-0124-FEDER-007383). TP107 Developmental Bisphenol A Exposure Results in Abnormal Larval and Adult Zebrafish Behavior D. Weber, Univ of Wisconsin-Milwaukee, Childrens Environmental Health Sciences Center, Univ of Wisconsin-Milwaukee, Great Lakes Water Institute, Univ of Wisconsin-Milwaukee; A. Patel, Univ of Wisconsin-Milwaukee, Dept of Psychology; K.S. Saili, Oregon State Univ, Environmental & Molecular Toxicology, Oregon State Univ, Environmental & Molecular Toxicolog; M.M. Corvi, S.R. Das, R. Tanguay, Oregon State Univ, Environmental & Molecular Toxicology. Bisphenol A (BPA) is a high production volume chemical found in polycarbonate plastic, resin can linings, and thermal printing paper. Ingestion is considered the primary route of human exposure. BPA is a suspected estrogen disruptor that may interfere with central nervous system (CNS) development. To determine whether environmentally relevant levels of BPA impact CNS development, we assessed the effect of BPA on larval and adult behavior endpoints. For the larval behavior tests, developing zebrafish embryos were exposed to a range of nonteratogenic BPA concentrations (0.001 to 10 μM) during neurogenesis (10 – 58 hours post fertilization, hpf). The 0.01, 0.1, and 1 μM exposure concentrations resulted in behavioral hyperactivity (response to light on-light off) in 120 hpf larvae (N=32-64/concentration; one way ANOVA, $P < 0.05$). For the adult behavior tests, zebrafish embryos were exposed as above to 0.1 or 1 μM BPA. Both exposure concentrations resulted in abnormalities in adult learning behavior. Cognitive flexibility, a measure of executive function, was examined in a computer-controlled reversal task. Individual adult fish (N=10; 8 months old) freely chose the left or right arm of a T-maze. Initial choice resulted in a mild shock. Criterion achieved upon 3 consecutive choices of non-shocking arm at which time an additional choice of that arm resulted in a shock. Criterion for second reversal achieved with 3 consecutive choices of newly, computer-designated non-shocking arm. While no significant differences were observed between male and female fish, there were significant, concentration-dependent differences in trials to first reversal, trials to second reversal, consecutive incorrect trials to first reversal, consecutive incorrect trials to second reversal, and number of larvae completing each reversal (one way ANOVA, $P < 0.005$). Research was supported by NIEHS T32ES7060, ES00210, ES04184, and EPA STAR Graduate Fellowship (KSS).

TP108 Effects of Methylmercury Chloride on Neurochemical Biomarkers in the Developing Chicken Embryo J. Rutkiewicz, Univ of Michigan; D. Nam, Univ of Michigan, Dept of Environmental Health Sciences; J. Head, Univ of Michigan, Cooperative Institute of Limnology and Ecosystem Research, Univ of Michigan, Cooperative Institute for Limnology and Ecosystem Research; N. Basu, Univ of Michigan, Dept of Environmental Health Sciences, Univ of Michigan, Dept of Environmental Health. Mercury (Hg) is an established neurotoxicant that has been linked to neurobehavioral changes in birds in both field and laboratory studies. Recently, changes in receptors and enzymes involved in neurotransmission have been studied as subclinical biomarkers of Hg's neurological effects in wildlife, including birds. These changes precede structural changes and potentially warn of changes in ecologically relevant behaviors. Avian embryos are exposed to maternally deposited methylmercury (MeHg) throughout development, but its effects on the embryonic brain are relatively unexplored. The objective of this work is to determine if in ovo MeHg exposure in chicken embryos is associated with alterations in the NMDA and GABA receptors and glutamine synthetase (GS) and glutamic acid decarboxylase (GAD) enzymes, which have previously been studied as biomarkers in wild bald eagles. White leghorn chicken eggs were injected with MeHg chloride (Study 1:, 0, 0.17, 0.62, or 2.0 mg/g egg; Study 2: 0, 0.62, 2, 3.2, or 6.2 mg/g egg) and were incubated until day 19, upon which embryos were dissected and brains (dissected into cerebrum, cerebellum, and optic lobe regions) were frozen until analysis. In both studies, mortality ranged from 0% to 29% and did not increase in a dose dependent manner. Brain Hg concentrations increased with dose in both studies, reaching a high mean concentration of 0.85 mg/g in the highest dose group in study 1 and 2.2 mg/g in the highest dose group in study 2. In study 1, Hg was not associated with receptor binding or enzyme activity in any brain region. Despite the higher brain Hg concentrations observed in study 2, no associations were found with binding to the NMDA receptor or GABA receptor in any brain region. Effects on GS and GAD activity are currently being studied. These studies suggest that unlike in adult birds, MeHg associated changes to the aforementioned neurochemical biomarkers may not occur in late stage embryos. Upcoming studies will investigate the effects of Hg exposure on neurochemistry at earlier developmental stages to determine if Hg disrupts critical developmental processes

in the brain, continue to study other neurochemical systems, and explore linkages between exposure and chick neurobehavior.

TP109 Effects of Non-selective Cyclooxygenase Inhibitor, Ibuprofen, on Gene Expression, Prostaglandin Synthesis and Reproductive Behavior in Zebrafish D. Martinovic-Weigelt, Univ of St. Thomas, Dept of Biology, USEPA, Mid-Continent Ecology Division, Mid-Continent Ecology Division, Univ of St. Thomas, Biology; J. Marchuk, Univ of St. Thomas, Dept of Biology; T. Firkus, Univ of St. Thomas. Prostaglandins are a class of hormones important for the regulation of gonadal steroidogenesis and ovulation in vertebrates. In fish they are also used as pheromones; they are released by ovulating females and are important for the initiation and synchronization of male reproductive behaviors. Commonly used pharmaceuticals such as nonsteroidal anti-inflammatory pharmaceuticals (e. g, ibuprofen (IB) etc.) inhibit cyclooxygenase (COX) enzymes which catalyze prostaglandin synthesis. Sexually mature zebrafish males (n=14) and females (n=14) were exposed to 50 µg/L of IB for 14 days and their reproductive behaviors were compared to well-water exposed controls (n=14 per sex). The present study also examined effects of IB exposure on prostaglandin synthesis pathway; we measured phospholipase, COX 1 and 2, and prostaglandin synthase mRNA abundance using real time polymerase chain reaction. In addition, the ovarian prostaglandin F2 alpha concentrations and COX enzyme activity, were evaluated. Exposure to IB caused decrease in COX activity and was mirrored downstream in the reduced (but not significantly different) production of PGF-2α. Our lack of ability to detect effects on PGF-2α was likely, in part, a result of a high variability due to the asynchronous ovarian maturation. Furthermore, exposed fish may have been able to compensate for the decreased COX activity by increasing abundance of mRNA for COX and prostaglandin synthases (as demonstrated by our gene expression data). Several courtship behaviors were significantly decreased in IB-exposed males, but they were not altered in females. These findings suggest that IB affects prostaglandin synthesis pathway and impairs performance of male sexual behavior and thus has a potential to impair the reproductive success of exposed individuals.

TP110 Effects of Non-selective Cyclooxygenase Inhibitor, Ibuprofen, on Gene Expression, Prostaglandin Synthesis and Reproductive Behavior in Zebrafish T. Firkus, Univ of St. Thomas; D. Martinovic-Weigelt, Univ of St. Thomas, Dept of Biology, USEPA, Mid-Continent Ecology Division, Mid-Continent Ecology Division, Univ of St. Thomas, Biology; J. Marchuk, Univ of St. Thomas. Prostaglandins are a class of hormones important for the regulation of gonadal steroidogenesis and ovulation in vertebrates. In fish they are also used as pheromones; they are released by ovulating females and are important for the initiation and synchronization of male reproductive behaviors. Commonly used pharmaceuticals such as nonsteroidal anti-inflammatory pharmaceuticals (e. g, ibuprofen (IB) etc.) inhibit cyclooxygenase (COX) enzymes which catalyze prostaglandin synthesis. Sexually mature zebrafish males (n=14) and females (n=14) were exposed to 50 µg/L of IB for 14 days and their behaviors (agonistic, courtship, and swimming behaviors) were compared to well-water exposed controls (n=14 per sex). The present study also examined effects of IB exposure on prostaglandin synthesis pathway; we measured phospholipase, COX 1 and 2, and prostaglandin synthase mRNA abundance using real time polymerase chain reaction. In addition, the ovarian prostaglandin F2 alpha concentrations and COX enzyme activity, were evaluated. Exposure to IB caused decrease in COX activity and was mirrored downstream in the reduced (but not significantly different) production of PGF-2 alpha. Our lack of ability to detect effects on PGF-2 alpha was likely, in part, a result of a high variability due to the asynchronous ovarian maturation. Furthermore, exposed fish may have been able to compensate for the decreased COX activity by increasing abundance of mRNA for COX and prostaglandin synthases (as demonstrated by our gene expression data). Several behaviors (agonistic, courtship and general activity) were significantly decreased in IB-exposed males, but they were not altered in females. These findings demonstrate that IB affects prostaglandin synthesis pathway, and impairs performance of fish reproductive behaviors. In conclusion, exposure to wastewater effluents (which frequently contain IB and other cyclooxygenase inhibitors) may impair reproductive success of fish.

TP111 Embryonic Exposure to Deltamethrin Results in Dopaminergic Gene Expression Changes and Behavioral Alterations in the Zebrafish T.S. Kung, Rutgers, the State Univ of New Jersey; J.R. Richardson, Univ of Medicine and Dentistry, New Jersey; K.R. Cooper, Rutgers, the State Univ of New Jersey, Dept of Biochemistry and Microbiology; L.A. White, Rutgers, the State Univ of New Jersey. Pyrethroids are one of the most commonly used insecticides and, when used properly, are generally considered to pose little risk to human and environmental health. However, there has been increasing concern that children are more susceptible to the adverse affects of pesticides. Previous work from our laboratory characterized the acute developmental toxicity of six common pyrethroids in the zebrafish and it was determined that the toxicities associated with acute exposures are similar to what has been shown in mammalian models, thus validating the zebrafish model system. Here, we are using the zebrafish model to test the hypothesis that developmental exposure to low doses of pyrethroid pesticides alters dopaminergic neuronal development, resulting in long-term gene expression changes and behavioral alterations. To assess the effects of low dose pyrethroid exposure during development, we exposed zebrafish embryos to deltamethrin at a dose below the LOAEL (0.5 mg/L), during the embryonic period (3-72hpf) using a static non-renewal water exposure. We found that embryos exposed to deltamethrin exhibited dopaminergic gene expression changes at 72 hpf, including increased expression of the dopamine transporter (DAT) (1.6-fold) and the dopamine receptor D1 (DRD1) (2.1-fold), which persists for at least 1-month post-exposure. To determine whether developmental deltamethrin exposure altered swimming behavior, we quantified the swim behavior of 6-week old zebrafish using the Noldus Ethovision System and found that treated zebrafish exhibited statistically significant increases in swim activity (3-fold) as measured by the total distance traveled in 30 min. These fish at 6 months of age also exhibited statistically significant increases in aggressive behavior; quantified by counting the number of times they attacked their own image in a mirror. Interestingly, this increase in aggression observed only in the male fish. Fish exhibiting altered behavior and the respective control fish were grown to sexual maturity and bred to obtain F_1 generation fish. The F_1 generation fish exhibited decreased expression of DAT (1.6-fold) and DRD1 (2.6-fold) and increased swim activity, suggesting that these changes may persist into the next generation. Our data indicate that developmental exposure to deltamethrin results in persistent dopaminergic gene expression changes and behavioral deficits. Funded by NIEHS ARRA432298, ES005022, and ES015991

TP112 Environmentally Relevant Concentrations of the Flame Retardant BDE-209 in Sediment Linked to Potential Developmental Effects on Zebrafish Embryos N. Garcia-Reyero, Jackson State Univ; L. Escalon, US Army, Engineer Research & Development Center; E. Prats, CSIC; B. Thienpont, IDAEA-CSIC; P. Babin, Universités Bordeaux 1 et 2; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division; D. Raldua, IDAEA-CSIC. Decabromodiphenyl ether (BDE-209) is a fully brominated diphenyl ether compound used as a flame retardant in polystyrene applications such as casings for computers, upholstery textile and televisions. It is highly lipophilic and persistent and as such it is prone to bioaccumulation and biomagnifications in the food chain. Increasing concentrations of polybrominated diphenyl ethers in wildlife have been documented since the mid 1990s. BDE-209 is a very large molecule, and the general thought was that due to its size it was not bioavailable, and therefore could not bioaccumulate in wildlife. Several studies now have proven this concept wrong, as BDE-209 has been found in many aquatic and terrestrial organisms. Concentrations as high as 707 ng BDE-209/g lipid weight have been found in carp (*Cyprinus carpio*) and barbel (*Barbus graellsii*) and values as high as 12 ug/g dry have been found in sediments downstream of an industrial park in Spain. Furthermore, concentrations as high as 1.23 ug/g lipid have been found in several fish species in Lake Michigan (USA). BDE-209 has been linked to decreased otolith increment widths in whitefish as well as failed eggs from white stork (*Ciconia ciconia*) in Spain. Exposure of Sprague-Dawley rats to BDE-209 resulted in significantly increased liver, thyroid, and adrenal gland weights, in addition to a reduction in total serum triiodothyronine (T3) and increase of thyroid-stimulating hormone levels. Exposure to BDE-209 has also been linked to decreased learning and memory in mice, behavioral changes in mice and inhibition of neural stem cells into neurons in culture. As many of the toxic effects of BDE-209 have been found on laboratory exposures, here we analyze the potential effects of an environmentally relevant dose of BDE-209 on zebrafish (*Danio rerio*) embryo. Zebrafish embryos were exposed to sediments that contained 12,500 mg/kg BDE-209 for eight days. We analyzed gene expression changes, thyroid function, and morphometric

parameters. While we did not detect changes in thyroid function, gene expression analysis highlighted the potential effects of BDE-209 on development, neurotoxicity, and liver toxicity.

TP113 Using Zebrafish Model (*Danio rerio*) to Investigate the Effects of Pyrethroid Insectide Deltamethrin on Glutamatergic System A. Truong, Rutgers, the State Univ of New Jersey, Dept of Biochemistry and Microbiology; T.S. Kung, Rutgers, the State Univ of New Jersey; K.R. Cooper, L.A. White, Rutgers, the State Univ of New Jersey, Dept of Biochemistry and Microbiology. Deltamethrin is a chemical belonging to the pyrethroid insecticide family derived from the natural compound found in the plant species *Chrysanthemum cinerariaefolium*. These insecticides are modified from their parent compound so that they are more potent to insects and more resistant to degradation. After the banning of organophosphates in the United States, this class of insecticides became very popular in household use. In the frequent testing conducted by the NHANES, the metabolite 3-phenoxybenzoic acid of pyrethroids was found in urine samples of children. These children also showed signs of hyperactivity. This study showed that children are being exposed to the compounds. In an effort to understand the effects of pyrethroid insecticides at doses below the lowest observed adverse effect level, several laboratories have found the changes in DAT expression level and as well as other genes involved in the dopaminergic system using mice and zebrafish. Results from these studies correspond to the previously observed relationship between change in dopaminergic system and hyperactive behavior. Some studies also showed the connections between the dopaminergic system and several other systems such as the glutamatergic. In this study we hypothesized that developmental deltamethrin insecticide exposure results in changes in the glutamatergic gene expression.

TP114 Use of Macrophage Immunoassays to Assess the Toxicity of Different OSPW Samples J. Ge, E. Garcia-Garcia, A. Oladiran, Univ of Alberta, Dept of Biological Sciences; M. Gamal El Din, L.C. Perez-Estrada, J.W. Martin, Univ of Alberta, Dept of Civil and Environmental Engineering; M. Belosevic, Univ of Alberta, Dept of Biological Sciences. The Oil Sands Process Water (OSPW) produced by the mining industry in northern Alberta constitutes a major environmental challenge. Naphthenic acids (NAs) are thought to be the primary toxic component in OSPW. Different OSPW samples are known to possess particular NAs compositions. It is unclear whether different NAs contents cause different toxic effects in multicellular organisms. In this study, we used in vitro bone marrow-derived macrophage (BMDM) assays to assess the toxicity of the organic fractions of two OSPW samples (OSPW1 and OSPW2) that have different NAs content. The extracted organic fraction of OSPW1 constituted 43% NAs, while that of OSPW2 was only 29%. OSPW2 had more NAs of higher molecular weight (carbon number) and ring number (*Z* values) than OSPW1. BMDM were exposed to increasing concentrations of NAs present in the extracted organic fraction of the OSPW samples, and the expression of pro-inflammatory genes, IL-1, IL-6, IL-12 and TNF-a, was determined using quantitative real-time PCR (qPCR). Both OSPW samples reduced non-stimulated expression of IL-1 and IL-12. OSPW2 also inhibited non-stimulated expression of IL-6, and increased the expression of TNF-α. Both OSPW samples decreased the LPS+IFNγ-stimulated expression of IL-1, but in addition OSPW2 increased the LPS+IFNγ-stimulated expression of IL-12 and TNF-α. Phagocytosis of BMDM was significantly reduced in both OSPW1 and OSPW2 treated cells. Both OSPW samples reduced the respiratory burst induced by PMA stimulation. OSPW1 significantly reduced the expression of the NADPH oxidase subunit $p91^{phox}$, while OSPW2 reduced the expression of the $p47^{phox}$ and $p67^{phox}$ subunits. Both OSPW samples reduced the production of nitric oxide, in activated BMDM, and the decreased nitric oxide production was related with reduced expression of the iNOS gene. Our results indicate that different NAs compositions in OSPW can have different effects on BMDM antimicrobial responses.

TP115 Mast Cell Function is Agonized by Exposure to Environmental Estrogen 4-Tert-Octylphenol R.K. Palmer, Univ of Maine, Molecular and Biomedical Sciences, The Univ of Maine, Molecular and Biomedical Sciences; J.H. Pelletier, Univ of Maine, Molecular and Biomedical Sciences; J.A. Gosse, Univ of Maine, Molecular and Biomedical Sciences, Univ of Maine, Graduate School of Biomedical Sciences. In addition to common industrial and pesticide applications, surfactants (wetting agents) are widely used in personal care products (e.g., soap and shampoo), and are also employed after oil spills as dispersants. Alkylphenol polyethoxylates (APEOs) are a major class of non-ionic surfactants that are known to pollute rivers, surface water, and tap water after their intended application. Stable metabolites of APEOs, such as nonylphenol (NP) and 4-*tert*-octylphenol (OP), have demonstrated estrogenic endocrine disrupting ability both in vitro and in vivo, which extends great concern, as they are found at detectable levels in biological samples of aquatic and terrestrial species. Adverse health impacts are known to arise from exposures to environmental endocrine disrupting chemicals, but not much is known about the ways in which they interfere with normal immune function and host defense mechanisms. Although a number of immunotoxicological effects due to sex steroids have been described (Watson & Gametchu, 2001, *Int. Immunopharm.*), very few have been explored mechanistically. Mast cells are immune effector cells that participate in both inflammatory and allergic signaling pathways, and are also the key players in the defense against parasitic attack. Recently, it was demonstrated in human and murine mast cells that estrogen receptor agonists amplify the degranulation function of these cells, resulting in elevated release of preformed allergic mediators from cytosolic granules (Narita, et al, 2007 *Environ. Health Persp.*; Zaitsu, et al., 2007 *Molec. Immunol.*). Using a fluorescent microplate assay to quantify the release of β-hexosaminidase from estrogen-starved mast cells (RBL-2H3), we demonstrate that OP amplifies IgE-dependent mast cell degranulation in a dose-dependent fashion following 1-h exposure: by 10% ± 2% at 5 μM, 22% ± 2% at 10 μM, and 34% ± 7% at 20 μM (mean ± SEM). Interestingly, we found these effects to require a co-stimulatory agent (i.e., multivalent antigen), as exposure to OP, alone, did not alter the degranulation endpoint. Importantly, doses used in the degranulation assay were found non-cytotoxic in lactate dehydrogenase and clonogenic cytotoxicity assays. We anticipate that these immunological effects are dependent on Estrogen Receptor (ER)-α, and in future studies will use an anti-estrogen to pharmacologically inhibit this receptor on the surface of mast cells.

TP116 An Investigation of the Effects of Bisphenol-A on the Development and Differentiation of Embryonic C57BL/6 Mice Thymocytes L. Leung Liu, The Univ of La Verne, Univ of La Verne; C. Broussard, The Univ of La Verne. The immune system is composed of structures and processes that help defend and protect organisms from pathogens and cancer. However, exposure to endocrine disrupting chemicals (EDCs) can disrupt the normal function of the immune system due to the capability of EDCs to mimic or block natural hormones. These effects can alter proper immune function and can lead to an increase in susceptibility to infectious diseases and an increase in autoimmune diseases. Great concern has arisen regarding an endocrine disruptor called bisphenol-A (BPA) that is used as an additive for the production of polycarbonate plastic and epoxy resin. Numerous studies have been performed to look at the effects of BPA in the reproductive system and in the nervous system; however, few studies have looked at the effects on the developing embryo, in particular on embryonic T cell development. The aim of this study was to investigate the effects of BPA at the gestational development stage on the different subpopulations of embryonic T cells. An in vitro assay was used to examine the development of T cells at different concentrations of BPA (0, 6.25, 12.5, 25, 50, and 100 μM). T cells were extracted from C57BL/6 mice embryos at 16 to 18 days of gestation. Our results indicate a dose dependent decrease in viability of the total number of T cells, as well as in the different T cell subpopulations. It was also found that the decrease in T cell viability was significant at 100 μM. These findings suggest that BPA affects normal development and survival rate of embryonic T cells, which can have detrimental effects on the organism's immune system. This research is supported by the Univ of La Verne Faculty Research Committee. The opinions expressed in this work are solely the authors'.

TP117 Estrogen Receptor Usage by Endocrine Disrupting Chemical DES and HPTE in Embryonic Thymocyte Differentiation A. Lim, Univ of La Verne; C. Broussard, The Univ of La Verne, Univ of La Verne, Biology, Univ of La Verne, Professor of Biology. Endocrine disrupting chemicals (EDCs) are synthetic organic compounds such as additives in plastic and pesticides that are commonly found in the environment. Research shows that EDCs are estrogen mimicking chemicals that can bind to estrogen receptors on a cell, disrupting normal hormonal actions. In addition, they can mimic or block endogenous hormones by behaving as biological signals and, thus, can be easilymisinterpreted by an organism's cell receptors. Evidence has shown that EDCs negatively affect the reproductive fitness of adults and the developing endocrine system of embryos. EDCs can also increase the risk of cancer in adults and increase the frequency of allergic diseases and

asthma in children. EDCs are especially detrimental to developing embryos because early lifetime exposures, such as during fetal or early postnatal periods, produce permanent effects. Two known EDCs that have been extensively studied in the past are diethylstilbestrol (DES) and 2,2-bis(p-hydroxyphenyl)- 1,1,1-trichloroethane (HPTE). Research shows that both DES and HPTE suppress the development of fetal immune systems with their estrogenic properties. However, little is known about the pathways that these two chemicals utilize to mediate their effects on the immune system of the body. There is no conclusive research on which estrogen receptors they bind to on the surface of T-cells in order to exert their effects on the cells. The focus of this study will be to determine which receptors DES and HPTE bind to on the surface of T-cells – whether they are the classical estrogen receptors, ER alpha and ER beta, or the nonclassical estrogen receptor, GPR 30. By gaining a better understanding of how EDCs interact with T-cells, we will be able to better understand the effects of EDCs on the immune system.

TP118 Per- and Poly-fluorinated Compound Occurrence, Profiles, and Time Trends in Landfill Leachate J.P. Benskin, AXYS Analytical Services Ltd; B. Li, Univ of British Columbia, Civil Engineering; M. Ikonomou, Fisheries and Oceans Canada, Contaminants Science Section; J. Grace, Univ of British Columbia, Chemical and Biological Engineering; L. Li, Univ of British Columbia, Civil Engineering. Per- and poly-fluorinated compounds (PFCs) have been used ubiquitously in consumer and commercial products for over 60 years. Many of these products are eventually disposed of in landfills, where PFCs may leach from them over time. In this study, we investigate the occurrence, profiles, and trends of PFC and PFC-precursors in landfill leachate, collected from February to June 2010 from a municipal landfill. Perfluorohexanoate (PFHxA) and perfluorooctane sulfonate (PFOS) were typically the dominant PFCs (present at up to several ppb); however, significant changes in the relative congener profile were observed over the 5-month sampling campaign. Most notably, PFOS concentrations increased by an order of magnitude from mid-March to mid-April, and then returned to original levels. This increase was strongly correlated to an increase in PFOS-precursor concentrations (e.g., perfluorooctane sulfonamide and N-alkyl substituted perfluorooctane suflonamido acids) over the same time period. A similar correlation was observed between several perfluorocarboxylates (PFCAs), and PFCA-precursors (e.g., 8:2 and 10:2 fluorotelomer acids), while for other congeners (e.g., perfluorohexane sulfonate and PFHxA), no increase was observed. Experiments were performed to investigate potential causes for the increase in PFC and PFC-precursor concentrations. One possibility is increased (bio-) degradation of higher precursors incorporated into various commercial and consumer products. These include phased-out materials such as the sulfonamide-linked phosphate diesters and fluoroacrylate polymers, or analogous telomer-linked polymers and surfactants manufactured today. Examination of PFOA isomer profiles suggests that contributions from both historical and contemporary production are significant. Overall, these data indicate that PFC-containing products disposed of in landfills may be a long-term source of PFCs. Management of landfill leachate through containment, collection, and treatment is important to prevent potential impacts to the environment.

TP119 Ultra-fast Separation of PFOS and PFOA Isomers J.P. Benskin, AXYS Analytical Services Ltd; M. Ikonomou, Fisheries and Oceans Canada, Contaminant Sciences Division; M.B. Woudneh, AXYS Analytical Services Ltd, R&D Chemist; F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment), Simon Fraser Univ; J.R. Cosgrove, AXYS Analytical Services Ltd. Historical manufacturing of perfluorooctane sulfonate (PFOS) and perfluorooctanoate (PFOA) by Simmons electrochemical fluorination results in an impure product of 70-80% linear and 20-30% branched isomers. Recent data demonstrated that branched perfluorinated acid (PFA) isomers can display significantly different physical, chemical, and biological properties, compared to their linear counterparts. Branched isomers can also respond differently to electrospray ionization and act as a potential source of error in total PFA quantification if they are not considered separately. Despite this, the most common HPLC-MS/MS methods for quantifying PFOS and PFOA involve eluting all isomers together and integrating them as a single peak. In part, this is because few methods currently exist for separation of branched from linear PFAs, and those that are in use employ long instrument runs (i.e., >30 min) or suffer from poor column stability. Here, we present an ultra fast (< 15 min) HPLC-MS/MS method for separation of PFOS and PFOA isomers using a fused-core perfluorophenyl stationary phase. Fused core HPLC-columns facilitate the use of high flow rates without a concomitant increase in back pressure. For PFOA, a total of 4 isomer peaks could be resolved to baseline in the m/z 413/369 product ion, while for PFOS, linear, total monoperfluoromethyl, and total diperfluoromethyl isomers were resolved to baseline in the m/z 499/80 product ion. Using characterized technical standards, branched and linear PFOS and PFOA isomers were quantified separately. This method provides potentially improvements in analytical accuracy and data quality over traditional methods, without the corresponding increase in costs or analysis time associated with previous isomer separation methods.

TP120 Gas/Particle Partitioning of Perfluoroalkyl and Polyfluoroalkyl Substances in the Atmosphere Using High Volume and Diffusion Denuder Samplers L. Ahrens, Environment Canada, Science And Technology Branch; M. Shoeib, Environment Canada, Atmospheric Science and Technology Directorate; D.A. Lane, Environment Canada; T. Harner, Environment Canada, Atmospheric Science and Technology Directorate; R. Guo, Univ of Toronto; R.J. Reiner, Ontario Ministry of the Environment. Perfluoroalkyl and polyfluoroalkyl substances (PFASs) are globally distributed in the environment by atmospheric and oceanic transport. Gas/particle partitioning is a key determinant of environmental fate and long-range transport (LRT) potential of PFAS. Previous studies using conventional high volume air samplers (hi-vol) utilizing glass-fiber filters (GFFs) for capturing the particle phase have shown that the majority of perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkane sulfonic acids (PFSAs) are present in the particulate phase. However, sampling artifacts were reported for perfluorooctanoic acid (PFOA) showing that vapour phase PFOA can "blow-on" the GFF and can adsorb to particulate matter already collected on the GFF, resulting in an overestimation of the particle phase concentration. In this study, PFAS were determined in the gas and particulate phase using co-located hi-vol and diffusion denuder samplers at an urban site in Toronto, Canada, from November to December 2010. Diffusion denuders overcome the 'blow-on' artefact because the gas-phase is collected first (using highly sorptive ground XAD-4 coated onto the annular denuder surface) followed by the particle-phase. Samples were analyzed for 7 PFAS classes (i.e., fluorotelomer alcohols (FTOHs), fluorotelomer acrylates (FTACs), fluorotelomer methacrylates (FTMACs), perfluorooctane sulfonamides (FOSAs), perfluorooctane sulfonamidoethanols (FOSEs), PFCAs and PFSAs). Total air concentrations for PFAS measured using hi-vol and diffusion denuder samplers were within a factor of two, however, much greater differences were observed for gas/particle partitioning. Hi-vol measurements resulted in much higher particle-associated fractions for perfluorooctane sulfonic acid (PFOS) and PFCAs compared to the diffusion denuder sampler. For example, PFOA had a particle-associated fraction of ~70% using hi-vol samplers whereas only ~3% was associated with particles using the annular diffusion denuder samplers. These results highlight problems associated with using conventional hi-vol samplers for assessing gas/particle partitioning of some PFASs due to sorption of gas-phase chemical onto the GFF. Overall, the results of this study improve our understanding of the gas/particle partitioning of PFASs in the atmosphere which is important for global transport models used to asses the LRT potential of PFASs.

TP121 Effect of Perfluorinated Compounds (PFCs) on Maternal Thyroid Hormones During Early Pregnancy: Results from the CHirP Study (Vancouver, Canada) G.M. Webster, Univ of British Columbia, School of Population and Public Health, School of Environmental Health, Univ of British Columbia; S.A. Venners, Simon Fraser Univ, Faculty of Health Sciences; A. Mattman, St Paul's Hospital, Pathology and Laboratory Medicine; J.W. Martin, Univ of Alberta, Dept of Laboratory Medicine and Pathology. Perfluorinated compounds (PFCs) are used as stain, grease and water repellents in many consumer applications and are detectable in most human serum samples. Although PFCs are known thyroid toxicants in animal studies, very little is known about their potential to disrupt thyroid hormone levels in humans. Thyroid disruption during early pregnancy is of particular concern, as maternal thyroid hormones in early gestation play a critical role in fetal brain development. This study examined the associations between perfluorohexanesulfonate (PFHxS), perfluorononanoate (PFNA), perfluorooctanoate (PFOA), perfluorooctanesulfonate (PFOS), sum perfluorosulfonates (SumPFSAs), sum perfluorocarboxylates (SumPFCAs), and sum perfluorinated compounds (SumPFCs) and free thyroxine (fT4), total thyroxine (TT4) and thyroid stimulating hormone (TSH) in

152 euthyroid pregnant women enrolled in the Vancouver (Canada) – based Chemicals, Health and Pregnancy study (CHirP). Mixed models were used to examine associations between PFCs (measured in maternal serum at 15 weeks gestation) and thyroid hormones (measured in maternal serum at 15 and 18 weeks gestation), while controlling for relevant covariates. To test the hypothesis that PFC effects on thyroid hormone concentrations might differ in women with and without markers of autoimmune hypothyroidism, we also considered models with an interaction between PFC levels and elevated versus normal levels of thyroid peroxidase antibodies (TPOAb). In women with elevated TPOAb levels (10% of the study population), significant negative associations were detected between maternal fT4 and PFHxS, PFOS and SumPFSAs. In the same women, positive relationships were detected between all measures of PFCs, except PFHxS, and maternal TSH. Regardless of TPOAb status, weaker positive trends were also found for PFNA, SumPFCAs and TSH across the whole population. We hypothesize that women with elevated TPOAb, which is a marker of autoimmune destruction of the thyroid gland, may have reduced capacity to compensate for PFC-induced reduction of T4 compared to women with normally functioning thyroid glands (normal TPOAb). If true, PFCs may exacerbate the already lower maternal fT4 and higher TSH levels due to autoimmune hypothyroidism in up to 10% of pregnancies, or 45,000 pregnancies per year in Canada, with unknown effects on fetal development. These results await replication in larger, population-based studies.

TP122 Sorption of Perfluorochemicals to Matrices Relevant to Sites Impacted by Aqueous Film-forming Foam J. Sepulvado, Colorado School of Mines, Hydrology; C. Higgins, Colorado School of Mines, Environmental Science and Engineering. The presence of perfluochemicals (PFCs) in groundwater as a result of the application of aqueous film-forming foams (AFFF) at fire training facilities has been documented. Concentrations of PFCs have been measured at these sites in the µg/L to mg/L range. Due to factors such as the recent push towards regulation of some PFCs in drinking water, recent concerns have arisen about the fate of PFCs in the subsurface. At fire training facilities, repeated applications of AFFF are used to extinguish fires ignited with hydrocarbon fuels. In some cases this has resulted in groundwater plumes containing PFC subclasses such as perfluorocarboxylic acids (PFCAs), perfluoroalkylsulfonates (PFAS), and fluorotelomer sulfonates (FtSs). These plumes also may contain co-contaminants such as hydrocarbon fuel components and chlorinated solvents, some of which may exist as nonaqueous phase liquids (NAPL). This study examined the sorption of PFCs to soil and aquifer material across the concentration range applicable to AFFF-impacted sites (µg/L – mg/L) and looked at the impact of co-contaminants, including NAPL, on PFC sorption. PFC sorption was variable and indicated that, similar to previous work on PFC sorption to sediment, subsurface PFC transport will depend on factors such as the sorbent, PFC subclass, solution chemistry, and PFC chain length.

TP123 Gene Expression Profiles in Male Largemouth Bass Induced by Chronic Exposure to an Environmentally Relevant Level of 17α-ethinylestradiol C.A. Richter, USGS – Biological Resources Division, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center; D.M. Papoulias, US Geological Survey, Columbia Environmental Research Center; K.J. Kroll, Univ of Florida, Physiological Sciences; A. Mehinto, Univ of Florida, Dept of Physiological Sciences; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology; D.E. Tillitt, US Geological Survey, Columbia Environmental Research Center. Estrogenic endocrine disruptors are of increasing concern in aquatic systems. The occurrence of ovo-testis in male fish has been reported from diverse regions of the United States, and has been hypothesized to be related to estrogenic contaminants. To better understand the effects of long-term exposure to estrogens in fish, we studied gene expression profiles and physiological changes induced by chronic exposure to an environmentally relevant concentration (5 ng/L) of 17α-ethinylestradiol (EE2) in virgin adult largemouth bass in outdoor mesocosms. Vitellogenin production was increased and GSI was reduced in exposed males. However, reproductive success did not differ between exposed and unexposed treatment groups and no testes contained oocytes. Gene expression profiles in males were measured using a 15K largemouth bass microarray. The number of genes with altered expression in testes increased greatly between 3 and 15 months of exposure. Five potential biomarkers with strongly up-regulated expression in testis after both 3 months and 15 months exposure were identified. Gene expression in testes and pituitary was highly responsive to EE2 after 15 months of exposure. Fewer changes in gene expression were observed in hypothalamus. In testis, after 3 months of exposure many genes related to regulation of the cell cycle were down-regulated. After 15 months of exposure, many genes related to aerobic production of ATP were down-regulated in testis and many genes related to protein synthesis were down-regulated in pituitary. The gene expression profiles observed in EE2-exposed males are consistent with delay of spawning readiness of the hypothalamus-pituitary-gonad axis in these fish.

TP124 Stressor Induced Changes in *Lumbriculus variegatus* Transcripts and Metabolites S.O. Agbo, Univ of Eastern Finland, Dept of Biology, Univ of Eastern Finland, Dept of Biology, Lab of Aquat Ecology & Ecotoxicology; J. Lemmetyinen, J. Akkanen, M.T. Leppanen, S. KeskiSaari, M. Keinanen, Univ of Eastern Finland, Dept of Biology; Z. Wang, H. Wang, Chinese Academy of Sciences, State Key Laboratory of Environmental Chemistry and Ecotoxicology; D.A. Price, Univ of Florida, The Whitney Laboratory for Marine Bioscience; J.V. Kukkonen, Univ of Eastern Finland, Dept of Biology. Exposures to contaminants can cause adverse effects that can be studied in organisms using classical life-history traits. The commonly used toxicity endpoints typically survival, mobility and reproductive success are some of the manifestations of the underlying molecular changes in organisms. Even though classical organism-level endpoints are realistic estimations of effects, they may not detect subtle changes and hence, are not suitable for use as early warning signs. Considering the widespread use of *L. variegatus* in ecotoxicology, extensive application of the OMICS technology is hampered by inadequate genome information. A combination of different methods may improve the understanding of contaminant mediated effects in relation to the underlying toxicity mechanisms. In this study, we report transcriptional changes in *L. variegatus* after waterborne exposures to B(a)P, cadmium, chlorpyrifos and pentachlorophenol (PCP). DNA damage was assessed by quantifying B(a)P Diol-Epoxide (BPDE)-DNA adducts using capillary electrophoresis laser induced fluorescence immunoassay, after exposures to B(a)P. In general, genes with involvement in oxygen transport, mitochondrial function, reactive oxygen species and oxidative stress regulations, and heavy metal markers were mostly induced. Microarray data revealed that the relative change in transcript levels increased up to 16.6 folds for the selected genes within 6 h of PCP exposures, but decreased rapidly in a time dependent manner. The highest induction ratio was noted at 2 h B(a)P exposure but barely changed at 6 and 24 h prior to a rapid decline thereafter. Transcripts encoding alpha b, histone 3, thioredoxin peroxidase, glutathione s-transferase and metallothionein were the most consistent in expression, and may suggest that excess reactive oxygen species were generated due to B(a)P exposures. Majority of the significantly up-regulated transcripts were noted in treatments with B(a)P, whereas tests with chlorpyrifos showed the least differential expression. However, most of the changes in expression occurred early rather than later in exposure. The amounts of BPDE-DNA adducts suggest that DNA damage peaked within 6 h, and this corresponds with the observed transcriptional changes. Regardless of a few discrepancies in transcript abundance between microarray data and the corresponding quantitative PCR validation, expression patterns were comparable and consistent with the DNA adducts profile.

TP125 Heart-specific Microarray Identification of AHR2-dependent and AHR2-independent Genes Involved in the Synergistic Developmental Toxicity of PAHs L. VanTiem, J. Meyer, J. Meyer, Duke Univ, Nicholas School of the Environment ; M. Kirby, Duke Univ, Dept of Pediatrics; K. Erwin, Duke Univ; H. Tsai, National Taiwan Univ; R. DiGiulio, Duke Univ, Nicholas School of the Environment. Numerous polycyclic aromatic hydrocarbons (PAHs) are teratogenic to fish. We have previously shown that binary co-exposures to a PAH that is an aryl hydrocarbon receptor (AHR) agonist and another that is a cytochrome P450 1 (CYP1) inhibitor result in synergistic developmental toxicity in fish embryos. The heart is a target organ for this toxicity, as pericardial effusion, impaired looping, elongated atrium and decreased cardiac output occur after these exposures. AHR2-morpholino (mo) knockdown prevents these deformities, providing evidence that AHR2 at least in part mediates PAH toxicity. However, the AHR2-dependent and AHR2-independent genes that control this synergistic toxicity remain largely unknown. In this study, microarrays were used to screen for the specific genes and pathways involved in the developmental toxicity caused by PAHs as well as genes dependent and independent of the AHR. We used zebrafish (*Danio rerio*) *cmlc2::GFP* embryos that express GFP in the heart, allowing for easy heart extraction. Embryos were injected with either

an AHR2-mo or Control-mo (Co-mo). At 36 hours post fertilization (hpf), mo-injected embryos were dosed with DMSO, 100 µg/L benzo[*a*]pyrene (BaP, an AHR agonist), 500 µg/L fluoranthene (FL, a CYP1 inhibitor) or BaP + FL. At four time points (2, 6, 12 and 18 hours after dosing), hearts were extracted, and RNA extracted from pools of five hearts per treatment group was used for microarray analysis. Time points were chosen to capture early and secondary cell signaling events before onset of hatching and gross deformities. At 18 hpd, 189 genes were differentially expressed between Co-Mo BaP + FL and AHR2-mo BaP + FL treatment. Out of these genes, 183 were upregulated in the Co-Mo BaP + FL compared to the AHR2-mo BaP + FL treatment, and many of these genes are involved in cell adhesion, oxidation-reduction processes, calcium ion binding, zinc ion binding and positive regulation of apoptosis. Certain upregulated genes are also involved in various heart functions including cardioblast differentiation, angiogenesis and heart tube development. Data for the other time points are currently being analyzed. At 18 hpd, gene expression changes in response to BaP + FL appear to be mediated by AHR2. NIEHS-supported Duke Univ Superfund Research Program (P42ES10356) and ITEHP (T32ES07031).

TP126 Biomarkers Screening and Proteomic Evaluation of Pesticides Toxicity on *Daphnia magna* T. Le, Chonbuk National Univ, Dept of Bioprocessing Engineering; S. Lee, Korea Research Institute of Chemical Technology, Toxicology Research Center; Y. Kim, Chungbuk National Univ, School of Life Science; J. Min, Chonbuk National Univ, Dept of Bio-process Engineering. Proteomic analysis was performed to identify proteins involved in the stress responses of a water flea, *Daphnia magna*, to glyphosate and methidathion pesticides. Two lethal concentrations of pesticides including LC50 and LC75, which were determined by a 24h acute toxicity assay, were used for a 24h exposure to 21d daphnids prior to isolate the total protein. The proteomic profile of the testing organisms was analysed by the two-dimensional electrophoresis method with a 3-10 pH range. Three replicates were carried out for each testing concentrations and the average of the spot intensity was analysed in Progenesis program to explore the differentially expressed proteins (DEPs). The DEPs was considered as down- or up-regulations only if expression level of the protein linearly and significantly decreased C>LC50>LC75 or increased C.

TP127 The Effects of the Ureic Based Herbicide Linuron on Reproductive Endpoints in the Fathead Minnow (*Pimephales promelas*) A. Ornostay, Univ of New Brunswick Saint John, Dept of Biology and Canadian Rivers Institute; V.L. Marlatt, B.P. Lo, J. Elphick, C.J. Kennedy, Simon Fraser Univ, Dept of Biological Sciences; C.J. Martyniuk, Univ of New Brunswick Saint John, Dept of Biology and Canadian Rivers Institute. Linuron, a ureic-based herbicide, is widely used in crop production throughout North America and has been detected in aquatic environments at concentrations in the ng/L to µg/L range. Recent studies suggest that linuron has an anti-androgenic mode of action (MOA) in fish and mammals. However, additional research is required to better characterize the MOA and impact on the teleost reproductive axis. To examine the MOA of linuron, male and female fathead minnows were exposed to 100 ng/L 17-β estradiol (E2), 100 mg/L dihydrotestosterone (DHT), and 1, 10, and 100 mg/L linuron, and co-treatments of linuron and DHT (100 mg/L each) according to the Fish Screening Assay (Test No. 230, Organization for Economic Co-operation and Development). There were no effects of any treatment on gonadosomatic index, egg hatching or 7 day egg survival. Female fathead minnows showed a significant increase in nuptial tubercles with DHT and co-treatments of DHT and linuron. There were no changes in nuptial tubercles in males in any treatment. In female fathead minnows, DHT and linuron alone significantly reduced vitellogenin (Vtg) production while in males, E2 and co-treatments of DHT and linuron significantly increased Vtg production. Expression patterns were examined for a number of key genes involved in steroid production in the female ovary, including P450 side chain cleavage, aromatase, 3-beta-hydroxysteroid dehydrogenase (3β-HSD), and 11-beta-hydroxysteroid dehydrogenase (11β-HSD). There were no significant effects of linuron or model compounds on steroidogenic gene expression except for P450 side chain cleavage, which was decreased with co-treatment of DHT and linuron. Clustering of the expression patterns of the steroidogenic genes suggested that gene expression patterns were most similar between linuron and E2 compared to the model androgen DHT. This study suggests that linuron may have multiple MOAs that mimic either anti-estrogenic or estrogenic effects in a sex-specific manner in the fathead minnow teleost model.

TP128 Using Genomics to Understand the Effects of Flame-retardant Chemicals on *Daphnia magna* L.D. Scanlan, Univ of California, Berkeley, Molecular Toxicology, U.C. Berkeley, Molecular Toxicology, U.C. Berkeley, graduate student; E. Lachenauer, K. Dailey, X. Lin, C. Vulpe, U.C. Berkeley. Flame-retardant chemicals used in furniture, building materials and plastics are prevalent in and pose a threat to the environment. We are looking at the toxicity of banned "legacy" and new "replacement" flame-retardants on eco-indicator organism *Daphnia magna*. *D. magna* is an important fresh-water crustacean that is considered a keystone species in fresh-water ecology. We are using both traditional toxicity LC50 determination and genomic microarray and high-throughput sequencing technologies to determine the mode of toxicity of flame-retardants to *Daphnia magna*.

TP129 Early Life Stage Salmonid Bio-monitoring in Polluted Environments Using Molecular and Physiological Bioassays C.J. Martyniuk, Univ of New Brunswick, Dept of Biology/Canadian Rivers Institute, Univ of New Brunswick, Biology; R. Sherrard, Univ of New Brunswick; J. Elphick, V.L. Marlatt, Nautilus Environmental. Molecular bioindicators were developed to enhance an existing in situ early life stage (embryos to swim-up fry) cutthroat trout bioassay for use in diagnostic assessment of chemical stressors in the aquatic environment. This field study was conducted using cutthroat trout embryos to evaluate water quality associated with three sites on an urban stream in British Columbia, two sites of which were subjected to various anthropogenic inputs and a third considered a reference site. Endpoints included survival, deformities, size, vitellogenin, metallothionein (Mt) protein, and gene expression assays for well characterized transcripts that are responsive to metals (Mt A/B), endocrine disruptors (vitellogenin, estrogen receptors) and stress (cyp1A3, glutathione transferases). Vitellogenin (Vtg) levels in the head/tail protein extracts from the 3 field sites were not detectable, however low levels of *vtg* mRNA were detectable in the liver of fry. There was no detectable induction of *vtg* mRNA in the sites. Similarly, there were no significant differences in metallothionein protein levels in the gill between sites. These endpoints suggest that there were no significant estrogen/metal inputs into the streams. However, at the gene level, *cyp1A3*, *gstk* and zinc transporters were significantly increased in steady state abundance in these sites suggesting some stress and response to metals such as zinc. Furthermore, the impacts on estrogen and androgen receptor isoforms showed differential responses, indicating complex regulation of steroid isoforms in the environment. Cluster analysis of all genes examined in this study revealed the gene expression profiles in streams receiving municipal effluent were more similar to each other than to the reference site. We have optimized and demonstrated the utility of combined measures of reproductive success using both biochemical and molecular endpoints to assess the potential of a holistic approach in bio-monitoring using an early life stage salmonid test.

TP130 Reproductive Effects of Sewage Effluents on Rainbow Darter (*Etheostoma caeruleum*) in Grand River, Ontario, Canada P. Bahamonde, Univ of New Brunswick, Dept of Biology, Univ of New Brunswick, Biology Dept; G.R. Tetreault, Univ of Waterloo, Biology; M.R. Servos, Univ of Waterloo, Dept of Biology and Canadian Water Network, Univ of Waterloo, Dept of Biology; C.J. Martyniuk, Univ of New Brunswick, Dept of Biology/Canadian Rivers Institute, Univ of New Brunswick, Biology; M.E. McMaster, Environment Canada, National Water Research Institute; K. Munkittrick, Univ of New Brunswick, Canadian Rivers Institute, Univ of New Brunswick, Dept of Biology. Sewage effluents are a complex mixture between residential, institutional and industrial effluents. Chemicals with adverse effects found in sewage effluents can be Endocrine Disrupting Compounds (EDCs). Grand River (Ontario, Canada) is a model river to study the effects of sewage effluents on fish populations. Rainbow darter (*Etheostoma caeruleum*) is a small benthic fish found in North America, is very abundant and spatially distributed throughout the Grand River system. Furthermore, it is sensitive to sewage effluents, showing the presence of intersex condition in males. The primary objective of this research was to identify pathways involved in the formation of intersex condition and to explore the impact of sewage effluent on higher level biological endpoints. In October 2010 we collected female and male rainbow darter at 3 sites in Grand River. There were no changes in condition factor, no significant increase in hepatosomatic index (LSI), and significant decrease in gonadosomatic index (GSI), in fish in polluted environments compared with the reference site. Histology revealed that males had high incidence of intersex in polluted sites as characterized by the presence of follicles within the testis. To better

understand mechanisms underlying intersex in the rainbow darter, known genes involved in sexual differentiation and reproduction were cloned and are currently being evaluated with real-time PCR in males and females, such as vitellogenin, Sox9, foxl-2, and androgen receptors. In addition, a rainbow darter microarray has been developed using 454 pyrosequencing to further identify molecular pathways that are involved in intersex. Because the use of non-conventional species is getting more common and necessary for environmental monitoring, new tools are required to better understand the impact of anthropogenic impacts on river systems.

TP131 Using Ingenuity Pathway Analysis® to Identify Early Developmental Networks Associated with ETBE and TAME Toxicity in Zebrafish (*Danio rerio*) J.A. Bonventre, Rutger, The State Univ of New Jersey, Joint Graduate Program in Toxicology; L.A. White, K.R. Cooper, Rutgers, the State Univ of New Jersey, Dept of Biochemistry and Microbiology. Gasoline additives ethyl tert butyl ether (ETBE) and tertiary amyl methyl ether (TAME) are used world wide to increase octane rating and burning efficiency of fuel. The consequence of developmental exposure to these hydrophilic chemicals is unknown for aquatic vertebrates. The effect of ETBE and TAME on zebrafish embryos was determined following OCED 212 guidelines. LC50s for ETBE and TAME were 14mM (95%CI=10 to 20) and 10mM (CI=8 to 12.5), respectively. A dose dependent increase in developmental lesions, including pericardial edema, abnormal vascular development, whole body edema, and craniofacial deformities, was observed with exposure to 0.625 to 10mM of either chemical. Similar lesions are associated with the dysregulation of matrix metalloproteinase (MMP) and Wnt protein families. We hypothesized that ETBE and TAME altered MMP and Wnt expression in the embryo. Exposure to 5mM ETBE or TAME decreased mRNA transcript levels of representative genes: *mmp2*, *mmp9*, and *wnt3a*, as well as structural component β-*actin*. ETBE reduced *mmp9* and *wnt3a* expression by 30 and 50%, but did not affect *mmp2*, while TAME decreased mRNA of both *mmp*s by 70% and *wnt3a* by 60%. Both chemicals reduced β-*actin* by 50 and 70%, respectively. To better understand the impact of a reduction of these genes on development, a time course analysis of normal global gene expression patterns was conducted using the Zebrafish Affymetix GeneChip®. Unexposed embryos were collected at 6-somites (15h), 21-somites (24h), and Prim-5 (30h), and processed for the microarray. Gene Spring® was used to determine genes that were differentially expressed from 15 to 24, and from 24 to 30h of development. Of the 1065 genes that were significantly altered, genes that had a greater than 2 fold change were entered into Ingenuity Pathway Analysis® software to determine the functional networks activated at each stage. From 15 to 24h MMPs and Wnts are involved in Cellular Assembly/Organization and Connective Tissue and Skeletal/Muscular system development networks. From 24 to 30h, these proteins are involved in Cellular Function/Maintenance and Molecular Transport networks. Using single gene endpoints for developmental toxicity studies provides a limited view of a chemical's toxicity. Understanding the networks that are involved in early development will help identify possible target pathways vulnerable to chemical insult, and may be used to direct future mechanistic studies.

TP132 Connecting Molecular to Population-level Responses: Coupling Gene Expression to Dynamic Energy Budget Modeling K.A. Gust, US Army, Engineer Research and Development Center, Environmental Laboratory, US Army, Engineer Research and Development Center, Us Army Engineer Research & Development Center, ERDC-EL-EP-P; R. Nisbet, Univ of California, Santa Barbara; E. Muller, Univeristy of California, Santa Barbara; B. Ananthasubramaniam, Univ of California, Santa Barbara; M.S. Wilbanks, ERDC-EL-EP-P; A.J. Kennedy, US Army Engineer Research and Development Center; J.D. Laird, Us Army Engineer Research & Development Center, SpecPro Incorporated, US Army Engineer Research & Development Center, Environmental Laboratory; B. Meeks, US Army Engineer Research and Development Center; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division. A significant challenge exists in bridging the rich data content resulting from contemporary genomics investigations to the prediction of population-level responses. As a means to tackle this challenge, we are coupling a dynamic energy budget (DEB) model (which has proven utility in predicting population dynamics) with gene expression data (specifically emphasizing responses in metabolic pathways related to energy metabolism and reproductive physiology). Our goal is to determine if bio-molecular responses to stimuli can be used to predict population dynamics. Our dataset was generated utilizing *Daphnia magna* reproduction bioassays where sublethal lead (Pb) concentrations and food rations were varied to affect juvenile production. First, conventional methods for DEB modeling are being conducted in which the input parameter (ie. food) is modeled to predict allocation of assimilated material, energy to maintenance, growth and egg production. Genomic investigations are being conducted to determine the impact of Pb exposure and food ration at periods of time where the majority of surplus energy was expected to be dedicated to growth versus egg production and vice versa to determine the critical metabolic functions affected by these stimuli. Once the impacts on metabolic functions have been validated, net impacts of Pb exposure and food ration on metabolic output will be estimated and integrated into predictions of maintenance, growth and egg production in *Daphnia*. The predictive ability of the conventional approach to DEB modeling and the genomics-enabled DEB model will be compared to determine if inclusion of molecular responses improve model predictions. To the best of our knowledge, this is the first attempt at coupling gene expression data to predictions of population dynamics using a DEB approach.

TP133 Global Metabolic Response in the Bile of Horned Frog (*Ceratophrys cranwelli*) Tadpoles Exposed to Endosulfan D.J. Marino, V. Sy, G.S. Natale, A.E. Ronco, Centro de Investigaciones del Medio Ambiente – UNLP, CONICET, Facultad de Ciencias Exactas, Universidad Nacional de la Plata; P. Carriquiriborde, Conicet, Centro de Investigaciones del Medio Ambiente, Facultad de Ciencias Exactas, Universidad Nacionala de la Plata, Quimica, Centro de Investigaciones del Medio Ambiente – UNLP, CONICET, Facultad de Ciencias Exactas, UNLP. The global metabolic response in the bile of horned frog (*Ceratophrys cranwelli*) tadpoles exposed to endosulfan was assessed using UPLC-MS/MS. Tadpoles were exposed to 0, 5 and 10 µg/L of endosulfan (a.i.) during 96 h. Treatments were performed by triplicate exposing seven organisms per replica. The gallbladders from five tadpoles per replica were pooled in a microtube with 1 ml of nanopure water, centrifuged and filtered through 0.22 µm. Samples were analyzed using an UPLC system (ACQUITY UPLC®) with a C18 column (ACQUITY BEH) and couple to a tandem quadrupole mass spectrometer (Quattro Premier™ XE) equipped with an electrospray atmospheric pressure ionization interface (ZSpray™). Data were acquired using the MassLynx™ software and processed for peak detection, matching and alignment using the XCMS open access software. The highest number of ions was achieved in ESI negative mode (1122 peaks). The number of ions 10-fold up and down regulated in tadpoles exposed to 5 µg/L, respect to the controls, was 64 and 59, respectively. In tadpoles exposed to 10 µg/L the number of peaks was 90 and 57, respectively. Most of these ions belong to the same time clusters, suggesting they were fragments of the same metabolites. The strongest down regulation was observed for a peak at m/z 367, showing a clear concentration dependent response with 7,684 and 15,311 fold reduction at 5 and 10 µg/L, respectively. The highest up regulation was observed for a peak at m/z 803, showing a concentration dependent response with a mean abundance of 0, 71 and 10,843 in 0, 5, and 10 µg/L, respectively. A characteristic response at the global metabolic profile was observed in the bile of *C. cranwelli* exposed to endosulfan, which could be useful as fingerprint of the exposure to this organochlorine. In addition, further identification of major responding compounds could help to gain insight on the toxic mechanisms of the insecticide.

TP134 Use of Network Inference to Unravel the Mechanisms of Action and Specificity of Aromatase Inhibitors T. Habib, BTS; L. Escalon, US Army, Engineer Research & Development Center; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; D. Bencic, USEPA, Office of Research and Development, USEPA; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division; N. Garcia-Reyero, Jackson State Univ. The vertebrate hypothalamus-pituitary-gonadal (HPG) axis is controlled through various feedback mechanisms in order to maintain a dynamic homeostasis during changing environmental conditions, including exposure to chemical stressors. In this study, three aromatase inhibitors, fadrozole, prochloraz, and ketoconazole, were chosen as model chemicals to assess their effects on the hypothalamus-pituitary-gonadal (HPG) axis in the fathead minnows (*Pimephales promelas*). All three chemicals have

been shown to inhibit aromatase activity and decrease estradiol (E2) levels. Fadrozole, a drug used to treat breast cancer, is a potent aromatase inhibitor. Prochloraz, an imidazole fungicide, affects multiple pathways, such as inhibition of aromatase and other CYPs, as well as antagonism of the androgen receptor. Ketoconazole, an anti fungal agent, affects multiple pathways as well, including inhibition of aromatase and other CYPs. We exposed female fathead minnows to two different concentrations of fadrozole (3, 30 ug/L), prochloraz (30, 300 ug/L), and ketoconazole (32, 310 ug/L) during 8 days. We then removed the chemical from the water and sampled for 8 more days. We analyzed plasma hormone levels, as well as gene expression changes in the ovaries using a 15k custom microarray. We used network analysis to try to elucidate the mechanisms of action of the chemicals and their degree of specificity as aromatase inhibitors. These chemicals significantly increased aromatase expression and reduced E2 production. Comparison of the three aromatase inhibitors based on the network inference showed that fadrozole acted as the strongest aromatase inhibitor. Therefore, microarray analysis supported the fact suggested by hormone levels that fadrozole is a more potent aromatase inhibitor than prochloraz and ketoconazole. The inferred network was also able to discern between fadrozole, a more specific aromatase inhibitor, prochloraz, and and ketoconazole, the last two being more general P450 inhibitors. The results also unraveled new connections that have been verified in the literature.

TP135 Toxicity Mechanism-based Classification of Environmental Contaminants Based on Transcriptional Level Cellular Stress Response Profiling A. Gu, Northeastern Univ, Dept of Civil & Env Engineering, Biotechnology Initiative Program, Dept of Civil & Env Engineering, Biotechnology Initiative Program; C. Gao, Northeastern Univ, Civil and Environmental Engineering; N. Gou, A. Onnis-Hayden, Northeastern Univ. The needs to evaluate the toxicity of an large and ever-increasing number of chemicals demand for development of toxicity mechanism and pathways-based cost-effective testing scheme, then in time we hope to eventually build predictive models and tools to provide toxicological information that transcends the limits of data generation. The advance in "-omics" technologies present promises for achieving this goal. In this study, we utilized a whole-cell array of *Escherichia coli* K12 strains carrying gene promoters with transcriptional *gfp* fusions, covering most known stress response-related genes, to develop a methodology for quantitative transcriptional level ecotoxicity assessment and classification of toxicants. We examined 11 toxicants including model chemicals such as Mitomycin C (MMC) and H_2O_2, and various contaminants such as 4-Nonylphenol (4-NNP), nano-silver (nAg) and single-walled nanotube (SWNT) at various dose concentrations. The real-time gene expression levels over the exposure of 2 hours was recorded, and transformed into a newly developed Transcriptional Effect Level Index (TELI) to quantify the molecular toxicological impacts. Classification and clustering of these compounds at different doses were conducted and compared based on both quantitative stress response TELI values patterns across different stress pathways as well as, based on 3-D temporal pattern and magnitude of altered gene expression levels. The results indicated that there were consistencies as well as discrepancy of the clusters formed among the materials, depending on the different clustering logic and methods used (Hierarchical Clustering (HCL) and Self-Organizing Maps (SOM)). In general, the same chemical of various dose concentrations or, chemicals sharing similar toxic mechanisms seemed to cluster together. Clustering using simplified stress response category patterns seemed to cluster more "logically" with HCL approach, whereas, clustering using more complex temporal altered expression profiles yielded more "reasonable" clustering with SOM approach. In conclusion, we have demonstrated that transcriptional level effects can be quantified and it exhibited dose-response patterns. And, classification of toxicants based on their stress response profiling, meaning their potential toxicity mechanisms, are possible, although the clustering results vary depending on the data and approach used.

TP136 Validation of a LC/MS/MS Method for Measuring BPA, BP-3, Triclosan, Parabens, and other Environmental Phenols in Human Urine Q.W. Gavin, State of Calfornia, Dept of Public Healthy, Environmental Health aboratory Branch; R. Ramage, P. Behniwal, J. She, State of California, Dept of Public Healthy. Bisphenol A (BPA) is used in the manufacture of food packing, drinking containers, dental sealants, and medical devices. 2-hydroxy-4-methoxybenzophenone (BP-3) is used as sunscreen agents for skin protection, and as UV filters in cosmetic products and plastics to improve stability. Parabens and triclosan are widely used as preservatives and antimicrobial agents, respectively, in personal care products, pharmaceuticals, and food processing. Chlorophenols have been used in the wood preservation industry, as intermediates in the production of pesticides, and as disinfectants or fungicides for industrial and indoor home use. Because of their widespread use and potential risk to human health, environmental phenols were selected as high priority chemicals to be monitored by the California Environmental Contaminant Biomonitoring Program (Biomonitoring California). Therefore, we need to develop and validate a reliable, specific, and accurate method. A sensitive HPLC-isotope dilution-MS/MS method was developed and validated using QTRAP 5500 to simultaneous measure the concentrations of BPA, BP-3, 4-tert-octylphenol (tOP), orthophenylphenol (OPP), triclosan, parabens (methyl-, ethyl-, propyl-, and butyl- parabens), and four environmental chlorophenols; 2,4-dichlorophenol, 2,5-dichlorophenol, 2,4,5-trichlorophenol, and 2,4,6-trichlorophenol in human urine. Prior to LC/MS/MS, analytes are preconcentrated by solid-phase extraction (SPE) on Varian C18 cartridges. This simple SPE procedure provides extraction recoveries above 85%. The method was validated using Quality Control samples prepared from pooled human urine at three spiking levels. Intra and inter-batch precision and accuracy assessments show good reproducibility (inter-day coefficient of variations ranging from 3.82% to 14.2%) and accuracy (spiked recoveries ranging from 90% to 103% at the three spiking levels). The detection limits for most of the analytes are below 1 ng/ml in 1 ml of urine. This method will be used and applied for analyzing samples in Biomonitoring California.

TP137 An Evaluation of Adducts of Cysteinylglycine as Potential Biomarkers of Exposure to Formaldehyde and Acetaldehyde from Cigarette Smoke E. Minet, British American Tobacco, R&D Center; G. Scherer, Analytisch-Biologisches Forschungslabor GmbH. Introduction: The WHO Study Group on Tobacco Product Regulation (TobReg) recommended a list of toxicants in mainstream smoke of cigarettes for mandated lowering. This list comprises 9 tobacco smoke constituents, including acetaldehyde and formaldehyde. A reduction in exposure to those toxicants, through the use of new filters and tobacco technologies, can be assessed with suitable biomarkers of internal dose measured in biofluids such as urine. As yet, no biomarkers for the smoking-related exposure to these two aldehydes are available. Previous investigations suggested that acetaldehyde forms a stable adduct (2-methyl-thiazolidine-4-carbonyl-glycine (MTCG)) with the cysteinylglycine (CysGly) dipeptide, which is a degradation product of glutathione (GSH). By analogy to acetaldehyde, we hypothesized that formaldehyde can also form a stable adduct with CysGly (thiazolidine-4-carbonylglycine (TCG)). However, MTCG and TCG have not been identified in urine of any species, including humans. Objective: The objective of this project was to develop an analytical method for the determination of MTCG, a biomarker for acetaldehyde, and TCG, a biomarker for formaldehyde, in human urine. Method: An LC-MS/MS method, comprising a derivatization step with propylchloroformate followed by organic extraction, was developed and applied to a urine sample series obtained from non-smokers (n=50) and smokers of 1 mg (n=46) and 6 mg (n=49) ISO tar yield cigarettes. Nicotine and 5 of its metabolites were also quantified to establish correlations betweens TCG, MTCG, and tobacco consumption. Results: Our results show that, for the first time, MTCG (0.72±0.45 ng/ml) and TCG (13.76±9.58 ng/ml) were detectable in human urine. No significant difference was recorded between smokers and non-smokers, and no correlation could be established with total nicotine measured in the urine of smokers. The high TCG and MTCG background observed in non-smoker urine indicates the interference of possible confounding factors at low level exposure. However, preliminary results indicate that MTCG could be a suitable biomarker for acetaldehyde as a by-product of ethanol consumption, and should be explored further.

TP138 Elimination of Pyrethroid Pesticides and Pyrethroid Metabolites from Brain of Dosed Rats J. Starr, D. Ross, C. Cunningham, M.F. Hughes, USEPA. Pyrethroids are an important class of insecticides. In mammals, pyrethroids are neurotoxic and generally act by prolonging the opening of voltage sensitive sodium channels. Established kinetic models of pyrethroids have been used to assess toxicity and to interpret biomonitoring data. Most studies have relied on parent depletion to establish kinetic rates, and have not directly measured product (metabolite) formation. The purpose of this research was to develop profiles for common pyrethroids and their oxidative metabolites in brain tissue. Rats were dosed orally with a pyrethroid mixture containing cypermethrin, deltamethrin, esfenvalerate,

cis/trans-permethrin, and cyfluthrin. The animals were sacrificed and brain samples taken at 2.5, 3.5, 5.5, 9.5 and 25.5 hours post dosing. Analytes included the parent pyrethroids and the following metabolites: cis/trans-dichlorovinyl-dimethylcyclopropane-carboxylic acid (DCCA), 3-phenoxybenzoic acid (3PBA), 4-fluoro-3-phenoxybenzoic acid (4F3PBA), and cis-dibromovinyl-dimethylcyclopropane-carboxylic acid (DBCA). Analytes were extracted with hexane:acetone (8:2, V:V), cleaned using a silica solid phase, then analyzed by liquid chromatography, tandem mass spectrometry. Maximum concentrations of the pyrethroids were reached at or before the 3.5 hour time point. By 25.5 hours, concentrations of almost all parent pyrethroids were below the detection limit. DBCA was not present in quantifiable amounts in any sample. The other metabolites were more persistent than their parent pyrethroids. Since the metabolites were eliminated from the brain more slowly than the parent pyrethroids, their concentrations relative to their respective precursors increased. The concentration of DCCA was low compared to 3PBA and 4F3PBA, however, the half-life of DCCA was longer than both 3PBA and 4F3PBA. Pyrethroid metabolites may be formed by enzymatic activity in the brain, liver, or serum. Therefore, their presence in the brain may be largely due to transport of the metabolites across the blood/brain barrier. Despite this, the observed difference in elimination rates between parents and metabolites shows the brain to be an important physiological compartment. These results can be used to more fully parameterize toxicokinetic models describing the clearance of pyrethroids. These models will be useful in risk assessment as well as exposure reconstruction studies where estimates of exposure are often based on urinary biomarker measurements.

TP139 Fast and Simultaneous Determination of Urinary 8-hydroxy-2'deoxyguanosine and Monohydrixylated Polycyclic Aromatic Hydrocarbons R. Fan, Key Laboratory of Ecology and Environmental Science in Guangdong Higher Education, College of Life Science, South China Normal Univ, California Dept of Public Health, Environmental Health Laboratory Branch; D. Wang, California Dept of Public Health, Environmental Health Laboratry Branch; R. Ramage, J. She, California Dept of Public Health, Environmental Health Laboratory Branch. 8-hydroxy-2'-deoxyguanosine (8-OHdG), as a biomarker of oxidative DNA damage, has been extensively studied to assess human exposure to those carcinogenic compounds. Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental contaminants. The published studies have associated levels of human urinary hydroxylated PAHs with those of 8-OHdG. However, the measurement of hydroxylated PAHs and 8-OHdG in urine was often carried out by using two different analytical methods, which consumed longer time and high cost. In this study, a novel method was developed to quantify 10 urinary hydroxylated OH-PAHs and 8-OHdG within 11min by liquid chromatography/tandem mass spectrometer simultaneously. Deuterated and 13C- labeled analogs were used as internal standards. The urine samples went through solid phase extraction and concentration, and were analyzed by an optimized LC/MS/MS method operated in the negative ESI and MRM mode. The method detection limits (MDLs) in pooled urine ranged from 0.023 μg/L to 0.625 μg/L. The calibration curves of all target analytes showed good linearity within the concentration range of 0.31-5.00 μg/L for 8-OHdG and 0.047-15.00 μg/L for different OH-PAHs. The method showed satisfied accuracy and precision by analyzing varied levels spiked pooled urine. The recoveries were in the range of 84%-115% with variation coefficient of less than 20%, except for 2-OHF and 1-+9-OHPhe.

TP140 Modulation of Thyroid Hormone Concentrations in Rats Co-administered with Perchlorate and Iodide-deficient Diet T. Kunisue, New York State Dept of Health, and Dept of Environmental Health Sciences, School of Public Health, State Univ of New York at Albany, Research Scientist, New York State Dept of Health, Research Scientist; K. Kannan, Wadsworth Center, New York State Dept of Health, and Dept of Environmental Health Sciences, School of Public Health, State Univ of New York at Albany; J.W. Fisher, Dept of Environmental Health Science, College of Public Health, Univ of Georgia. Perchlorate can perturb thyroid hormone (TH) homeostasis by competitive inhibition of iodide uptake by the thyroid gland. Until recently, the effects of perchlorate on TH homeostasis were examined by measuring serum concentrations of THs by immunoassay (IA) methods. IA methods are sensitive, but for TH analysis, they are compromised by the lack of adequate specificity. In this study, we determined the concentrations of six THs: L-thyroxine (T4), 3,3',5-triiodo-L-thyronine (T3), 3,3',5'-triiodo-L-thyronine (rT3), 3,5-diiodo-L-thyronine (3,5-T2), 3,3'-diiodo-L-thyronine (3,3'-T2), and 3-iodo-L-thyronine (3-T1) in the serum of rats administered perchlorate by isotope (13C6-T4)-dilution liquid chromatography (LC)-tandem mass spectrometry (MS/MS). The method recoveries for THs spiked into a serum matrix were between 97.0% and 115%, with a coefficient of variation (CV) of 2.1% to 9.4%. Rats were placed on an iodide-deficient or iodide-sufficient diet for 2.5 months, and for the last 2 weeks of that period, they were provided drinking water either without or with perchlorate (10 mg/kg bw/day). No significant differences in serum concentrations of T3 and T4 were observed between rats given iodide-deficient and iodide-sufficient diets for 2 or 2.5 months. After 24 h of perchlorate exposure, significantly lower concentrations of T3 and T4 were found in the serum of rats administered the iodide-deficient diet but not in rats administered the iodide-sufficient diet. However, following 2 weeks of perchlorate exposure, TH levels in rats fed with the iodide-sufficient diet were also significantly lower than those in control rats. Our results suggest that perchlorate affects TH homeostasis and that such effects are more pronounced under iodide-deficient nutrition.

TP141 Occurrence of Benzotriazole UV Stabilizers and Synthetic Musks in Human Adipose Tissues Collected from Japan, South Korea, China, Spain, and the USA H. Yanagimoto, Kumamoto Univ, JAPAN, Kumamoto Univercity; H. Nakata, Kumamoto Univ, Graduate School of Science and Technology, Kumamoto Univ, Dept of Environmental Science; R. Shinohara, Kumamoto Univ, Graduate School of Science and Technology; T. Isobe, Ehime Univ, Senior Research Fellow Center, Ehime Univ, Senior Research Fellow; S. Tanabe, Ehime Univ, Center for Marine Environmental Studies; N. Nose, H. Komori, N. Arita, N. Ueda, Ehime Univ; M. Watanabe, National Institute for Environmental Studies; B. Jemenez, Spanish Council for Scientific Research; J. Yang, Catholic Univ of Daegu, Dept of pharmacology and toxicology; T. Kunisue, New York State Dept of Health, and Dept of Environmental Health Sciences, School of Public Health, State Univ of New York at Albany, Research Scientist, New York State Dept of Health, Research Scientist; K. Kannan, New York State Dept of Health, Wadsworth Center. The benzotriazole UV stabilizers (BUVSs) and synthetic musks have been used in a wide variety of plastic materials and personal care products, respectively. In recent years, ubiquitous contamination by BUVSs and musks has been reported in the aquatic environment. These compounds accumulate in higher trophic species, such as marine mammals and coastal birds, which indicate their bioaccumulation potential through the marine food-chain. Despite this, very few studies have examined the occurrence and concentrations of BUVSs and synthetic musks in human adipose tissues. In this study, we analyzed four BUVSs, such as UV-320, UV-326, UV-327 and UV-328 and five synthetic musks, such as HHCB, AHTN, Musk-xylene, Musk-ketone and OTNE in human adipose tissues collected from Japan, South Korea, China, Spain, and the USA. UV-327, UV-328, HHCB, and AHTN were detected in most samples analyzed. High concentrations of BUVSs were found in adipose tissues collected from Japan and South Korea, at the levels of several tens of ng/g on a lipid wt. basis. HHCB showed higher concentration in samples from Spain and the USA. Significant correlation between UV-327 and UV-328 concentrations was found in human tissues, implying that these compounds might have originated from similar sources. The profiles of geographic distribution of BUVSs and synthetic musk concentrations in human tissues were similar to that of mussels collected from the Asia-Pacific region. No gender- and age-related differences were observed in the concentrations of BUVSs and musks in human tissues. These results were different from that for persistent organic pollutants (POPs), which indicate that biodegradation and metabolism of these compounds. To our knowledge, this is the first study to report the occurrence bioaccumulation and widespread contamination of BUVSs in human adipose tissues.

TP142 Optimization and Validation of a New Analytical Method for the Monitoring of Metabolites of Organophosphate Flame Retardants and Plasticizers in Urine N. Van den Eede, Univ of Antwerp, Pharmaceutical Sciences; A.C. Dirtu, Univ of Antwerp, Pharmaceutical Sciences, "Al. I. Cuza" Univ of Iasi, Chemistry; H. Neels, Univ of Antwerp, Pharmaceutical Sciences; A. Covaci, Univ of Antwerp. Since 2004, the demand for alternative flame retardants has increased as a result of the ban on the use of Penta- and Octa-BDE mixtures by the European Union. Organophosphate esters (OPEs) are one type of such alternatives and have become widely used since then. Now they are largely present in the indoor environment, mainly in air (ng/m^3) and dust (μg/g). Human exposure to these chemicals may

be therefore high, both for adults, who are mainly exposed via inhalation, and for toddlers who are exposed via inhalation and dust ingestion. OPEs are hydrolyzed in the liver to form dialkyl phosphates or diaryl phosphates (DAPs), depending on the structure of the parent compound. These DAPs can be traced in human urine and can serve to monitor human exposure to OPEs. We aimed at developing an analytical method for the quantification of six DAPs in human urine, namely bis(1-chloro-2-propyl) phosphate (BCPP), bis(2-butoxyethyl) phosphate (BBEP), bis(2-chloroethyl) phosphate (BCEP), bis(1,3-dichloropropyl) phosphate (BDCPP), diphenyl phosphate (DPP) and di-(*iso/n*-)butyl phosphate (DBP). Sample preparation was based on solid phase extraction using a weak anion exchange sorbent (Varian NH_2, 1 ml/50 mg) and elution with 5% ammonium hydroxide in methanol. Chromatographic separation was achieved on an Agilent 1200 series LC using a Kinetex HILIC 150 mm x 2.1 mm x 2.6 µm column, coupled to an Agilent 6410 triple quadrupole mass spectrometer employed in electrospray negative ionization mode. DAPs were quantified on four labeled internal standards, namely BCEP-d8, DPP-d10, BDCPP-d10, BBEP-d4, using multiple reaction monitoring. The method was optimized using spiked urine and further validated by matrix spiking at 3 concentrations. Matrix effects were assessed for both DAPs and their corresponding internal standards. The method is currently employed in various biomonitoring studies, with the aim to characterize the human exposure to OPEs.

TP143 Urinary Bisphenol-A and Triclosan Levels in a Belgian Obese Population During a 12-month Follow-up Study T. Geens, Univ of Antwerp, Pharmaceutical Sciences; A. Dirtu, Univ of Antwerp; E. Dirinck, Univeristy Hospital of Antwerp; H. Neels, Univ of Antwerp; L. Van Gaal, P. Jorens, Univeristy Hospital of Antwerp; A. Covaci, Univ of Antwerp. Bisphenol-A (BPA) and triclosan (TCS) are two phenolic chemicals with endocrine disrupting properties. Distribution of these compounds in the environment is widespread (water, soil, fish, dust) and almost all humans in occidental countries are exposed. For BPA, food is the most important exposure pathway, while for TCS, the use of personal care products is the most dominant source. Due to their fast biotransformation and urinary excretion of their conjugated form, urine is the most appropriate matrix for biomonitoring of these compounds. In this study, BPA and TCS were determined in a group of obese patients visiting the Obesity and Diabetes Clinic of the Univ Hospital of Antwerp, Belgium. At the start of this weight loss program, about one-third of the patients underwent bariatric surgery followed by diet recommendations and physical exercise, while the other two-third was treated with only diet recommendations and physical exercise. Urine spot samples were collected at the start of the program (N=102) and after approximately 3 months (N=57), 6 months (N=33) and 12 months (N=10) during follow-up visits. The analytical procedure included a deconjugation step, after which BPA and TCS were extracted from 3 mL urine by solid phase extraction with Oasis HLB (60 mg, 3 mL) followed by derivatization with pentafluorobenzoylchloride and detection with gas chromatography coupled to negative ionization mass spectrometry. The method limit of quantification was 0.1 µg/l for both contaminants analyzed. Both BPA and TCS were quantified in more than 99% of the samples. Overall, BPA ranged between 0.1 and 13.2 µg/L with a median concentration of 1.42 µg/L, while TCS showed a wider concentration range of 0.1 – 1048 µg/L with a median of 1.49 µg/L (75^{th} percentile: 5.4 µg/L and 90^{th} percentile: 132.6 µg/L). Levels of BPA were more constant at the different time points, indicating a more uniform exposure. The presence of outliers for TCS, on the other hand, is more indicative for spikes in exposure. Urinary concentrations were creatinine-adjusted and correlated with a set of clinical parameters. Since the changing of the diet might have an influence on the exposure to BPA, time-trends were examined in relation with the type of diet, also taking into account factors such as weight loss, BMI, etc.

TP144 Air-Water Gas Exchange of Legacy and Currently Used Pesticides in the Arctic L.M. Jantunen, Environment Canada; F. Wong, Univ of Toronto, Chemistry; A. Gawor, Univeristy of Toronto; T.F. Bidleman, Environment Canada; G. Stern, Freshwater Institute, Dept of Fisheries and Oceans; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch; H. Kylin, Swedish Univ of Agricultural Sciences, Aquatic Sciences and Assessment. The arctic has been contaminated by legacy organochlorine pesticides (OCPs) and currently used pesticides (CUPs) through atmospheric transport and oceanic currents. Although CUPs are less persistent than OCPs, they are still detected in the arctic air and water. Endosulfan is the most reported CUP in the arctic environment but little is known about other CUPs especially in the ocean water, although several have been found in arctic lakes, snow and ice. The spatial trends and air-water exchange of these pesticides were studied by collecting parallel water and air samples from shipboard expeditions in sub-arctic and arctic regions between 1993-2010. Over the many years, similar air and water sampling and analytical methods were employed, ensuring data comparability. Compounds found in this study include the legacy OCPS: hexachlorocyclohexanes (HCHs), chlordanes, dieldrin and toxaphene and the CUPs: dacthal, endosulfans, chlorothalonil, chlorpyrifos and trifluralin. Based on two samplings in 1999 and 2007/08, concentrations of the legacy compounds HCHs and chlordane are declining in Canadian Archipelago water, whereas some CUPs, notably endosulfan, are increasing. Within the Canadian archipelago there is also an east-west spatial gradient, most notably for the HCHs, dieldrin, dacthal and endosulfan. Gas exchange varies by compound, year and location, but generally in the Canadian Archipelago, legacy OCPs are undergoing net outgassing where CUPs are undergoing net deposition. Understanding the processes and current state of air-surface exchange is important in order to assess human and environmental exposure, evaluate the effectiveness of International Protocols and in turn provide insights for new and emerging chemicals.

TP145 Contribution of Air-to-Surface Partitioning to Deposition Potential for Airborne Cyclic Methylsiloxanes: A Modeling Assessment S. Xu, Dow Corning Corporation, Health and Environmental Sciences. Partition of airborne contaminants to surface media such as soil, biota, aquatic suspended particulates, and sediment have been identified as significant contributors to deposition potential for known persistent organic pollutants (POPs) such as PCBs and pesticides. In this study, the effects of partitioning of airborne cyclic volatile methylsiloxanes (cVMS) to soil, plant biomass, suspended particles and aquatic sediments in the remote region on the deposition potential of cVMS were estimated by equilibrium modeling. For each process, partitioning equilibrium between surface medium and air was assumed and the partitioning coefficients were estimated based on available data and approaches reported in literature. It was found that cVMS have surface media/air partition coefficients 3 to 6 orders of magnitude lower than those of the most volatile POP reference materials such as hexachlorobenzene (HCB) and PCB 28 congener. This is especially true for D4 and D5. Consequently, gas absorption via soil/air, plant/air, suspended particulates/air, and air/water/sediment partitioning contributes minimally (< 1% of total airborne D4 or D5) to the deposition potential of D4 and D5 in the remote region. For D6, partition from air to plant biomass, suspended particulates and sediment contribute minimally to the deposition of airborne D6 to surface media, while soil/air partitioning may account for a small fraction (e.g., 3%) of airborne D6 transferred from air to soil under the low temperatures (e.g., -20 oC) in the remote region.

TP146 Are the Electronic Wastes and Wastes Generated from Ship Breaking Sites Increasing the Atmospheric Load of Polychlorinated Biphenyles in India? P. Chakraborty, K. Sajwan, Savannah State Univ, Dept of Natural Science; G. Zhang, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences; K. Jones, Institute of Environmental and Natural Sciences, Lancaster Univ, Lancaster, Dept of Environmental Sciences. Asia has become hotspots of polychlorinated biphenyles (PCBs) though Asia was not identified as an important source in global emission inventories of PCBs. There are growing concerns that most of the electronic waste (e-waste) generated in developed countries is ending up in developing countries that are economically challenged and lack the infrastructure. India is of prime concern because tropical climate of India would facilitate the rapid entry of PCBs to the atmosphere from some sources such as incineration of PCB containing materials, vaporization from landfill, air–water/soil exchange, vaporization from contaminated surfaces, sludge dewatering beds, and electronic devices containing PCBs. Incomplete combustion of e-waste in open air and dumping of processed materials are the major sources of various toxic chemicals including PCBs. Co-disposal of e-waste with domestic waste in open dumps is generally practiced in India. Another important source for PCBs in India may include dumping of PCB-containing wastes with release via volatilization and uncontrolled burning, and the storage and breakup of old ships. India is world's largest ship breaking nation in terms of volume. Most of the ships dismantled today were built in the 1970s. That is to say prior to the banning of many hazardous materials. Presently atmospheric levels of PCBs in India seem to have largely increased since early 1990s. A predominant

gradient in the maximum concentration of ∑25PCB has been observed between urban-rural-wetland/background with an exceptionally higher level in the wetland region of Sunderban (544 pg.m-3). PCBs in the Indian atmosphere showed a dominance of congeners with 5-7 chlorine atoms (heavy PCBs), and dioxin-like PCBs were significant in the descending order of Mumbai, New Delhi, Agra, Kolkata, and Chennai. The metro-cities are of prime interest in this case because of the electronic waste generated with the rapid growth of improper electronic waste recycling units. Elevated levels observed in the wetland regions of Sunderban highlights regional atmospheric transport of PCBs from major cities to remote/pristine sites in India.

TP147 Estimating Hourly Passive Sampler Mass Transfer Rates and Concentrations in an Urban Landscape Using a Numerical Weather Prediction Model N.T. Petrich, Univ of Iowa, Environmental Engineering. Nicholas T. Petrich, Scott N. Spak, Dingfei Hu, Zach L. Rodenburg Gregory R. Carmichael, Keri C. Hornbuckle Polyurethane foam (PUF) passive air samplers represent an inexpensive and practical way to sample semivolatile organics compounds and their spatial gradients over urban areas. However, canonical methods for estimating concentrations from passive sampling assume constant empirical mass transfer rates and temperature, which add unquantified uncertainties in temporal representativeness to concentrations estimated from raw sampled mass. These methodological choices currently limit the ability to calculate and constrain uncertainty in estimated concentrations, and to directly compare passive sampler concentrations with time-resolved concentrations from active sampling methods and chemical transport models. Here we present an alternative method for estimating hourly flow rates, mass transfer coefficients, and concentrations—including average concentration at a reference temperature—from first principles using hourly meteorology (temperature, wind direction, and wind speed) simulated by the Weather Research and Forecasting (WRF) model. This method is applied to gas and aerosol polychlorinated biphenyl (PCB) congeners at an urban passive sampling network in Chicago, Illinois during 2008. We evaluate the importance of sampler height and orientation, temperature, sub-gridscale turbulent mixing, internal fluid dynamics within the PUF housing, and PUF air concentration gradients. Effects of model spatial resolution are considered using nested WRF simulations on 12 km, 4 km, and 1.33 km grids over the city. Spatial variability in mass transfer coefficients and concentrations are compared with results from canonical empirical methods, and temporal variability evaluated through comparison with cotemporaneous concentrations from high volume air samplers.

TP148 Halogenated Polycyclic Aromatic Hydrocarbons in Urban Air from Albany, USA Y. Horii, Center for Environmental Science in Saitama; T. Ohura, Meijo Univ; B.R. Johnson, Univ of Cartagena; K. Kannan, Wadsworth Center. Polycyclic aromatic hydrocarbons (PAHs) are widespread environmental pollutants. Chlorinated PAHs (ClPAHs) and brominated PAHs (BrPAHs) are structurally similar to other halogenated hydrocarbons such as dioxins. Cl-/BrPAHs with three to five aromatic rings have been reported to occur in various environmental matrices. Recent synthesis and purification of individual halogenated PAHs in our laboratory made the congener-specific analysis of Cl-/BrPAHs possible. Previous studies have focused on occurrence, profiles, and atmospheric behavior of Cl-/BrPAHs in urban air from Japan. In this study, we determined individual concentrations of 26 ClPAHs and 15 BrPAHs in gaseous and particulate phases of urban air collected in Albany, NY, USA. We also investigated seasonal changes of Cl-/BrPAHs and the correlation between Cl-/BrPAH and the corresponding parent PAH concentrations to understand the atmospheric behavior of these compounds. This is the first report to analyze Cl-/BrPAHs in American air samples. Monitoring was conducted every month from June, 2007 to May, 2008 at the Empire State Plaza located in Albany, NY. Two days of air samples were collected using high-volume air sampler attached with quartz fiber filter (QFF) and polyurethane form (PUF) and XAD-2 adsorbent sandwich (ORBO 2500Puf sandwich, Supelco). Concentrations of ClPAHs, BrPAHs, and PAHs in the QFF and PUF sandwich samples were determined using a GC/HRMS. Concentrations of sum of ClPAHs varied from 0.29 pg/m^3 to 5.6 pg/m^3 in gaseous phase and from 0.11 pg/m^3 to 4.8 pg/m^3 in particulate phase. The mean concentrations of target chemicals in total of gaseous and particulate phases decreased in the following orders: PAHs (3800 pg/m^3) > ClPAHs (3.2 pg/m^3) > BrPAHs (0.089 pg/m^3). Significant correlation between the concentrations of Cl-/BrPAHs and the corresponding PAHs was observed in total of gaseous and particulate phases. The concentrations of low molecular weight Cl-/BrPAHs (e.g., 9-ClPhe) in gaseous phase were 3-5 times higher than those in particulate phase, while the concentrations of high molecular weight Cl-/BrPAHs (e.g 6-ClBaP) were higher in particulate phase. Although seasonal trends of ClPAHs in urban air from Japan which showed higher concentrations of ClPAHs in colder seasons, were found in previous studies, the seasonal trend was not clearly shown in our results. The concentration levels of Cl-/BrPAHs in the urban air from Albany were one order of magnitude lower than those from Japan.

TP149 Pesticides in Air in the Mississippi River Valley: A Comparison Between 1995 and 2007 W.T. Foreman, US Geological Survey, National Water Quality Laboratory; P.D. Capel, M.S. Majewski, S.J. Kalkhoff, R.H. Coupe, R.C. ReVello, US Geological Survey. Weekly-composite air samples were collected using a glass-fiber filter/polyurethane foam plug high-volume air sampler during the 1995 and 2007 April through September growing seasons at two agricultural locations in Iowa and Mississippi. Samples were analyzed by GC/MS using selected-ion monitoring for a variety of pesticides and degradates, 31 of which overlapped the two sampling periods. At least 26 compounds were detected during the growing season from each site in both years. The number of pesticides detected in more than 50% of the samples doubled for 2007 compared to 1995. Pesticide use patterns (amounts, crop types, application procedures), coupled with seasonal weather and atmospheric processes influence detection frequencies and aerial concentrations. For example, trifluralin was detected nearly 100% of the time at both sites during both years; likely because it is used on a variety of different corps and is incorporated into the soil prolonging its period of volatilization following initial application. Atrazine (and its primary degradate chloroisopropylamino-s-triazine; CIAT) and metolachlor, which are extensively applied at both locations, were detected at least 50% of the time at all sites during both years. The insecticide chlorpyrifos increased in detection frequency from about 38% to 95% at both sites in 2007 compared to 1995; its concentration was greater in 2007 than 1995 in Iowa, but was comparable between the two years in Mississippi. Similarly, the pyrethroid insecticide cis-permethrin was detected more frequently and had greater concentrations at both sites in 2007 compared to 1995 that likely is a result of replacement of some use-restricted or eliminated organophosphorus or carbamate insecticides. Some pesticides were detected frequently at one location (acetochlor at Iowa) but not the other, as predicted based on crop and pesticide usage differences. Five compounds were detected only in 1995 or 2007. Voluntary removal of cyanzine from the US marketplace and its subsequent cancellation of registered uses in December 1999 resulted in a reduction from at least a 25% detection frequency at both sites in 1995 to no detections in 2007 samples.

TP150 Derivation of a Site-specific Clean-up Level for Creosote-derived Polycyclic Aromatic Hydrocarbons N. Bonnevie, ARCADIS, Risk Assessment and Ecological Services; J. Iannuzzi, D. Bax, P. Anderson, T. Iannuzzi, ARCADIS. There is increasing evidence that the assumptions used to derive default sediment benchmarks for polycyclic aromatic hydrocarbons (PAHs) are not applicable when evaluating the potential toxicity at sites where creosote-derived PAHs are expected to be the primary risk drivers. In particular, creosote-derived PAH in sediments appear to be less bioavailable than assumed by existing benchmarks. This is an important consideration when developing remedial goals for these sites as the standard screening benchmarks used to evaluate the potential toxicity of PAHs in sediments (e.g., Threshold Effect Level, Probable Effect Level, Threshold Effect Concentration, Median Effect Concentration, Extreme Effect Concentration, and the Equilibrium Partitioning Sediment Benchmark Toxic Unit [ESBTU]) may greatly overestimate the toxicity of creosote-derived PAHs to benthic invertebrates and possibly result in unnecessary and overly conservative remedial actions. This paper examines the toxicity of PAHs in sediments from multiple former wood-treating facilities using standard laboratory toxicity tests. Based on co-located sediment chemistry and toxicity data, the dose response curves indicated increasing toxicity with increasing PAH concentration. However, statistically significant toxicity did not occur until bulk sediment concentrations were much higher than would be predicted based on the currently available sediment benchmarks. In fact, there were samples with total PAH concentrations close to 200 mg/kg that exhibited little or no toxicity. The results of this investigation are consistent with previous evaluations suggesting site-specific clean-up levels for creosote-derived PAHs could range from 100 to more than 200 mg/kg.

TP151 Ecological Risk Assessment of Oil Spill Affected Area: Visited After Two Years the *Hebei Spirit* Oil Spill, Korea S. Hong, J. Khim, Korea Univ, Division of Environmental Science and Ecological Engineering; J. Ryu, Korea Ocean Research and Development Institute, Office of Policy Research; J. Park, S. Song, Korea Univ, Division of Environmental Science and Ecological Engineering; K. Choi, Seoul National Univ, School of Public Health, Seoul National Univ, Dept of Environ. Health; K. Ji, J. Seo, S. Lee, Seoul National Univ, School of Public Health; J. Park, W. Lee, Soonchunhyang Univ, College of Natural Sciences; Y. Choi, Citizens' Institute for Environmental Studies; K. Lee, C. Kim, NeoEnBiz Co, Institute of Environmental Protection and Safety; W. Shim, Korea Ocean Research and Development Institute; J. Naile, J. Giesy, Univ of Saskatchewan, Dept of Veterinary Biomedical Sciences and Toxicology Centre. In order to assess the ecological risk by residual crudes in coastal area after two years the *Hebei Spirit* oil spill (occurred in 2007), the crude-derived hydrocarbons, sediment toxicity, and benthic response were collectively investigated. Total of 50 surface and subsurface sediments from 22 locations along the coast of oil spill site were collected and measured for 1) hydrocarbon chemistry followed by 2) toxicity screening (H4IIE-luc bioassay), and 3) benthic macrofauna mapping (visual analysis). First, the concentrations of residual crude-derived hydrocarbons greatly varied among regions (or locations) and depth reflecting the impact of crude oils in site-specific manner. For example, the elevated residual crudes were mainly found in muddy bottom compared to sand sediments, particularly accumulated at subsurface layers. Some samples contained relatively great concentrations of several PAHs exceeding the corresponding ERL and ERM values. Looking for sediment toxicity, there was a good agreement between sedimentary concentration profiles and potential toxicity of organic extracts in concentration-dependant manner. A significant correlation ($r > 0.73$, $p < 0.01$) between log PAHs and dioxin-like activities also indicated a reasonable mass balance. However, highly weathered samples containing greater proportion of alkylated PAHs showed relatively greater dioxin-like activities indicating certain interaction under the modified composition of known and/or unknown Ah-R agonists from crude oils. Meanwhile benthic community response reflected somewhat confounding result that greater biodiversity and larger abundance in more contaminated sites, which suggested species-specific tolerance and/or recolonization of certain species (such as *Batillaria* spp.) during the weathering periods. All together, the site experienced a severe oil exposure seemed to be recovered to a certain degree after two years the *Hebei Spirit* oil spill occurred.

TP152 PAHs Burden and Partitioning in Ten Biochar Matrices A. Freddo, Univ of East Anglia; B. Reid, Univ of East Anglia, Environmental Sciences. When organic matter undergoes a pyrolysis process biochar is formed to obtain heat and power. During this process: the proportion of C increases by over 50% by weight with respect to the original feedstock; the structure of the matrix becomes porous and rich in biologically nutrients (e.g., potassium, phosphorous) and microelements (e.g., magnesium, calcium, manganese). Thus, it has been suggested that biochar can be amended to soil with a view to improving plant growth. Moreover, as a consequence of biochar's stable composition, the release of carbon (as CO_2) back into the atmosphere is slow. Thus, there is the opportunity to sequestration of CO_2 into biomass (used as feedstock for biochar production) and then to store this carbon when biochar is used as a soil amendment. However, as pyrolysis products, biochars may contain significant levels of polycyclic aromatic hydrocarbons (PAHs). Amounts of these priority pollutants dependent upon feedstock type and the production processes (e.g., temperature). Establishing PAH concentrations and partitioning within biochar is essential to ensure safe incorporation of biochar in the environment. This study investigated exhaustive and non-exhaustive concentration of PAHs from ten complex carbonaceous matrices, produced from different starting material and under different pyrolysis temperature. We intend to present validation data for the extraction of PAHs from biochar to exemplify approaches that indicate PAHs partitioning and bio-availability. In light of these results, assessment of the risk represented by biochar and the risks associated with biochar incorporation into the soil will be evaluated, considering the toxic impact of biochar also in relation to the feedstock and pyrolysis temperature.

TP153 A Toxiological Perspective on Alkylated PAHs as it Relates to Risk Assessment A. Pawlisz, Conestoga-Rovers&Associates. Recent crude oil spills have reinvigorated the debate whether all polycyclic aromatic hydrocarbon (PAH) toxicity is accounted for in ecological and human health risk assessments. PAHs are a mixture of hundreds of individual compounds and only a small fraction are routinely analyzed for, regulated, and assessed for harm to biological receptors. Increasingly, the alkylated homologs of PAHs are gaining attention in risk assessment due to their abundant constitution in fresh crude oils, relative persistence, bioaccumulation potential, not being quantified by common analytical methods, increasing relative proportion as crude oil ages, and potentially higher toxicity than the parent compounds. While one of the assessment methodologies is to consider homologue additive toxicity at par with their parent compounds, after applying an expanded scan for alkylated PAHs, there may be instances where this approach may still not accurately estimate the total PAH toxicity. A review of recent toxicological literature on alkylated PAH is provided with an insight on how to effectively account for added toxicity in an environmental risk assessment.

TP154 Dermal Cancer Risks Associated with Exposure to Benzo[*a*]pyrene – of Potentially Greater Importance than Oral Exposures A.L. Knafla, Equilibrium Environmental Inc. Humans are exposed to benzo[*a*]pyrene, a known carcinogen, at contaminated sites. An examination of rodent toxicity data indicates that on a per kilogram body weight basis, the skin may be a more sensitive organ following dermal exposure in comparison to other target tissues following ingestion exposure. Furthermore, traditionally human health risks from dermal contact with benzo[*a*]pyrene have been conducted by estimating the proportion of the dose that penetrates through exposed skin for comparison with an oral route Risk Specific Dose limit. However, as recently published by a group of investigators (Knafla et al. 2010), the development of epidermal tumours is a more sensitive endpoint than systemic tumours following dermal exposure. A mathematical algorithm was developed to allow for risk assessors to evaluate skin cancer risks following human exposures to benzo[*a*]pyrene in soil.

TP155 Bioavailability Studies: The Last Available Tools For Evaluating PAH Risks Realistically B. Magee, G. Hoeger, ARCADIS; B.J. Locey, ARCADIS, Risk Assessment and Environmental Services; K. Connor, ARCADIS. Polycyclic aromatic hydrocarbon (PAH) risk assessment is currently overly conservative, with Regional Screening Levels that are orders-of-magnitude below anthropogenic background in most urban areas. Additionally, the United States Environmental Protection Agency (USEPA) is proposing to increase the Relative Potency Factors (RPFs) for 5 PAH and to increase the number of carcinogenic PAHs with RPFs from 6 to 26. Several proposed RPFs are 10x or greater including dibenz[*a,h*]anthracene (10x), benzo[*c*]fluorene (20x), dibenzo[*a,l*]pyrene (30x), and benz[*j*]aceanthrylene (60x). If this approach is adopted, human health risks from exposure to PAHs will increase considerably, and risk-based clean-up levels will drop to below background even for commercial/industrial receptors at the high end of the Superfund risk range. It is clear from the literature, however, that the mammalian bioavailability of PAH from weathered soils/sediments is considerably less than 100%. EPA and many State agencies have increasingly rejected the use of bioavailability adjustments derived from literature values. EPA has issued a recent report on the bioavailability of dioxins and furans in soils. In this report, the agency has supported a policy of performing in vivo bioavailability studies on site-specific media impacted by complex organic compounds. This paper will summarize literature bioavailability results for PAHs including a recent study performed by the authors on soils containing coal tar. Finally, the paper will discuss methodological issues regarding the planning and execution of a robust, internally consistent animal bioavailability study with site aged soils. Issues that will be discussed include type of controls (internal versus external), target PAHs, animal species and strain, sampled biological media (blood, urine, feces, other tissues), pharmacokinetic issues (single time point versus area under the curve), and analytes of interest (parent PAHs versus PAH metabolites vs DNA or protein adducts).

TP156 An Analysis of Human Health Risks Arising from Exposure to PAHs Adjacent to Coal Tar Sealed Asphalt Parking Lots E.S. Williams, Baylor Univ, Bayor Univ; B.J. Mahler, P.C. van Metre, United States Geologic Survey. Recent studies have demonstrated that concentrations of carcinogenic polycyclic aromatic hydrocarbons (PAHs) are higher in house dust in residences and soils adjacent to asphalt parking lots sealed with coal-tar based sealant (CSA) compared to the concentrations of PAHs in the same media adjacent to unsealed asphalt (UA) lots. Ten exposure scenarios were used to assess human health risks associated with ingestion exposure to

PAHs in soil and dust in CSA and UA settings. House dust PAH concentrations were from a study in Austin TX and soil PAH concentrations were from studies in Chicago IL and Durham NH. Maximum intake estimates for benzo[*a*]pyrene (BaP) in house dust and soil were considerably higher in exposure scenarios in CSA settings than in exposure scenarios in UA settings (55.6 and 1.79 ng BaP/kg/day, respectively). Excess lifetime cancer risk (ELCR) estimates associated with BaP and BaP equivalents (BaP_{EQ-7}) were calculated using a cancer slope factor of 7.3 $mg/kg/day^{-1}$. For lifetime incidental ingestion of house dust and soil in CSA settings, ELCR for BaP_{EQ-7} is estimated at 1.3×10^{-4}, a 34-fold increase in risk relative to that for UA settings (3.8×10^{-6}). Estimated ELCR increases 11-12-fold in CSA settings relative to UA settings over the first 6 years of life because of higher ingestion rates and lower body weights. When ingestion of only house dust was considered, PAH exposures through incidental ingestion in CSA settings were estimated to increase ELCR 13-fold relative to UA settings, with 46% of that increase resulting from childhood exposure (ages 0-6) as a result of higher dust ingestion rates during childhood. Soil-mediated PAH exposures were estimated to elevate ELCR to a larger extent than house-dust-mediated ingestion, as PAH concentrations in soils in CSA settings are much higher than those in house dust and ingestion rates for soil are higher than those for house dust. On the basis of these results, we conclude that the use of coal-tar-based asphalt sealant products is associated with increased risk of cancer resulting from exposure to carcinogenic PAHs in soil and dust.

TP157 Use of Mass Balance Bounding Estimates and Sensitivity Analysis to Prioritize PAH Inputs in Urban Systems R.P. DeMott, T.D. Gauthier, Environ International. PAH transport via the atmosphere and runoff inputs related to high density population and traffic in urban areas have been extensively studied for decades. In recent years, several studies focused on the use of specific PAH-containing materials, particularly pavement sealer products, as possible sources of sediment PAHs. The big-picture studies are advantageous for documenting patterns of PAH distribution actually established in the environment, but typically provide limited information about specific source inputs in a given location. Product-based studies can serve to identify locally relevant sources, but typically have limited resolution to evaluate relative inputs from numerous sources in larger systems. And, the types of controlled monitoring programs that can provide empirical information on the connections between specific sources and environmental load in an urban area are large, expensive and time-consuming. As a study design tool to help optimize monitoring programs, we first developed bounding estimates based on available literature for inputs that affect relative mass loading from long-range atmospheric, local combustion, traffic and pavement sealer sources of PAHs. We then used Monte Carlo-type simulations varying water body sizes, flow regimes and rainfall patterns, along with the ranges of values for the PAH input sources, to get a probabilistic sensitivity analysis. The output shows that critical factors include traffic density, rainfall washout patterns and the size of sealed parking lots relative to streams receiving uncontrolled runoff. These findings are useful in targeting streams and urban setting characteristics to monitor how municipal pavement sealer bans affect overall PAH exposure.

TP158 Polycyclic Aromatic Hydrocarbons Analysis Using Chemical Mass Balance Model C. Julias, CDM, CDM, Chemical Engineer; C. Liu, N. Luke, CDM. Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous organic chemicals that persist in the environment. PAHs are formed through an incomplete combustion of most organic material and also occur naturally at low levels in crude oil and coal. Elevated concentrations of PAHs were found in soils in residential areas near an inactive chemical facility. The Chemical Mass Balance model (CMB-8.2) developed by the United State of Environmental Protection Agency is used to identify the source(s) of anthropogenic PAH contamination in the residential areas. CMB model is a fundamental receptor model based on the use of the mass balance concept. Twelve parent PAHs are used in the CMB modeling because all 12 are frequently detected in soil samples and are included in many source profiles available in the literature. Concentrations of the 12 PAHs and total PAH for individual samples are used to generate PAH source profiles that are entered into the model. The CMB model consists of a least squares solution to a set of linear equations which expresses each receptor concentration of a chemical species as a linear sum of products of source profile species and source contributions. The model assumes that: (1) the composition of each source emission is consistent over the period represented by receptor data, (2) chemical species do not react with each other or with the environment, (3) all sources that contribute significantly to the receptor have been identified and their chemical profile is known, (4) the composition of each source is linearly independent of other sources, and (5) measurement uncertainties are random, uncorrelated, and normally distributed. The CMB model attempts to derive source profiles from the covariation in space and/or time of many different samples of atmospheric constituents that originate in different sources. These profiles are then used in a CMB solution to quantify source contributions to each ambient sample. As a result, the CMB model is used to determine whether historical processes at the chemical facility that may relate to the deposition of contaminants in the residential areas.

TP159 Managing Risks: Will Banning Pavement Sealers Have the Desired Effect? K. O'Reilly, Exponent; J. Pietari, Exponent Inc.; P. Boehm, Exponent, Environmental & EcoScience Group, Exponent, Environmental Group, Exponent, Inc., Environmental & EcoScience sGroup. The USGS and others have raised the concern that refined tar pavement sealers are a significant source of polycyclic aromatic hydrocarbons (PAHs) in urban sediments. The researchers involved have been actively advocating product bans at the federal, state, and local level. While outlawing the use of an established product is one means of managing risks, it should be implemented only if it will have the desired effect. The USGS hypothesis is based in part on the similarity in PAH profiles between sealers and sediments. Our recent work has demonstrated that this profile is not unique, but common to a range of environmental particles that become entrained in sediments. Inconsistencies in the results of different forensic methods applied to the data used by the USGS further weaken their hypothesis. This presentation focuses on an evaluation of three urban water bodies, from the west coast, midwest, and east coast. Inclusion of these data in USGS publications has led to actual or proposed product bans. In each case, the water bodies are in air sheds that are part of atmospheric source studies. Forensic comparison of the PAH chemistry of the sediments, regional depositional particles, and sealers indicates that the sealers are not a controlling factor. The results suggest that implementing a sealer ban will not result in a change in local sediment chemistry. The implication of these findings in setting policies for risk management will also be discussed.

TP160 Analytical and Relative Potency Factor Approach for Effective Evaluation of Polycyclic Aromatic Hydrocarbons for Risk Assessment E. Krupka, S. Kirchner, V. Macwan, CDM. Polycyclic aromatic hydrocarbons (PAHs) are chemicals that include organic compounds containing either two or more, or three or more, fused rings made up of hydrogen and carbon atoms. PAHs are persistent and primarily occur in the environment as complex mixtures produced from the incomplete combustion of substances containing hydrocarbons. Using a weight-of-evidence approach, the United States Environmental Protection Agency (EPA) has determined that 24 PAHs are carcinogenic based on toxicological similarities to the indicator compound benzo[*a*]pyrene. EPA has proposed using a relative potency factor (RPF) approach for estimating the cancer risk of PAH mixtures by summing doses of component PAHs using scaled doses of the individual PAHs relative to the potency of benzo[*a*]pyrene. Previously, RPFs were developed for seven carcinogenic PAHs by EPA in 1993. In this paper PAH analytical methods are compared for their potential effectiveness to yield useable data to evaluate all 24 carcinogenic PAHs necessary for the EPA's proposed RPF approach for use in risk assessment. The application of the methods for specific matrices, target compounds, quality control procedures, and reporting limits are evaluated and presented to add better understanding of analytical methods for data end users such as risk assessors. This information will assist in the selection of the appropriate method that can be applied to their study. Particular attention is paid to the method reporting limits and the analytical and sample matrix factors that affect data evaluation and application in risk assessments. Controlling the variables associated with method reporting limits is instrumental in enhancing the effectiveness of the data when applying derived results to the PAH mixture risk evaluation.

TP161 Passive Dosing of Terrestrial Springtails – Linking Toxicity of PAHs and PAH Mixtures to Their Chemical Activity S.N. Schmidt, Aarhus Univ, NERI, Environmental Chemistry and Microbiology; M. Holmstrup, Aarhus Univ, NERI, Terrestrial Ecology; K.E. Smith, P. Mayer, Aarhus Univ, NERI, Environmental Chemistry and Microbiology. The chemical activity of organic soil contaminants has been proposed as an exposure parameter that quantifies the potential, direction and extent for psysicochemical processes such as diffusion, partitioning and chemical

reactions. Thus, the partitioning of organic soil contaminants into soil living organisms is driven by their chemical activity. Passive dosing with the silicone poly(dimethylsiloxane) (PDMS) was used to control defined chemical activities of six polycyclic aromatic hydrocarbons (PAHs) and their mixtures in bioconcentration and toxicity tests with the terrestrial springtail Folsomia candida. The test animals could move freely on the PDMS loaded with PAHs, resulting in exposure through direct contact and saturated air. This presentation will summarize the results from bioconcentration and toxicity tests with single PAHs and their mixtures: (1) The uptake kinetics of naphthalene, anthracene, pyrene, benz(a)anthracene and benzo[*a*]pyrene were studied in bioconcentration experiments. The PAHs were extracted from springtails, and the extracts were analysed by high performance liquid chromatography with fluorescence detection. The results showed that stable equilibrium concentrations were reached for naphthalene, anthracene and pyrene within 7 days, and the three PAHs were therefore selected for two acute toxicity tests (7-days tests). (2) Naphthalene, phenanthrene (the toxic isomer of anthracene) and pyrene were tested at a wide range of chemical activities in order to establish chemical activity response relationships, and in order to determine effective chemical activities (La-50) for these three compounds. Single PAH lethality was successfully linked to chemical activity (a), and the three La-50's were all within a narrow range of chemical activity (0.019-0.052). (3) Finally, the springtails were exposed to 12 PAH mixtures with naphthalene, phenanthrene and pyrene at defined chemical activities in order to relate the lethality to the sum chemical activity (∑a) of the PAH mixtures. The toxicity data of all tested mixtures were successfully fitted to one chemical activity response relationship (r2=0.89), and the La-50 of 0.027 was comparable to La-50's for single PAHs. In summary, passive dosing was successfully applied to control the chemical activity of PAHs and their mixtures in bioconcentration and toxicity tests. The toxicity of 12 PAH mixtures could be fitted to a single activity response curve when using ∑a as a novel exposure parameter.

TP162 Chlorinated Polycyclic Aromatic Hydrocarbons from the Combustion of Polyvinyl Chloride and Polyvinylidene Chloride Y. Miyake, Univ of Shizuoka, Institute for Environmental Sciences; L. Tang, Univ of Shizuoka; Y. Fujimine, Otsuka Pharmaceutical Co. Ltd.; Y. Horii, Center for Environmental Science in Saitama; T. Amagai, Univ of Shizuoka. Chlorinated polycyclic aromatic hydrocarbons (ClPAHs) such as chlorobenz[a]anthracene and Chlorobenzo[*a*]pyrene have received worldwide attention because of their environmental persistence and widespread distribution. Recent reports have showed the occurrence of chlorinated or brominated polycyclic aromatic hydrocarbons in flue gas and fly ash from municipal and industrial waste incinerators. However, little is known about ClPAHs formation from combustion of chlorinated polymer such as polyvinyl chloride and polyvinylidene chloride alone or the influence of chlorinated polymer as a chlorine source in municipal and industrial waste incinerators. In this study, emissions evolved from the combustion of polyvinyl chloride and polyvinylidene chloride were studied between 500 to 1000°C in a cylindrical furnace with a diameter of 28 mm and a length of 405 mm, in order to analyse the influence of both temperature and materials on the by-products such as ClPAHs. Twenty individual ClPAHs, representing mono- through trichloroPAHs, were determined to be from the following: chlorofluorene (ClFle), chlorophenanthrene (ClPhe), chloroanthracene (ClAnt), chlorofluoranthene (ClFlu), chloropyrene (ClPyr), chlorochrysene (ClChr), chlorobenz[a]anthracene (ClBaA), and chlorobenzo[*a*]pyrene (ClBaP).

TP163 Effects of Bioremediation on Toxicity and Genotoxicity of PAH-contaminated Soil Using Genetically Engineered DT40 Cell Lines J. Hu, J. Nakamura, S.D. Richardson, M.D. Aitken, Univ of North Carolina at Chapel Hill, Dept of Environmental Sciences & Engineering. Bioremediation is one of the commonly applied remediation strategies at sites contaminated with polycyclic aromatic hydrocarbons (PAHs). However, it remains controversial whether bioremediation could reduce health risks while removing the target compounds. This study investigated changes in the toxicity and genotoxicity of PAH-contaminated soil from a former manufactured-gas plant site before and after two simulated bioremediation processes: treatment in a laboratory sequencing batch reactor system and a long-term, continuous-flow column system. Toxicity and genotoxicity of the residues from soil extracts were determined by multi-well plate-based DNA damage response analysis using the chicken DT40 B-lymphocyte isogenic cell line and its DNA-repair deficient mutant cell lines. The results demonstrated that both bioremediation processes can significantly remove PAHs from the contaminated soil (bioreactor 52% removal; biostimulated column 63% removeal). However, the bioreactor treatment resulted in an increase of toxicity and genotoxicity, whereas long-term column treatment resulted in a decrease of toxicity and genotoxicity. The LD_{50} for DT40 and the RAD54 mutant decreased from 1.31±0.08 μg/mL and 0.53±0.10 μg/mL, respectively, to 0.60±0.03 μg/mL and 0.12±0.02 μg/mL, respectively in the bioreactor The LD_{50} for DT40 and RAD54 increased from 2.36±0.17 μg/mL and 1.25±0.01 μg/mL to 8.61±0.17 μg/mL and 3.48±0.10 μg/mL, respectively in the biostimulated column. We also found that when controlling $1/C_{tPAHs}$, the partial correlation between LD_{50} values and $1/C_{residue}$ was statistically significant ($p < 0.01$); but when controlling $1/C_{residue}$, the partial correlation between LD_{50} values and $1/C_{tPAHs}$ was not statistically significant. Furthermore, when screening the column soil with a battery of DT40 mutants for genotoxicity, the results showed that mutant XPA was not sensitive to either untreated soil or treated soils; mutants RAD9, RAD17, MSH2, RAD54, RAD18, PCNA, REV1 and POLQ were sensitive to both untreated and treated soils; mutants POLB, FEN1, KU70, REV3, POLK and POLH were only sensitive to treated soils but not to untreated soil. These results suggest that bioremediation does not necessarily reduce the toxicity and/or genotoxicity of PAH-contaminated soil, and that different bioremediation processes can have different effects on toxicity or genotoxicity.

TP164 PAH Body Residues and Lysosomal Membrane Destabilization in Mussels Impacted by *T/V Dubai Star* Oil Spill H. Hwang, Univ of California, Davis, Dept of Civil and Environmental Engineering, Univ of California, Dept of Civil and Environmental Engineering; B. Stanton, California Dept of Fish and Game; T. McBride, US Fish and Wildlife Service; M. Anderson, California Dept of Fish and Game. A fuel oil spill from the *T/V Dubai Star* occurred in San Francisco Bay on October 30, 2009. It is important to assess the impacts of spilled oil on living organisms in a timely manner considering that evidence such as body residues and biological responses can diminish over time as the levels of various toxic chemicals in the water column decline by dilution and natural weathering. Mussels were collected over three months from the eastern shorelines of the central bay for the measurement of PAHs and lysosomal destabilization. PAH body burdens increased sharply and declined exponentially during 90 days of the study period. Environmental half-life of PAH body residues was 16 days. PAH body residues were above critical body residue (2,100 ng/g dry wt.) in some highly impacted sites. Lysosomal destabilization exhibited a positive correlation with PAH body residues. Though sample size is small, this study demonstrates that lysosomal destabilization could be used successfully as a rapid, cost-effective screening tool to identify exposure to and potential injury by spilled oil as well as help guide further possible damage assessment studies.

TP165 Classifying Environmental Hazards under CLP – Incorporating Science and Best Practices J. Small, Merck & Co., Inc., Global Safety and the Environment, Merck & Co., Inc.; G. Gagliano, L. Ziv, J. Tell, K. Silverman, Merck & Co., Inc., Global Safety & the Environment. On January 20, 2009, Regulation (EC) No 1272/2008 on the classification, labeling and packaging of substances and mixtures (CLP), replaced the Dangerous Substance Directive 67/548/EEC and the Dangerous Preparations Directive 1999/45/EC. CLP is part of the Globally Harmonized System (GHS) of Classification and Labeling of Chemicals in the European Union (EU) and is aligned with EU legislation already in existence. The system is designed to facilitate international trade of chemicals and to maintain existing levels of protection for human health and the environment. One of its main intentions was to introduce consistency in how chemicals are classified and labeled. However, our initial experiences have revealed potential shortcomings in the guidance that could result in misinterpretation, and a final result that is not harmonized. These inconsistencies in classification can have implications for downstream users (customs officials, shipping/transportation Depts, environmental scientists, first responders) unfamiliar with the parameters used for the classification assessment. The environmental classification system consists of five categories for labeling, and includes one acute toxicity category and three levels of chronic toxicity based on effect and/or lethal concentration values of various aquatic indicator species. The fifth category, labeled Chronic Aquatic Hazard Category 4, is known as the "safety net classification." This category was created to help classify compounds with ambiguous toxicity that may be a potential for concern. The guidelines outline certain parameters that places a compound in this category; however, they are not exhaustive and leave room for interpretation and professional judgement. Our experience has identified key decision points to consider

when classifying chemicals in order to reduce ambiguity and increase overall consistency among risk assessors. Critical to these decisions are consideration of more than just the acute toxicity to aquatic organisms, the octanol/water partition coefficient (kow) and/or bioconcentration factor (BCF) of a compound. We suggest also including environmental fate factors such as water solubility, ionization and degradability during classification assessments. Examples and lessons learned are presented.

TP166 ERA and Human Medicinal Product Marketing Authorization: Framework for an Optimized Risk Information Strategy L. Meisel, INFARMED; A. Pena, CEF, Faculty of Pharmacy, Univ of Coimbra, Coimbra, Helath Surveillance Group; N. Adler, UBA Umweltbundesamt. EU environmental policy is based on the precautionary principle and state that preventive action should be taken. Thus, in accordance with Article 8(3) of Directive 2001/83/EC the environmental risk for Human Medicial Products should be assessed. However, the evaluation outcomes does not constitute criterion for a Marketing Authorisation refusal. In this case, an understanding of risk and the application of risk assessment methodology is essential to being able to effenciently and effectively create minimisation, safety measures which will be communicate in product labelling. Unfortunately limited data, essencially for "older" Human Medicinal Products make difficult to determine the likelihood of the risk and possible impact values. Generally a standard statement is included in package leaflet as consumer information to appropriate disposal of unused pharmaceuticals. Moving to a more science-based ecological risk communication for the pharmaceuticals we developped a framework of an Optimized Risk Information Strategy (*what, whom and how*) for the Summary of Products Characteristics (health profissionals) as well as for Package Leaflet (consummers, public). As such, efforts will be made towards to collect valid information: (1) from quantitative or qualitative risk assessment; (2) from minimization measures considering particular vulnerabilities which apply to the different pharmaceutical groups e.g., cytostatic, antibiotics; (3) from fundamental precept information supporting, for instance, ocorrence, consumption in various EU member states. This strategy should comprise a part of an overall risk comunication aproach agreed upon outside manager parties to the information dissemination, during the use, waste phase of Human Medicinal Products.

TP167 Evaluation of a Method for Conducting OECD Testing for Transformation of a Material in an Aquatic Sediment System and Toxicity to a Benthic Organism C. Picard, Smithers Viscient, Sediment Ecotoxicology; S. McLaughlin, K. Malekani, Smithers Viscient, Environmental Fate and Metabolism; M.J. Bradley, Smithers Viscient, Sediment Ecotoxicology. The current European Medicines Agency risk assessment guidance calls for investigation of toxicity to sediment dwelling midge larvae (OECD 218 guideline) when greater than 10% of the test material partitions to the sediment at day 14 or later in sediment/water systems under aerobic conditions (OECD 308 guideline). The typical maximum exposure duration in the OECD 218 testing is 28 days. While this guidance may provide information on the toxicity of a parent compound to a sediment dwelling organism, it does not address the effects of a test material to sediment dwelling organisms over longer durations that may be encountered in the environment. Material may degrade in the sediment or bind tightly over longer periods of time potentially affecting the toxicity to sediment dwelling organisms. In this hybrid study design we attempt to achieve the following: (1) investigate the biological performance of midge larvae (*Chronomus riparius*) in two natural sediments historically used in OECD 308 testing and compare to performance in OECD formulated sediment. (2) characterize the microbial biomass in these natural sediments as well as the formulated sediment at various time points in order to compare as it pertains to degradation rates. (3) develop and validate a test method that investigates the transformation of a known test material applied to the water in the various sediment/water test systems over 100 days while synchronously exposing multiple populations of midge to the changing test system throughout the duration of the test. The typical biological endpoints of percent emergence and development rate will be measured on each midge population throughout the various phases of the study. This test method will theoretically provide information on the transformation of a test material in various sediment/water systems over time while also providing toxicity information as it regards to the parent compound as well as any metabolites that are produced throughout the 100 day test period. This test method could be used as a possible supplement to the typical OECD 308 and 218 guidelines.

TP168 Life-Cycle Exposure of *Daphnia magna* to Environmentally Relative Mixtures of Pharmaceuticals D.N. Wolfe, S. Richards, Univ of Tennessee at Chattanooga; M. Hanson, Univ of Manitoba. Due to the global detection of pharmaceuticals in surface water, risk assessments require toxicity testing to be preformed to close knowledge gaps for effects assessment regarding impacts on aquatic food web dynamics. The widespread use of pharmaceuticals has resulted in mixture concentrations of mg/l in effluent and ug/L concentrations in surface water. Their potential toxicological effect on fresh water ecosystems remains largely unknown, especially as complex mixtures. Toxicity data on the effect of pharmaceuticals has expanded in the past decade, but has mainly focused on single, acute pharmaceutical exposures, not environmentally realistic mixtures. By determining the threshold of response for environmentally relavant mixtures, the risk that these compounds may pose to the environment will be determined more accurately. In 2008, thirteen pharmaceuticals were quantified in the Tennessee River, USA and its tributaries, ranging from 0.1757 to 0.0028 ug/l. Using the same ratios of individual compounds, but increased concentrations, the present study conducted chronic life cycle toxicity test on the cladoceran *Daphnia magna.* Tests were performed using 10x, 100x and 1000x the concentrations detected in the Tennessee River, resulting in a total concentration of 6.031, 60.31, and 603.1 ug/l of total pharmaceutical exposure, respectfully. Mortality, time to first brood, size and fecundity were use as endpoints of toxicity. Test solutions were renewed three times a week and neonate removed each day until the conclusion of the experiment. *D. magna* showed a statistically significant decrease in the number of neonate produced when exposed to 100x and 1000x ($p < 0.003$). When *D. magna* was exposed to the 10x concentration, no significant decrease in neonate production was observed. Neither time to first brood nor size was affected at 10x, 100x, or 1000x. Studies are on going to pinpoint the threshold of effects occurring between 10x and 100x. These data will provide risk assessors more accurate data when analyzing non-lethal effects of pharmaceutical mixtures on aquatic ecosystems.

TP169 PhATE Model for Predicting Concentrations of Trace Organics in Sludges and Biosolids from Municipal Wastewater Treatment Plants (WWTPs) V.L. Cunningham, Sustainability Sciences LLC; V.J. D'Aco, Quantum Management Group, Inc.; D. Pfeiffer, Arcadis US, Inc.; P. Anderson, ARCADIS; M. Buzby, Merck & Co., Inc.; R.E. Hannah, GlaxoSmithKline; J.J. Jahnke, Merck & Co., Inc.; N.J. Parke, Eli Lilly and Company. PhATE™, now expanded to include sludges and biosolids, was originally developed to estimate potential concentrations of active pharmaceutical ingredients (APIs) in US surface and drinking waters that could result from patient use of medicines. The model estimates the mass of API in WWTP influent based on the population served, the API per capita use, and the potential loss of the compound associated with human use (e.g., metabolism). The mass of API on the treated biosolids is then estimated based on partitioning to primary and secondary solids, potential loss due to biodegradation in secondary treatment (e.g., activated sludge), and potential loss during sludge treatment (e.g., aerobic digestion, anaerobic digestion, composting, etc.). Simulations using two surrogate compounds show that predicted environmental concentrations (PECs) generated by PhATE are in very good agreement with measured concentrations, i.e., well within one order of magnitude. Model simulations were then carried out for 18 APIs representing a broad range of chemical and use characteristics. These simulations yielded four categories of results: (1) PECs are consistent with measured data for nine compounds with high analytical detection frequencies; (2) PECs are greater than measured data for three compounds with high analytical detection frequencies, possibly as a result of as yet unidentified depletion mechanisms; (3) PECs are less than analytical reporting limits for five compounds with low analytical detection frequencies; (4) the PEC is greater than the analytical method reporting limit for one compound with a low analytical detection frequency, possibly again as a result of insufficient depletion data. Overall, these results demonstrate that because of the concordance between measured concentrations and those predicted by PhATE, it has the potential to be a very useful tool in the evaluation of APIs in biosolids. Possible applications include: prioritizing APIs for assessment even in the absence of analytical methods; evaluating sludge processing scenarios to explore potential mitigation approaches; and developing realistic nationwide concentrations, since PECs can be represented as a cumulative probability distribution. Finally, comparison of PECs to measured concentrations can also be used to identify the need for fate studies of compounds of interest in biosolids.

TP170 Mercury Concentrations in Fillets of Fish Collected in the USEPA National Rivers and Streams Assessment of the Continental USA J.M. Lazorchak, US Environmental Protection Agency, Office of Research and Development, USEPA Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research Branch; E. OByran, J. Webb-Turbeville, Dynamac Corp c/o USEPA Office of Research and Development, National Exposure Research Laboratory; M. Crane, A.L. Batt, USEPA Office of Research and Development, National Exposure Research Laboratory; L.L. Stahl, J.B. Wathen, USEPA Office of Water, Office of Science and Technology. The National Rivers and Streams Assessment (NRSA) is a statistical survey of flowing waters of the US The purpose of this survey was to assess the condition of the Nation's rivers and streams, establish a baseline to evaluate progress of pollution control activities in flowing waters of the US, and generate statistically valid and environmentally relevant reports on the condition of the Nation's water resources. The survey measured a wide variety of variables intended to characterize chemical, physical, and biological condition. These variables included nutrients, chlorophyll-a, other water chemistry analytes, sediment enzymes, enterococci, fish tissue, physical habitat, and biological characteristics, including assessments of phytoplankton, periphyton, benthic macroinvertebrates, and fish communities. In 2008 and 2009, fish were collected from about650 streams and rivers, including a representative subset of 183 urban river sites. The USEPA analyzed fish fillets for 22 pesticides, 20 congeners of PCBs, 8 congeners of PBDEs, mercury, selenium, % lipids and % moisture. Mercury was detected in all samples and ranged from 14.8 to 1418.54 ng/g in the fish fillet samples, an unaverage concentration across all samples of 230.91ng/g and a median of 174.95 ng/g. Nearly 26% of the samples exceeded the EPA 300 ng/g screening value for recreational fishing and about 98% of the samples exceed a wildlife screening value of 30 ng/g. A statistical analyses and assessment from a national scale will be presented.

TP171 Comparison of Mercury and Selenium Concentrations in Whole Fish and Fillets Analyzed in Fish Collected in the Lower Mississippi River M. Crane, USEPA Office of Research and Development, National Exposure Research Laboratory; E. OBryan, J. Webb-Turbeville, Dynamac Corp c/o USEPA Office of Research and Development, National Exposure Research Laboratory; A. Batt, USEPA Office of Research and Development, National Exposure Research Laboratory; J.M. Lazorchak, US Environmental Protection Agency, Office of Research and Development, USEPA Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research Branch; T. Angradi, D. Bolgrien, USEPA Office of Research and Development, National Health and Environmental Effects Research Laboratory; L.L. Stahl, USEPA, Office of Water, Office of Science and Technology, Office of Science and Technology. The science and practice of environmental assessment have been advanced by research done by the EPA Office of Research and Development's (ORD) Environmental Monitoring and Assessment Program (EMAP). In short, the condition of a resource can be estimated from key chemical, physical, and biological measurements at relatively few sites. It is analogous to a public opinion survey where the responses of a few people provide estimates for the entire population. EMAP's statistical sampling designs and biological indicators are well developed. The Office of Water (OW) has adopted them for its national assessments of aquatic resources. As part of the USEPA National River and Streams Assessment (NRSA) and EMAP Great Rivers Projects, 13 urban sites and 43 non urban sites on the lower Mississippi River were sampled for fish to be analyzed for mercury and selenium in whole fish and fillets. In a previous EMAP GRE study, the upper Mississippi River was sampled but only whole fish samples were analyzed for Hg. EMAP-GRE focused on whole fish because of its emphasis on the health of the ecosystem. Although whole-fish contamination is primarily an indicator of risk to piscivorous wildlife, whole fish data are still relevant for estimating human risk from fish consumption. At each of the 56 sites, three fish samples were collected: a primary, a secondary sample and a sample for fillets. A comparison was made between whole fish secondary samples and fillets. Preliminary analyses indicates that whole fish levels of Hg were found to be from 19% less to 30% higher than fillets and selenium was found to be 13% less and 42% higher than fillets. A statistical analyses and assessment of whole fish and fillets concentrations vs. wildlife and human risk of consumption will be presented.

TP172 Form of Methylmercury Present in Diet Does Not Affect Bioaccumulation in Various Tissues in the Zebra Finch (*Taeniopygia guttata*) C.W. Ramos, M. Whitney, J.P. Swaddle, D.A. Cristol, College of William and Mary. Most methylmercury in living organisms is found bound to the amino acid cysteine. In this form it can be readily taken up by tissues, incorporated into proteins, and is even actively transported across the blood brain barrier. Although methylmercury-cysteine is the most common form of mercury in natural food webs, most methylmercury dosing experiments use methylmercury-chloride, a commercially available salt. It is unknown whether these compounds may behave differently within an organism. In this study we investigate whether the form of methylmercury presented in the diet affects bioaccumulation of mercury in various tissues in the Zebra Finch (*Taeniopygia guttata*), particularly focusing on whether the more natural form, methylmercury-cysteine, may more easily pass into the brain or into the egg. Birds were maintained on a diet containing either methylmercury-cysteine or methylmercury-chloride at one of two levels (0.5 ppm or 1.0 ppm) for 10 weeks until blood mercury levels stabilized. The birds were then allowed to breed and eggs were collected for mercury analysis. After approximately 25 weeks, the birds were humanely sacrificed and mercury levels were measured in the blood, brain, liver, kidney and muscle. There was no difference in the amount of bioaccumulation of mercury between the two forms in any of the tissues measured. It is possible that because of methylmercury's high affinity for cysteine, it becomes quickly associated with cysteine during the digestion process. These results suggest that the form of mercury used in dietary dosing experiments has little effect on levels of mercury bioaccumulation in tissues throughout an organism.

TP173 Study Design and DQO for Development of Plant and Invertebrate Preliminary Remedial Goals for the US Dept of Energy Hanford Site C. McCarthy, CH2M Hill, Environmental Services; B. Sample, Ecological Risk, Inc.; J. Lowe, CH2M HILL Plateau Remediation Company; A. Aly, Interra; J. Hansen, United States Dept of Energy. The US Dept of Energy, Hanford Site has soil concentrations of non-radioactive chemicals that exceed the State of Washington and EPA plant and invertebrate screening levels. However, these screening levels may not reflect Hanford Site specific conditions. A study was designed to: (1) perform plant and soil invertebrate bioassays on field-collected soils, 2) perform detailed soil chemistry analyses on these samples, and (3) integrate the chemistry and effects data to identify analyte specific thresholds for effects reflective of the Hanford Site. A three-step process was employed to identify sample locations representing a range of soil analytical chemistry and geochemistry present throughout the site: 1) low, medium, and high priority analytes were identified; 2) low, medium, and high target concentration ranges were established for priority analytes through comparison of site data to existing screening values, background, and cleanup goals; and 3) historic data were reviewed to identify possible sampling locations with contaminant levels within the target concentration ranges. To optimize the number of bioassay samples within established target concentration ranges, the analytical chemistry and bioassay samples were collected in one mobilization with the bioassay samples being archived until the chemical analysis was complete. Analytical chemistry and geochemical data (pH, TOC, CEC, grain size) were then reviewed to select a subset of samples for bioassays. Bioassays were not performed on samples with detections of pesticides or herbicides or field controls with measured concentrations above background. The selected bioassays included Sandberg bluegrass (Poa secunda) 14 day post germination and 28 day growth bioassays and springtail (Folsomia candida) 28-day reproduction and survival bioassays. These tests were selected for their broad applicability to all terrestrial environments found at the Hanford Site. The study design's analytical approach calls for: establishing significance of observed effects relative to field controls; analysis of paired chemical, geochemical and bioassay data to identify dose-response relationships, linear regression analysis, establishment of NOECs, LOECs, 20 and 50 percent effects levels; and multivariate analysis as warranted.

TP174 Ecotoxicological Assessment of Arsenic and Lead Contaminated Soils in Former Orchards at the Hanford Site D. Delistraty, Washington State Dept of Ecology, Washington State Dept of Ecology; J. Yokel, Washington State Dept of Ecology. The purpose of this study was to assess ecotoxicity of former orchard soils contaminated with lead arsenate pesticides at the Hanford Site in Washington state (USA). Surface soil, plant, and invertebrate samples were collected from 11 sites in former orchard areas near the 100-H Area during May and August 2010. Mean (standard deviation [SD]) As and Pb concentrations in soil were 39.5 (40.6) and 208 (142) mg/kg dry weight (dw), respectively (n=11). As and Pb concentrations

in surface soils were positively and significantly correlated (r=0.87, P< 0.05). Speciation of total inorganic As in soil (n=6) demonstrated that mean As+5 was the dominant form (>99%), whereas mean As+3 was minor (< 1%). Mean (SD) As and Pb in cheatgrass were 3.91 (7.89) and 12.4 (20.0) mg/kg dw, respectively (n=11), while mean (SD) As and Pb in darkling beetles were 5.37 (2.64) and 3.87 (2.95) mg/kg dw, respectively (n=8). Simple linear regressions were constructed to estimate soil to plant uptake for As and Pb, as well as soil to invertebrate uptake for As and Pb. Regressions were significant (P< 0.05) only for soil vs. plant (As) and soil vs. invertebrate (Pb). Standardized lettuce seedling and earthworm bioassays were performed with a subset of soil samples (n=6). No significant effects (P>0.05) were observed in lettuce survival or growth nor in earthworm survival or sublethal effects, relative to negative laboratory controls. In particular, metallothionein (a protein biomarker for metal exposure) in these earthworms showed no significant difference (P>0.05), relative to its control. Based on these bioassays, unbounded NOECs in soil for As and Pb were 128 and 390 mg/kg dw, respectively, representing the maximum soil concentrations observed in our study. These NOECs are applicable only to former orchard soils at Hanford (due to limited soil sampling), and their associated uncertainty relates in part to an incomplete dose-response relationship with non site-specific test organisms. Data from the literature demonstrated that mean As and Pb soil concentrations exceeded Hanford background levels but were similar to other orchard soils. Furthermore, although mean As and Pb soil concentrations were below bioassay-derived NOECs in this study, mean soil concentrations were in the range of ecotoxicological benchmarks reported in the literature.

TP175 Pentachloronitrobenzene/Quintozene in the Great Lakes L.M. Jantunen, Environment Canada; J. Struger, Environment Canada, Water Science and Technology Directorate; K. Su, K. Brice, Environment Canada; H. Hung, Environment Canada, Science and Technology; S. Backus, Environment Canada. Pentachloronitrobenzene (PCNB), the active ingredient in quintozene, is a fungicide de-registered for usage in Canada and the USA. in December 2010, although existing stocks can be used through December 2011. Its main usage is to control mould on golf courses. In contrast to other pesticides, quintozene is applied to golf courses in late fall and early spring. Due to its solubility and vapour pressure, it is expected to be found in air and water around the Great Lakes. Thirteen Lake Ontario tributaries were sampled monthly starting in October 2010 and three Lake Huron tributaries were added in May 2011. The highest level was found at Spencer Creek in December 2010 at 187 ng/L, this creek runs through a golf course. Other water samples sites showed spikes in the late fall/early winter where some sites showed spikes in February/March. Additionally, the Integrated Atmospheric Deposition Network (IADN) investigated PCNB in air at three Canadian sites from January 2004 to the present. The sites were in rural areas: Point Petre is on the north shore of Lake Ontario, Burnt Island is in northeastern Lake Huron and Egbert is an agricultural site not situated on a lake. Egbert had the highest median air concentration of PCNB (32 pg/m3), followed by Point Petre (14 pg/m3) and the lowest levels were seen at Burnt Island (6.8 pg/m3). As with the water measurements, PCNB also showed seasonality, with the lowest levels in June to October at all three sites. Levels were highly variable during other times of the year, showing spikes with a maximum concentration in November 2006 of 2.9 ng/m3 at Egbert.

TP176 Acute Toxicity of Five Fungicides to Select Freshwater Invertebrates J.L. Kunz, USGS; C. Ingersoll, USGS, Columbia Environmental Research Center; R.D. Calfee, USGS, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center; E. Little, USGS, Columbia Environmental Research Center; K. Kuivila, K.L. Smalling, US Geological Survey. The objective of this study is to conduct a series of acute toxicity range-finding tests using five fungicides and select freshwater aquatic invertebrates, given the limited availability of toxicity data for invertebrates other than cladocerans. Results of these studies will be used to identify species and fungicides that might be evaluated in more definitive acute toxicity tests or in chronic water-only or chronic spiked-sediment toxicity tests. Given the modes of action through which fungicides exert toxic effects (e.g., disruption of mitosis, suppressed respiration, altered lipid and protein synthesis), these chemicals will likely exhibit toxicity to a broad range of taxa. Five fungicides with unique modes of action, included in parentheses, are being evaluated: (1) azoxystrobin (respiration); (2) boscalid (respiration) (3) myclobutanil (sterol biosynthesis in membranes); (4) iprodione (signal transduction/osmoregulation/oxidative damage); and, (5) propiconazole (sterol biosynthesis in membranes, demethylase inhibition (CYP450). The high concentrations (10x reported LC50s for cladocerans) for the 5 fungicides of interest ranged from 259 to 110,000 ug/L. The test organisms being evaluated include: (1) Cladocerans (*Ceriodaphnia dubia*, *Daphnia magna*); (2) Amphipods (*Hyalella azteca*); (3) Mayflies (*Hexagenia* spp.): (4) Midge (*Chironomus dilutus*, *C. riparius*); (5) Mollusks (mussels, *Lampsilis siliquoidea*; snails *Lymnaea stagnalis*); and, (6) Oligochaetes (*Lumbriculus variegatus*). Endpoints being evaluated include: (1) 48-h survival after exposure to select fungicides spiked in water and (2) 4-h survival after a subsequent pulse exposure to 25 μW/cm2 UV lighting to assess potential photo-enhanced toxicity of UV to exposed invertebrates.

TP177 Assessment of Aerial Fungicide Application Drift and Toxicity to Freshwater Organisms B. Holzer, Oklahoma State Univ, Dept of Zoology, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology; M. Lydy, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology; J.B. Belden, Oklahoma State Univ, Dept of Zoology. Previous studies indicate that strobilurin fungicides are toxic to freshwater fish and invertebrates, as well as amphibians. The foliar fungicide Quilt Xcel™, which contains the active ingredients propiconazole (triazole fungicide) and azoxystrobin (strobilurin fungicide), is applied one to two times per growing season to prevent disease in cereal crops and legume vegetables. Because this fungicide is often applied aerially, there is potential for spray drift to contaminate adjacent untreated fields as well as nearby aquatic systems. Additionally, if the fungicides reach the ground following application, they may subsequently enter aquatic systems in runoff. Although propiconazole and azoxystrobin have been shown to cause low to at moderate toxicity (respectively) to freshwater aquatic organisms, very little information is available concerning chronic and joint toxicity. Furthermore, limited information is available for nontarget fungi. The objectives of this study were to: monitor fungicide application and potential aerial drift to corn and soybeans at varying vertical locations from plant canopy to soil in both treated and adjacent untreated fields; assess the effect of the fungicides on soil fungal activity; assess the potential of aerially applied fungicides to contaminate nearby aquatic systems in a post-application runoff event; and assess toxicity of propiconazole and azoxystrobin individually and as a mixture to freshwater aquatic organisms including *Hyalella azteca*, *Daphnia pulex*, *Danio rerio*, and *Pimephales promelas* using chronic endpoints.

TP178 Acute Toxicity of Three Strobilurin Fungicide Formulations and Their Active Ingredients in Tadpoles E.A. Hooser, S.T. McMurry, J.B. Belden, Oklahoma State Univ, Dept of Zoology; L.M. Smith, Oklahoma State Univ. In the past decade, field applications of strobilurin fungicides has sharply increased due to disease outbreaks and proclaimed plant yield benefits. Although not labeled for aquatic systems, spray drift, overspray, and runoff during storm events can result in pesticide input in adjacent non-crop areas, including wetlands embedded in agricultural fields. Active ingredients (AIs) in some fungicide formulations have shown acute toxicity to selected aquatic organisms at environmentally relevant concentrations. In addition, a recent study demonstrated acute toxicity of formulations to amphibian larvae at and below environmentally relevant concentrations. However, there is a lack of comparable data for toxicity between AIs and formulations. Adjuvant chemicals, which may have toxic effects separate from AIs, are the majority component of formulations. The mode of action for strobilurins is not specific to fungi as they bind to mitochondria and inhibit cellular respiration and ATP acquisition, thus there is potential for having deleterious effects on non-target species. However, adjuvant chemicals have an unrelated mode of action specific to the formulation, which may also cause toxicity. Expanding upon previous investigations, acute toxicity of Headline®, Stratego®, and Quilt® and their AIs (pyraclostrobin, trifloxystrobin & propiconazole, and azoxystrobin & propiconazole, respectively) were tested separately using mortality as the endpoint. Comparisons of mortality responses were made using Great Plains toads, *Bufo cognatus*, as the model species because of its high probability of being exposed and its ability to be a good surrogate for other *Bufo* species. Tadpoles were exposed to four concentrations of fungicides for 96 hours to assess the dose-response relationship, to determine 96hr-LC_{50} values, and to compare the toxicity of AIs and formulations at multiple concentrations. Mortality responses were recorded after 24, 48, 72, and 96 hours. This experiment will help further refine our understanding of toxicity responses observed in previous studies

on Great Plains toads by elucidating the role of AIs versus other formulation ingredients.

TP179 Asymmetric Patterns of Cranial Skeleton of Zebrafish Induced After Exposure to NaPCP in different Embryonic Developmental Stages F. Lopez-Romero, Escuela Nacional de Ciencias Biológicas-I.P.N.; G. Zuniga-Bermudez, Instituto Politecnico Nacional, Escuela Nacional de Ciencias Biológicas; F. Martinez-Jeronimo, Escuela Nacional de Ciencias Biológicas-I.P.N., Zoology, E.N.C.B.-I.P.N. Organisms with bilaterally symmetry produce a reflected morphological copy in both sides of their body, which develops under control and regulation of the same gene array. Environmental factors influence the phenotype and the exposure to teratogenic pollutants produce disruption in development when a specific developmental stage is exposed. Sublethal toxicity tests were conducted at different developmental stages (zygote-blastula, blastula-gastrulation, gastrulation-segmentation, segmentation-pharyngula, and pharyngula-larva) of zebrafish (*Danio rerio*), exposing to the non-observable effect concentration (NOEC) of the pesticide Sodium Pentachlorophenate (NaPCP), to find susceptibility windows. Shape variation in the viscero-cranium induced by NaPCP was estimated as Fluctuating Asymmetry (FA) (which is thought to increase with environmental stress), using geometric morphometric techniques, which eliminate differences in size and evaluates only changes in shape. A Procrustes ANOVA was done from a symmetric consensus, measuring variation around this consensus for the following factors: Individual variation in shape (Individuals), side variation (Sides), Individuals x Sides interaction (FA), and the effect for exposure in the developmental stage (Stage). Individual variation, Stage and FA were the factors which accounts for most of the variation ($p< 0.0001$). The exposure window comprising Segmentation to Pharyngula exhibited more deformities among all the structures in viscero-cranium. Results suggest that NaPCP might disrupt signaling pathways involved in the development of cranial skeleton and osteogenesis.

TP180 Biomarkers to Access Metal Exposure in Estuarine Fish A. Machado, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas; J. Cardozo, E. Gomes, M. Muller Hoff, Universidade Federal do Rio Grande – FURG; A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. Several human activities have contributed to increase copper input into aquatic environments. In order to access aquatic health, environmental regulations usually establish the water quality criteria for copper based on its concentration in the water. However, biological impact associated with copper contamination usually cannot be inferred from this parameter. In this context, biomarkers can be useful tools to access potential impacts. However, there is a lack of information on biomarkers in tropical estuarine fish exposed to environmentally relevant concentrations of copper. In the present study a set of biomarkers were evaluated in the fish *Poecilia vivipara* exposed to waterborne copper (0, 5, 9 and 20 µg Cu/L) at salinity 24 ppt. Following exposure, whole body copper accumulation and ions concentration (Na, K, Ca and Mg) were measured. Superoxide dismutase activity (SOD) and lipid peroxidation (LPO) were evaluated in muscle, liver and gills. Nuclear anomalies were also accessed in erythrocytes. Copper accumulation and whole body Mg concentration were dependent on copper concentration in the water (r^2=0.60 and 0.94, respectively). However, whole body Na, K and Ca concentrations, muscle LPO, SOD activity (muscle, liver and gills), and frequencies of erythrocytes with bilobed nucleus, binuclei and apoptotic fragments were not affected by copper exposure. In the other hand, a nonlinear relationship was observed between budding in erythrocytes and copper concentration. Also, a linear correlation between water copper concentration and micronuclei frequency (r^2=0.85) in erythrocytes, liver LPO (r^2=0.80) and gill LPO (r^2=0.68) was observed. Taken altogether, results indicate that copper exposure is inducing physiological (whole body Mg concentration), biochemical (LPO) and genetic (micronuclei) damage in the tropical estuarine fish *P. vivipara*. These findings indicate that some biomarkers in different fish tissues are potentially suitable for monitoring ecologically relevant concentrations of copper in estuarine waters. Future studies will evaluate the reliability of the use of these biomarkers under field conditions. [Supported by the Brazilian CNPq (INCT-TA) and CAPES (Ciências do Mar)].

TP181 Incorporating the 3R's While Improving Bioaccumulation Assessments for Product Stewardship R. Hoke, DuPont, Haskell Global Centers; X. Han, DuPont, Haskell Global Centers, Haskell Global Centers; D. Nabb, R. Mingoia, DuPont, Haskell Global Centers. Product stewardship is an integral, on-going aspect of environmental programs at major corporations. Animal welfare concerns as exemplified by the 3R's are an important consideration in product stewardship testing and the evolution of regulatory testing guidelines. Intelligent testing strategies that incorporate tiered testing and evaluation schemes help guide efficient use of limited resources, including test organisms, and facilitate scientifically-based chemical evaluations to ensure achievement of product stewardship and environmental protection goals. An example of a tiered assessment framework for bioaccumulation assessment is presented that incorporates data mining, modeling, physical-chemical property measurements, in vitro assays, and in-vivo toxicity tests to provide an assessment of bioaccumulation potential in fish. Examples of the application and limitations of the framework for bioaccumulation assessments will be presented including an evaluation of the animal welfare benefits of the framework and suggestions for additional research to improve the framework.

TP182 Effects of Multi-walled Carbon Nanotubes on Germination, Growth, Water-use Efficiency and Photosynthetic Rate of Four Plant Species B. Shrestha, Texas Tech Univ, The Institute of Environment and Human Health, Dept of Environmental Toxicology, Texas Tech Univ; P. Payton, USDA-ARS; J. Canas, Texas Tech Univ, Dept of Environmental Toxicol. Very few studies have been conducted on the effects of CNTs on plants. Existing studies on toxicity of CNTs on plants have shown mixed results of no effect, increased germination and growth, and inhibition in root elongation. However, all of these studies were conducted under different conditions on different plant species, which makes it difficult to compare the varying results. Thus, it is significant to do an extensive study on the effects of CNTs on different plant species. C4 and C3 plants differ in their photosynthesis pathways. In addition, C4 plants are able to grow in high temperature, high light conditions and have greater water-use efficiency. Since the past studies demonstrated variation in toxic effects of CNTs in different plant species, it is significant to compare the difference in CNTs toxicity on plant species that differ in their photosynthetic pathways. A series of experiments were conducted on the effects of multi-walled carbon nanotubes (MWCNTs) on germination, growth, water use efficiency and photosynthetic rate of different plants in soil. Two locally grown C3 plants (alfalfa and cotton) and two C4 plants (corn and sorghum) were chosen for this study. The study was conducted at MWCNTs soil concentrations of 0, 10, 100, 1000 and 10000 mg/kg. In a preliminary study conducted in pot, alfalfa and cotton percent germination decreased from the control to the highest concentration (mg/kg) by 27% and 80%, respectively. However germination increased in cotton by 55% from controls to a medium concentration (100 mg/kg). However, in corn and sorghum grown in petri dishes, germination occurred more rapidly and germination increased by 100% and 175%, respectively, from the control to the highest concentration (10000 mg/kg). No effects were observed during the preliminary study on water-use efficiency in alfalfa. A root inhibition and germination study will be conducted in an incubator at 24 oC for five days with all four plant species. Total germinated seedlings and shoot and root lengths will be quantified at the end of each study. Plants (alfalfa, corn and cotton) will be grown for three months to evaluate the effects on photosynthetic rate and long term growth. Shoot length, visual symptoms of toxicity and photosynthetic rate will be measured every week for eight weeks. This study will provide valuable information on the effects of MWCNTs on different plant species and allow for a comparison of the effects of MWCNTs on C3 and C4 plants.

TP183 Flow Visualization Study of Interactions Between Nanoparticles and Air Bubbles S. Jeong, Kunsan National Univ, Dept of Environmental Engineering; J. Hur, Kunsan National Univ; A.A. Keller, Univ of California-Santa Barbara. Nanoparticles released into the environment can accumulate on the soil layers or infiltrate into the groundwater. Nanoparticles traveling through the environment may be hazardous to humans and the environment. Although nanomaterial hazards have been much researched recently, the transport and fate of nanomaterials in the environment have not received sufficient attention. Fate and transport of nanoparticles flowing through soil and groundwater would be affected by the presence of unsaturated conditions or air bubbles in the flow paths. This study investigated interactions between nanoparticles and air by analyzing visualizations of nanoparticle aggregation and deposition on the air-water. The 2-dimensional heterogeneous type porous medium was manufactured by etching glass plates. Suspended nanoparticles of fullerene and zinc oxide were separately injected into the partially saturated porous medium and their transport was

investigated as time elapsed. Air bubbles significantly affected transport of nanoparticles thorough the flow paths. Nanoparticles were easily deposited on the interfacial thin flow paths between solid grains and air bubbles, which significantly affected their transport. However, the intermittent movement of air bubbles accelerated nanoparticle transport through preferential flow paths and resulted in breakthrough of the nanoparticles.

TP184 Fundamental Assessment of Relationship Between Asian Dust and Influenza Infection-1: Immunotoxicity of Asian Dust for the Future Risk Analysis Y. Yoshioka, Osaka Univ, Laboratory of Toxicology and Safety Science, Graduate School of Pharmaceutical Sciences, Osaka Univ, The Center for Advanced Medical Engineering and Informatics; M. Fujimura, K. Yamashita, K. Higashisaka, Osaka Univ, Laboratory of Toxicology and Safety Science, Graduate School of Pharmaceutical Sciences, National Institute of Biomedical Innovation, Laboratory of Biopharmaceutical Research; Y. Morishita, Osaka Univ, Laboratory of Toxicology and Safety Science, National Institute of Biomedical Innovation, Laboratory of Biopharmaceutical Research; P. Huiyan, T. Ogura, H. Nabeshi, Osaka Univ, Laboratory of Toxicology and Safety Science, Graduate School of Pharmaceutical Sciences, National Institute of Biomedical Innovation, Laboratory of Biopharmaceutical Research; K. Nagano, Y. Abe, National Institute of Biomedical Innovation, Laboratory of Biopharmaceutical Research; H. Kamada, S. Tsunoda, National Institute of Biomedical Innovation, Laboratory of Biopharmaceutical Research, Osaka Univ, The Center for Advanced Medical Engineering and Informatics; M. Nasu, Osaka Univ, Laboratory of Environmental Science and Microbiology, Graduate School of Pharmaceutical Sciences; N. Itoh, T. Yoshikawa, Y. Tsutsumi, Osaka Univ, Laboratory of Toxicology and Safety Science, Graduate School of Pharmaceutical Sciences, National Institute of Biomedical Innovation, Laboratory of Biopharmaceutical Research. Asian dust has been public concern about their potential risks to human health. Epidemiological studies have suggested that increased levels of Asian dust are associated with adverse effects in the respiratory and cardiovascular systems. However the immunological mechanism of Asian dust-induced exacerbations of allergic airway diseases or viral infection is not fully understood. Therefore, it is essential to examine the biological effects of Asian dust for the prevention of Asian dust-related diseases. Here, we examined the inflammatory effects of Asian dust in vitro, and we investigated the mechanisms by which Asian dust-induced inflammation. Asian dust collected in China and soil collected in dust source region (Loess Plateau, China) were used. At first, we compared the inflammatory effects of Asian dust and soil of Loess Plateau in vitro. We incubated mouse macrophage cells, RAW264.7 cells, with Asian dust or soil of Loess Plateau and measured tumor necrosis factor-alpha (TNF) production in the culture supernatant, because TNF is a crucial modulator of inflammation. Asian dust induced higher production of TNF than did soil of Loess Plateau. In addition, purified particle from soil of Loess Plateau with a diameter < 10 _m induced higher production of TNF than did soil of Loess Plateau, indicating that small particles in Asian dust might possess a more potent inflammatory effect than did the larger particles in Asian dust. Next, to investigate the mechanisms of Asian dust-induced inflammation, we analyzed TNF production in RAW264.7 cells treated with Asian dust in the presence of an inhibitor of mitogen-activated protein kinases (MAPKs), such as ERK or JNK. Asian dust-induced TNF production was almost completely suppressed by the inhibitors, indicating that Asian dust-induced TNF production was mediated by ERK and JNK. Next, to investigate the involvement of reactive oxygen species (ROS) in Asian dust-induced TNF production, we measured the TNF production induced by Asian dust in the presence of ROS inhibitor. ROS inhibitor significantly suppressed Asian dust-induced TNF production, suggesting that Asian dust-induced production of ROS plays an important role in inflammatory responses. These results provide basic information for the prevention of inflammatory disease induced by Asian dust. Acknowledgement: This research was supported by the Environment Research and Technology Development Fund of the Ministry of the Environment, Japan.

TP185 Fundamental Assessment of Relationship Between Asian Dust and Influenza Infection-2: Biodistribution of Asian Dust for the Future Risk Analysis K. Yamashita, Osaka Univ, Laboratory of Toxicology and Safety Science, Graduate School of Pharmaceutical Sciences; Y. Yoshioka, Osaka Univ, Laboratory of Toxicology and Safety Science, Graduate School of Pharmaceutical Sciences, Osaka Univ, The Center for Advanced Medical Engineering and Informatics (MEI center); M. Fujimura, Osaka Univ, National Institute of Biomedical Innovation (NiBio); K. Higashisaka, Y. Morishita, H. Pan, T. Ogura, Osaka Univ, Laboratory of Toxicology and Safety Science, Graduate School of Pharmaceutical Sciences, National Institute of Biomedical Innovation (NiBio), Laboratory of Biopharmaceutical Research (LBR); H. Tsunoda, National Institute of Biomedical Innovation (NiBio), Laboratory of Biopharmaceutical Research (LBR), Osaka Univ, The Center for Advanced Medical Engineering and Informatics (MEI center); M. Nasu, Osaka Univ, Laboratory of Environmental Science and Microbiology, Graduate School of Pharmaceutical Sciences; N. Itoh, T. Yoshikawa, Y. Tsutsumi, Osaka Univ, Laboratory of Toxicology and Safety Science, Graduate School of Pharmaceutical Sciences, National Institute of Biomedical Innovation (NiBio), Laboratory of Biopharmaceutical Research (LBR) Summary: The health impact of Asian dust events has been public concern within China and in its neighboring countries. It is known that Asian dust is involved in many diseases such as allergic disease, cardiovascular disease or viral infection by epidemiological studies. However, little is known about detailed immunological mechanism of Asian dust-induced exacerbations of allergic airway diseases or viral infection. Therefore, it is essential to examine the biodistribution and biological effects of Asian dust for the prevention of Asian dust-related diseases. In this study, we examined the biodistribution and inflammatory effects of Asian dust in vivo. Asian dust collected in China and soil collected in dust source region (Loess Plateau, China) were used. At first, we examined the biodistribution of Asian dust and soil of Loess Plateau following intranasal injection by transmission electron microscope (TEM). BALB/c mice were treated with 30 μg/mouse of Asian dust or soil of Loess Plateau via intranasal injection. After 24 h, tissues and organs, such as lung, spleen, liver, brain and nasal cavity, were analyzed by TEM. TEM analysis revealed that small particles of soil of Loess Plateau were found in surface of alveolar epithelial cells. Furthermore, small particles of Asian dust were found in surface and cytosol of the alveolar epithelial cells. No particles were seen in the spleen, liver, brain and nasal cavity of mice treated with Asian dust or soil of Loess Plateau. However, purified particle from soil of Loess Plateau with a diameter

TP186 Influence of Multi-walled Carbon Nanotubes (MWNTs) on Sorption and Desorption of Polyaromatic Hydrocarbons (PAHs) in Soil S. Li, Texas Tech Univ/The Institute of Environmental and Human Health, Environmental Toxicology; T. Anderson, Texas Tech Univ/The Institute of Environmental and Human Health, 1002 Frankford #1122B; J. Canas, Texas Tech Univ/The Institute of Environmental and Human Health. Carbon nanotube (CNT) containing products are available in US markets and have various applications, such as coatings, computers, clothing, wastewater treatment plants, medical devices and pesticides. An increase in CNT applications leads to the potential for CNTs to be released into the environment in large amounts. Therefore, studies related to CNT effects on ecosystems to verify their safety are necessary and vital. Previous studies have provided valuable information regarding the interactions between CNTs and organic contaminants, including PAHs. However, few published studies illustrate such interactions in a soil environment, which could provide more useful information about what might happen in a real soil environment. Recent studies estimated that nanotube concentrations in soil would be a factor of 20 higher than that in water. Thus, there is a need for such studies to be conducted in a terrestrial environment. Sorption tests were conducted by batch equilibrium method at room temperature. Briefly, PAHs in HPLC-grade methanol were added to a background solution containing 5 mM CaCl2 and 1×10-5 mM HgCl2 to maintain a constant ionic strength and to inhibit microbial activity, respectively. Methanol concentrations were maintained at less than 0.1% (v/v) and pH was adjusted to pH 7.0 for all experiments. PAHs were added to 40 mL glass screw cap centrifuge tubes containing previously weighed samples. Tubes were agitated at 25 ºC in the dark at 250 rpm for four days and then centrifuged for 20 minutes at 10000g. Supernatant was removed using a glass pipette and replaced with fresh background solution. Tubes were then further agitated under the same conditions described above. One sequential desorption step was performed. Preliminary data showed the ability of MWNTs to adsorb phenanthrene

dramatically decreased in a sandy loam soil. Additional studies with more PAHs and soil types are currently being conducted.

TP187 Nanoparticle Toxicity and Bioavailability in *Hyalella azteca* Revealed by Ecotoxicogenomics H.C. Poynton, US Environmental Protection Agency, Molecular Indicators Research, Univ of Massachusetts-Boston, Environmental, Earth and Ocean Sciences; J.M. Lazorchak, US Environmental Protection Agency, Office of Research and Development, USEPA Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research Branch; C. Hering, The McConnell Group; C. Vulpe, Univ of California – Berkeley, Nutritional Science and Toxicology; J.K. Colbourne, Indiana Univ, and Mount Desert Island Biological Laboratory , The Center for Genomics and Bioinformataics; M.S. Sepulveda, Purdue Univ, Forestry & Natural Resources and School of Civil Engineering, Purdue Univ, Forestry & Natural Resources & Nanoparticles (NPs) are expected to make their way into the aquatic environment where sedimentation of particles will likely occur in most aquatic environments putting benthic organisms in these areas at particular risk. Therefore, organisms such as *Hyalella azteca*, an epibenthic amphipod which forages at the sediment surface, is likely to have a high potential exposure. Previous research has shown that *H. azteca* is several times more sensitive to zinc oxide (ZnO) NPs compared with the water column dweller, *Daphnia magna* perhaps due to the settling of the NPs. Once the particles settle on the sediment surface, sediment composition will likely play a role in the bioavailability and toxicity of the NPs. Understanding how water chemistry and sediment composition affects the bioavaibility of NPs will help to define which organisms and ecosystems are most vulnerable to nanomaterials. Recently, we developed an oligonucleotide microarray for *H. azteca*, to better understand the mechanism of toxicity of NPs to sediment-dwelling organisms and identify biomarkers of exposure to nanomaterials. Transcriptomic analysis was performed to reveal genes which respond specifically to ZnO NP and Ag NP exposure and can be used to distinguish exposure between the nanoparticles and their metal ions. Further development of these biomarkers will be used to assess the bioavailability of NP to *H. azteca* in sediments of varying composition.

TP188 Promotion of Antigen-specific IgE Production by Intranasally Administrated Nanosilica Particles in Mice T. Yoshioka, Graduate School of Pharmaceutical Sciences, Osaka Univ, Laboratory of Toxicology and Safety Science, Osaka Univ, The Center for Advanced Medical Engineering and Informatics (MEI_center); M. Fujimura, S. Tochigi, T. Hirai, M. Uji, K. Misato, Graduate School of Pharmaceutical Sciences, Osaka Univ, Laboratory of Toxicology and Safety Science, National Institute of Biomedical Innovation (NiBio), Laboratory of Biopharmaceutical Research (LBR); H. Takahashi, Graduate School of Pharmaceutical Sciences, Osaka Univ, Laboratory of Toxicology and Safety Science; A. Udaka, K. Ichihashi, T. Mori, T. Akase, H. Nabeshi, Graduate School of Pharmaceutical Sciences, Osaka Univ, Laboratory of Toxicology and Safety Science, National Institute of Biomedical Innovation (NiBio), Laboratory of Biopharmaceutical Research (LBR); K. Nagano, Y. Abe, National Institute of Biomedical Innovation (NiBio), Laboratory of Biopharmaceutical Research (LBR); H. Kamada, S. Tsunoda, National Institute of Biomedical Innovation (NiBio), Laboratory of Biopharmaceutical Research (LBR), Osaka Univ, The Center for Advanced Medical Engineering and Informatics (MEI_center); N. Itoh, T. Yoshikawa, Y. Tsutsumi, Graduate School of Pharmaceutical Sciences, Osaka Univ, Laboratory of Toxicology and Safety Science, National Institute of Biomedical Innovation (NiBio), Laboratory of Biopharmaceutical Research (LBR). With the recent development of nanotechnology, many nanomaterials (NMs) with innovative functions have been developed. For example, nanoparticles of titanium dioxide and silica have been used in commercial applications related to medicine, cosmetics and food. In particular, amorphous nanosilica particles (nSPs) possess extraordinary advantages, including straightforward synthesis, relatively low cost, and easy surface modification. nSPs are increasingly being used for many applications, including cosmetics, food technology, medical diagnosis. As the use of NMs increases, there is rising concern regarding their potential health risks because there is preliminary evidence that the unique electrical and mechanical properties of NMs is associated with undesirable biological interactions. However, few studies have assessed the role of the different physical characteristics of NMs, including nSPs, in allergic responses. Here, we examined whether intranasally-administered various sizes of silica particles have the capacity to promote allergic immune responses in mice. We used nSPs with diameters of 30 or 70 nm (nSP30 or nSP70, respectively), and conventional micro-sized silica particles with diameters of 300 or 1000 nm (nSP300 or mSP1000, respectively). Mice were intranasally exposed to chicken egg ovalbumin (OVA) plus various sizes of silica particles, and the levels of OVA-specific antibodies (Abs) in the plasma and the release profiles of cytokines from the splenocytes were determined. Intranasal exposure to OVA plus smaller nSP tended to induce a higher level of OVA-specific immunoglobulin (Ig) E, IgG and IgG1 Abs than did exposure to OVA plus larger silica particles. Splenocytes from mice exposed to OVA plus nSP30 secreted higher levels of Th2-type cytokines (IL-4, IL-5) than mice exposed to OVA alone. Taken together, these results indicate that nSPs below 100 nm can induce allergen-specific Th2-type immune responses in vivo. We believe that these data should provide basic information that can help risk analysis of NMs. Acknowledgement: This study was supported in part by Health Labour Sciences Research Grants from the Ministry of Health, Labor and Welfare of Japan. TP189 The Effects of Multi-walled Carbon Nanotubes on Soil Microbial Communities B. Shrestha, Texas Tech Univ, The Institute of Environment and Human Health, Dept of Environmental Toxicology, Texas Tech Univ; V. Acosta-Martinez, USDA-ARS; S. Cox, Texas Tech Univ, Dept of Environmental. Toxicolgy; J. Canas, Texas Tech Univ. Applications of nanomaterials, including carbon nanotubes (CNTs), are increasing; however, their impact on the environment is still not well understood. Microbial toxicity of CNTs in pure culture conditions has been reported, however, it is crucial to assess their risks beyond pure culture in an actual ecosystem A semi-arid agricultural sandy soil was treated with multi-walled carbon nanotubes (MWCNTs) at four different concentrations (10-10000 mgMWCNTs kg-1soil), and incubated with a control (soil only) in the dark at 23oC for 90 d. Soil microbial-basal respiration, enzymatic activities and microbial community structure were evaluated. There was no significant difference in soil basal respiration monitored every week for 28 d among the different treatment groups and control. Acid phosphatase activity was affected after 28 d, but no significant effects were observed on β-glucosidase and β-glucosaminidase activities. There was an overall decrease in all enzyme activities after 90 d; however, β-glucosidase and β-glucosaminidase activities were higher in the 10000 mgMWCNTs kg-1soil treatment than the control and other treatments. Also, the effect of MWCNT concentration on acid phosphatase activity observed on day 28 subsided after day 90. Dehydrogenase activity was very low in the 10000 mgMWCNTs kg-1soil treatment on days 28 and 90; however activity was lower in the controls than the 10- and 100 mgMWCNTs kg-1soil treatments on day 90. Separate tests demonstrated an interference of the MWCNTs (≥10000 mgkg-1soil) with the measurement of dehydrogenase activity by affecting absorbance of a color product. Total microbial biomass, determined with the sum of fatty acids methyl esters (FAMEs), was highest in the 10000 mgMWCNTs kg-1soil treatment for both 28 and 90 d samples. Principal component analysis of FAME profiles for both 28 and 90 d samples showed separation of 10000 mgMWCNTs kg-1soil treatment from the control along principle component 1(89% and 80% of variance respectively). This study suggests the presence of MWCNTs may cause shifts in soil microbial community structure and enzyme activities (Carbon and Nitrogen cycling). However, an extensive study is required with evaluation of other components of soil ecosystems to support the preliminary results. The study will be able to provide valuable information on the effects of carbon nanotubes on soil microbial communities, which will be valuable in risk assessments of carbon nanotubes.

TP190 Trophic Transfer of Au Nanoparticles Along a Simulated Terrestrial Food Chain J.M. Unrine, Univ of Kentucky, Dept of Plant and Soil Sciences, Univ of Kentucky, Dept of Plant & Soil Sciences; W.A. Shoults-Wilson, Roosevelt Univ, Dept of Biological, Chemical and Physical Sciences; O. Tsyusko, Univ of Kentucky, Dept of Plant & Soil Sciences. Recent studies have suggested that terrestrial environments will serve as the ultimate sink for several commonly used engineered nanoparticles (NPs),

primarily through application of sewage sludge applied as biosolids to agricultural soils. Little is known concerning the fate and adverse ecological effects of nanomateirals in terrestrial ecosystems. Our previous studies demonstrate that detritivores (earthworms) accumulate manufactured nanoparticles from soil in their tissues. In this study, we used Au NPs as a stable probe to determine if nanoparticles in soil can be taken up by detritivores (*Eisenia fetida*) and transmitted to carnivores (*Rana catesbeiana*) in a simulated laboratory food chain. Au NPs were used in order to circumvent difficulties involved in differentiating uptake of intact particles from dissolution products since they are redox stable under ambient conditions. We also tested the hypothesis that Au NPs are more bioaccumulative through trophic exposure than direct exposure by exposing bullfrogs to Au NPs either through the simulated food chain (soil-earthworm-bullfrog) or directly via oral gavage. Gold concentrations in soil were approximately 200 mg/kg. Accumulation of Au NPs in earthworms was characterized by a rapid increase in whole body concentrations for the first 10 days, followed by a rapid decrease in body concentrations over the subsequent 10 days. Whole body concentrations ranged from < 1 ug/g fresh mass on day one to 9.5 ug/g FM at the peak of uptake on day 10. Following transfer to clean soil media, body concentrations did not decrease over a 60 day period indicating slow or nonexistent elimination. Gold was detected in all of the organs of the exposed bullfrogs. The highest concentrations were found in spleen, and they exceeded 2 ug/g dry mass in some samples. The remaining organs had concentrations decreasing in the following order (intestine>kidney>stomach>liver>muscle) and ranged from 24.8 ng/g to 2.4 ug/g. The results demonstrate that, trophically exposed bullfrogs accumulated twice as much of the applied dose than the directly exposed bullfrogs. This suggests that nanoparticles are transformed in soil and/or along the food chain in a way that enhances their bioavailability. We did not observe evidence for biomagnification as in our previous study with tobacco horn worms.

TP191 Assessment of Immunological Health and Mercury Exposure in Common Loons of the Adirondack Mountains K. Grasman, Calvin College, Dept of Biology, Calvin College, Dept of Biological ; J. Singer, R. Abma, Calvin College, Dept of Biology; N. Schoch, Biodiversity Research Institute. Exposure of common loons (*Gavia immer*) to mercury through atmospheric deposition and biomagnification is a concern throughout the upper Midwestern and Northeastern US and Canada. This study assessed potential associations between mercury exposure and immune function in wild loons in the Adirondack Park of upstate New York using lymphocyte cryopreservation and in vitro proliferation assays. During 2008-09, loons were spotlighted and netted at night for collection of heparinized blood. During 2008 lymphocytes were isolated within six hours of collection using a slow spin technique at several centrifuge speeds to optimize lymphocyte collection. White blood cells were counted in the field using a hemacytometer using Natt-Herricks stain. The slow spin method (150xg) worked well in loons, although thrombocyte and heterophil contamination was higher than in other species. In both years lymphocyte samples were frozen in culture medium with 10% DMSO and stored in liquid nitrogen. Samples were thawed, and proliferation lymphocytes was induced via mitogens (phytohemagglutinin (PHA), Concanavalin-A (Con-A), lipopolysaccharide (LPS), and phorbol myristate acetate (PMA)). Proliferation was assessed by an ELISA measuring the incorporation of bromodeoxyuridine (BrdU) into newly synthesized DNA. Storage of lymphocytes for up to 22 months did not significantly reduce post-thaw viability. Proliferation assays demonstrated low replicate variability and high reproducibility. In adult loons lymphocyte proliferation indices were not directly associated with blood mercury, nor any other contaminants (selenium, DDE and PCBs). The proliferation of T lymphocytes in response to PHA + PMA was elevated nonsignificantly in low pH lakes (< 6.3) and significantly during 2009. Lakes sampled in 2009 had lower pHs than in 2008. In chicks, blood mercury showed nearly linear relationships with several lymphocyte proliferation indices, but evaluation of these potential relationships was hampered by low sample sizes. Hence, future investigations should emphasize greater sampling of loon chicks. Potential relationships between altered immune function and mercury exposure in young loons are consistent with the general sensitivity of the developing immune system to contaminants and with a previous laboratory study that demonstrated immunotoxicity of environmentally relevant exposures of mercury in young loons.

TP193 Effects of Environmentally Relevant Levels of Methylmercury on Flight Performance in European Starlings (*Sturnus vulgaris*) J.R. Carlson, D. Cristol, J. Swaddle, The College of William and Mary, Biology. Recent studies indicate that methylmercury bioaccumulates and biomagnifies in terrestrial habitats. Unusually high blood mercury has been reported in multiple passerine species living in contaminated areas, and in some cases these levels equaled or exceeded levels of piscivores in the same area. Despite these findings, little is known about the biological consequences of sublethal, ecologically relevant mercury levels in songbirds. Flight performance was analyzed in European Starlings (*Sturnus vulagris*) dosed with environmentally realistic levels of methylmercury-cysteine. Sixty birds were treated with dietary doses of 0.00ppm, 1.5ppm or 3.0ppm, but after four weeks on treatment three birds in the high dosage group died of kidney failure—an interesting result in itself. After two weeks off treatment, the levels were then adjusted to 0.00ppm, 0.75ppm, and 1.5ppm. Birds were tested pre-dosage and after their blood mercury levels plateaued for (1) Take-off angle and speed combined into a metric of energy gained during flight in response to a predator stimulus and (2) Velocity and angle while maneuvering around an obstacle in the flight path. Continuous retesting will establish longer term effects of chronic exposure on flight performance. Environmentally relevant levels of dietary methylmercury are predicted to cause decreased flight performance in European Starlings due to potential disruption of neuromuscular functioning, bioenergetics, and behavior that have been observed in multiple species at similar or higher doses. Flight is of paramount importance for fitness because it plays a critical role in virtually all life history traits of a typical songbird.

TP194 Effects of Mercury on Yellow Perch Reproductive and General Health in Kejimkujik National Park and Historic Site, Nova Scotia K. Fischer, Canadian Rivers Institute, Univ of New Brunswick; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology; K. Munkittrick, Canadian Rivers Institute, Univ of New Brunswick; N. Burgess, Environment Canada, Ecotoxicology & Wildlife Health Division; P. Drevnick, Université du Québec, INRS-ETE. Kejimkujik National Park and National Historic Site (KNPNHS), located in southwestern Nova Scotia, Canada, has been designated a biological Hg "hotspot" due to the high concentrations of this pollutant in common loons (*Gavia immer*) and their main prey yellow perch (*Perca flavescens*). In KNPNHS concentrations of total Hg in yellow perch have increased over the last decade, and many currently exceed the tissue threshold level estimated for adverse effects in juvenile and adult fish (0.2 μg Hg g^{-1} (ww)). Our objective was to determine whether elevated Hg is adversely affecting the general and reproductive health of yellow perch. To determine this we collected male and female perch in the fall of 2009 and 2010 from 12 lakes known to contain fish with differing Hg concentrations. Several health variables (condition, liver somatic index (LSI), gonadosomatic index (GSI), macrophage aggregates, oocyte development, sex steroid concentrations and gene expression in the liver) were examined in these fish, compared between lakes, and related to tissue Hg concentrations. Across lakes, mean total mercury concentrations ranged from 0.29 – 0.55 μg Hg g^{-1} (ww) (n = 14 – 46 fish/lake) in dorsal muscle and from 0.26 – 2.12 μg Hg g^{-1} (ww) (n = 11 – 23 fish/lake) in liver of the perch. Additionally, in the liver the mean % total Hg present as methyl Hg ranged from 28.3-66.5% across lakes (n=11 – 23 fish/lake). Significant among-lake, within-sex differences in condition and GSI do not appear to be related to tissue Hg concentrations, and no effects of Hg on oocyte development were found. However, LSI was negatively related across lakes to total Hg in livers of perch ≤ 1 year old, and the proportion of macrophage aggregates (an indicator of oxidative stress and tissue damage) found in the liver, kidney and spleen were positively related to tissue total Hg for all ages. Analyses of plasma sex steroids, and the expression of stress related genes in the liver, are ongoing. We concluded that elevated Hg concentrations in KNPNHS yellow perch are associated with adverse general health effects at the cellular and organ level. The lower range of Hg concentrations found in KNPNHS perch is common among wild yellow perch populations of Northeastern North America. Given that Hg is global pollutant, this raises concern for the health of this species as well as other wild fishes.

TP195 Mercury and Selenium Bioconcentration, Bioaccumulation, and Biomagnification in Sarasota Bay Ecosystems Y. Hong, Johns Hopkins Univ, Geography and Environmental Engineering; E. Rifkin, Nationa Aquarium Baltimore, National Aquarium Conservation Center; R. Wells, Chicago Zoological Society, Mote Marine Laboratory; P. Hull, Mote Marine Laboratory; E. Bouwer, Johns Hopkins Univ, Geography and Environmental Engineering. Mercury (Hg) is a highly toxic metal and readily

accumulates in biota, hence elevated Hg concentrations are often observed in fish raising a significant health concern for piscivorous animals. To better understand Hg distribution and to better assess the risk associated with dietary mercury exposure in ecosystems, a field experiment was conducted in Sarasota Bay, FL. Published studies have suggested that selenium (Se) in diets can antagonistically reduce the toxicity of mercury, so Se distribution was also investigated. Diffusive gradient in thin film probes were deployed to determine labile methylmercury (MeHg) and total mercury (THg) concentrations in the overlying water and in sediment porewater in situ. Environmental samples, including water, sediment, clams (Pinna nobilis, Mercenaria mercenaria, Venus affinis), plankton, and seagrass (Thalassia testudinum), were collected from several locations in the area and analyzed for THg, MeHg, and Se. THg and Se levels in fish and Sarasota Bay resident bottlenose dolphins were obtained from previously published work. The trophic levels of the collected samples were characterized by nitrogen isotope (δ15N) analysis. From the results, bioconcentration factors of THg, MeHg, and Se from water to plankton, sediment to benthic organisms, and sediment porewater to benthic organisms, were evaluated and compared with published values reported from other environments. To compare biomagnification across food webs, the linear relationships between Log (THg and MeHg) and δ15N were evaluated and the regression slopes and the intercepts were used as a measure of biomagnification rate and the baseline values for primary producers, respectively. The results showed between a 4 and 6 orders-of-magnitude increase in the Se and THg concentrations from the environmental matrix, such as water and sediment, to the Sarasota resident bottlenose dolphins' blood and skin tissue samples. The results suggested that the co-accumulation and biomagnification of Hg and Se is occurring in the food web of Sarasota Bay and that the top predators in aquatic ecosystems may encounter potential health risks associated with dietary Hg exposure even in a relatively uncontaminated coastal area.

TP196 Mercury and Selenium in Sharks of the Northeastern United States: A Multi-species Approach Towards Potential Sub-lethal Effects D.H. Adams, Florida Fish and Wildlife Conservation Commission, Fish and Wildlife Research Institute, Cape Canaveral Scientific, Inc., Fish & Wildlife Research Institute; D. Nam, Univ of Michigan, Dept of Environmental Health Sciences; N. Basu, Univ of Michigan, Dept of Environmental Health Sciences, Univ of Michigan, Dept of Environmental Health. There continues to be concerns about mercury in the US Atlantic ecosystem, with regard to health of marine biota, as well as human consumers. Dorsal muscle, brain, and liver were collected from a wide array of shark species from Atlantic Ocean offshore waters of the northeastern United States, including shortfin mako shark (*Isurus oxyrinchus*), porbeagle (*Lamna nasus*), common thresher shark (*Alopias vulpinus*), blue shark (*Prionace glauca*), smooth dogfish (*Mustelus canis*), blacktip shark (*Carcharhinus limbatus*), sandbar shark (*Carcharhinus plumbeus*), dusky shark (*Carcharhinus obscurus*), scalloped hammerhead (*Sphyrna lewini*), and tiger shark (*Galeocerdo cuvier*). These mercury results, coupled with data regarding diet, feeding ecology, and life history parameters of these species, provide further insight into mercury bioaccumulation in this large marine region. We found strong positive correlations between mercury and shark size, and clear linkages between mercury concentrations and trophic position of these species within the US Atlantic ecosystem. Total mercury in several of these important apex predators can exceed current US and international regulatory guidelines. Preliminary results for shortfin mako sharks suggest there are sub-lethal neurochemical effects directly related to mercury concentrations. We will also report selenium concentrations for a representative group of these shark species and provide insight into mercury-selenium interactions in these important apex predators.

TP197 Mercury Contamination in Turtles of Eastern Oklahoma: Food Consumption Advisories and Nonlethal Tissue Analysis A.L. Powell, Oklahoma State Univ, Dept of Zoology; J.R. Bidwell, School of Environmental and Life Sciences; J.B. Belden, Oklahoma State Univ, Dept of Zoology. Mercury is a naturally occurring element, however its persistence as an anthropogenic pollutant continues to adversely affect wildlife. Significant research effort has focused on characterizing mercury residues in fish tissue due to the high consumption of fish by humans. For example, according to the Oklahoma Dept of Environmental Quality, the results of 3 years of testing predator fish in the lakes of Oklahoma indicate at least 16 lakes have fish mercury levels exceeding safe consumption levels. Much less work has been conducted on turtles despite the predominately aquatic nature of many species, their relatively high trophic status, and the fact that turtles are also harvested for human consumption in some parts of the United States. Furthermore, studies designed to measure mercury in turtles are often complicated by necessity to sacrifice individuals from long-lived and slowly reproducing species. Thus, the objectives of this study were to 1) determine if mercury concentrations in two freshwater turtle species of Oklahoma, *Trachemys scripta* and *Chelydra serpentina*, are high enough to necessitate consumption advisories for turtles; 2) determine if concentrations in tissues that can be collected through nonlethal means (scute, tail clip, claw) adequately predict concentrations in tissues that likely require lethal sampling (muscle and liver). Regardless of the tissue used, mercury analysis was accomplished by traditional wet digestion followed by CVAAS. Turtles were collected across 8 sites (rivers and lakes) all located in Eastern Oklahoma. Hg levels in leg muscle differed among sites (P=0.0167) but not between species, sex, or size. Hg levels in liver tissue also differed among sites (P=0.0172), but were not equivalent to site differences in leg muscle. Based on the EPA's food consumption guidelines, we calculated elevated Hg concentrations in turtle leg muscle samples, eliciting consumption limits (>0.1 ug/kg day^{-1}) at 2 of the 6 sites analyzed thus far. Claw and muscle Hg concentrations were strongly correlated ($R2$=0.81, P< 0.0001), suggesting that claw is a useful indicator of muscle Hg burden, which can be sampled using non-lethal sampling techniques.

TP199 The Deposition of Mercury Through Throughfall and Litterfall in Yangsu-ri Forest, Korea M. Kim, J. Han, S. Jung, S. Yi, Seoul National Univ; K. Zoh, Seoul National Univ, Seoul National Univ, Dept of Environmental Health, School of Public Health. Mercury deposition to the landscape is typically evaluated using data from precipitation Hg deposition. Litterfall is an important flux of mercury (Hg) to soils in forested landscapes, yet much less is known about litterfall Hg. We measured dry and wet deposition, throughfall, litterfall, soil, and soil water of Hg contributions in Yangsu-ri forest, Gyeonggi-Do, Korea, in order to investigate how the Hg species present in the atmosphere is being transferred to other media. Dry and wet deposition and throughfall samples have been were collected every two weeks from September 2008 to February 2010 and analyzed for total mercury (THg). Litterfall and soil have been sampled monthly from December 2008 to October 2010 and analyzed for THg. Soil water has been sampled using replicate zero tension lysimeters placed beneath the A horizon at four replicate plots. Soil water has been sampled monthly beginning in July 2009 and analyzed for Hg content. The reactive gaseous mercury (RGM) flux of dry deposition was 1.16 ± 0.34 ng m-2 h-1 in spring. The particulate mercury (Hgp) flux of dry deposition was 1.11 ± 1.05 ng m-2 h-1 in summer. The fluxed of precipitation and throughfall were 4.33 and 6.41 μg m-2 yr-1, respectively. Precipitation and throughfall were higher in the summer by rain. The THg in soil was the highest concentration in A horizon of fir habitat (77.82±3.04 μg kg-1). Total litterfall fluxes were 9.95 μg m-2 yr-1 for coniferous tree and 4.61 μg m-2 yr-1 for deciduous tree. During the entire sampling period, the THg concentration of soil water was 6.45 ± 6.25 ng L-1. Based on the measured result in this study, rate of wet deposition, throughfall, and litterfall was 1 : 1.48 : 2.30. The ratio was somewhat lower than those values reported in other studies, suggesting that this study site is clean, uncontaminated by pollutants, and has relatively little airborne mercury inputs.

TP200 Where's the Mercury? Constructing and Applying Spatial Models to Indentify Lakes with Potentially High Fish Hg Concentrations in New York, USA M. Turnquist, State Univ of New York – College of Environmental Science and Forestry, Environmental Forest Biology, Biodiversity Research Institute, SUNY-ESF, Environmental Forest Biology; M.A. Schlaepfer, State Univ of New York – College of Environmental Science and Forestry, Environmental and Forest Biology; C. Driscoll, Syracuse Univ, Dept of Civil & Environmental Engineering. Numerous studies have examined the relationship of fish mercury (Hg) concentrations to environmental factors and here we increased model predictability by using landscape features depicted through GIS and atmospheric Hg deposition in New York (NY), USA. The objective was to construct models that integrate water chemistry and landscape features to empirically predict Hg in four standard-size fish species; yellow perch (229mm, *Perca flavescens*), smallmouth bass (356mm, *Micropterus dolomieu*), largemouth bass (356mm, *M. salmoides*), and walleye (457mm, *Sander vitreus*), and apply the models to NY lakes. Linear regression models were parameterized using 171 lakes with both fish Hg and environmental parameters. Akaike's information criterion and the

relative weight were used to determine the most suitable models. The prominent model parameters were the mean gaseous elemental Hg deposition, the % wet area relative to the lake, and acid neutralizing capacity, resulting in coefficients of determination (R^2) as follows, yellow perch $R^2 = 0.59$, smallmouth bass $R^2 = 0.64$, largemouth bass $R^2 = 0.39$, and walleye $R^2 = 0.15$. The models were validated. In 359 NY lakes, fish Hg concentrations were predicted. Consumption risk levels were determined using the 95% prediction interval and where the mean predicted Hg concentration fell in relation to the USEPA Action Limit (0.3 µg/g) for fish consumption advisories. For yellow perch, smallmouth bass, largemouth bass, and walleye, 34%, 80%, 87% and 97% of the 359 lakes, respectively, had mean predicted Hg concentrations above the USEPA Action Limit. Model outputs identified individual lakes as well as regions where fish Hg was likely to exceed safe consumption limits.

TP201 Capabilities and Method Improvements of Single Particle (SP)-ICP-MS for the Detection of Silver Nanoparticles D. Mitrano, Colorado School of Mines, Chemistry and Geochemistry; H. Pace, Colorado School of Mines, grad student; A. Barber, Colorado School of Mines, Dept of Chemistry and Geochemistry; C. Higgins, Colorado School of Mines, Environmental Science and Engineering; A.J. Bednar, US Army Engineer Reseach and Development Center; J. Ranville, Colorado School of Mines, Chemistry and Geochemistry, Colorado School of Mines. One of the most rapidly growing classes of nanoproducts are consumer materials that generate silver ions or contain nanosilver. The environmental prevalence of nanomaterials, particularly nanosilver, is expected to increase substantially in the future. Thus, it is imperative to develop techniques capable of determining key characteristics of nanosilver in complex media including, but not limited to, wastewater and biological samples. Of the standard analytical techniques that currently exist, few seem fully capable of determining the concentration, size, and composition of this new class of emerging contaminant. Single Particle ICP-MS (SP-ICP-MS), a novel application of ICP-MS, provides number, size, and composition data for nanoparticles as small as 40nm at environmentally relevant concentrations as low as 25 ppt. Furthermore, the distinction and quantification of dissolved vs. nanoparticlate concentrations is advantageous over other techniques available; as each may behave differently in biological and environmental systems and this ratio may prove important in many instances. Specific method improvements will be discussed such defining the dissolved metal background, dwell time choice, and ICP-MS optimization for the SP-ICP-MS technique. Suggested developments were validated using well-characterized and stable silver nanoparticles of discrete sizes from 20 to 100nm and cross-checked on several ICP-MS instruments to determine sensitivity and applicability in various laboratories. The validation and application of this analytical technique will result in a powerful tool for the continued investigation of inorganic nanoparticulate behavior in both environmental and biological systems.

TP202 Use of AF4-UV-Vis-MALLS/DLS-ICP-MS for Characterization of Silver Nanoparticle Behavior in Aquatic Microcosms J.M. Unrine, Univ of Kentucky, Dept of Plant and Soil Sciences, Univ of Kentucky, Dept of Plant & Soil Sciences; B. Colman, A. Bone, C. Matson, Duke Univ, Center for Environmental Implications of Nanotechnology. Recent studies of silver nanoparticle (Ag NP) toxicity in aquatic mesocosms have suggested that toxicity is diminished relative to laboratory assays in simple media. In support of toxicity studies that aimed to identify factors contributing to this amelioration of toxicity, we investigated the aggregation and dissolution of silver nanoparticles in aquatic microcosms that contained components of the mesocosms. The aquatic microcosms contained either just mesocosm water (W), mesocosm water and sediment (WS), mesocosm water and aquatic plants (WP; *Egeria densa* and *Potamogeton diversifolius*) or water, sediment and plants (WSP). We analyzed particle size distribution using asymmetrical flow field flow fractionation (AF4) with UV-Vis diode array, multi-angle/dynamic light scattering (MALLS/DLS), and inductively coupled plasma mass spectrometry (ICP-MS) as detection methods. Microscosms contained either 2 mg/L of 60 nm polyvinylpyrrollidone (PVP) coated Ag nanoparticles, 6 nm gum Arabic (GA) coated Ag nanoparticles or Ag+ from $AgNO_3$. For the PVP Ag NPs, heteroaggregation was observed in the W and WS treatments, but not the WP or WSP treatments. Greater dissolution also occurred in the W and WS treatments. Few large Ag containing aggregates were detected in the GA treated waters from any treatment; however, concentrations of primary particles in the WP and WSP treatments were only about half of those in the W and WS treatments. The combination of sediment with plants enhanced the reduction in suspended primary particle concentrations. We also observed binding of Ag+ ions to dissolved organic matter (DOM) in the treatments containing plants. Microcosms containing Ag+ and plants also displayed peaks for Ag bound to DOM. Overall, we observed that the presence of plants had a stabilizing effect on primary PVP Ag NP and a destabilizing effect on primary GA Ag NP concentrations in the water column. DOM from plants also bound considerable amounts of Ag+ ions. These results may help to explain reductions in Ag NP toxicity observed in both microcosm and mesocosm studies relative to simple laboratory studies.

TP203 Size and Composition Separation of Engineered Nanomaterials by Ultracentrifugation J. Sylva, Student Services Contract to EPA; C.G. Rosal, G. Momplaisir, USEPA, ORD/NERL/ESD. The production of engineered nanomaterials (ENMs) has tremendously increased to satisfy their demand in technological, medical, pharmaceutical, and personal care products. This in turn translates into higher potential for these materials' release in the environment. Nanoparticles have unique chemical and physical characteristics depending on their sizes and shapes relative to their corresponding bulk materials. Determination of these intrinsic properties can be complicated due to the wide distributions of sizes. To determine potential exposure of metal- and metal oxide-based ENMs in aqueous matrices, we propose to use ultracentrifugation for size separation followed by elemental detection using inductively coupled plasma-mass spectrometry (ICPMS). Scanning electron microscope (SEM) and capillary electrophoresis (CE)-ICPMS will also be employed as confirmation and complimentary techniques. Preliminary results will be presented in this poster.

TP204 Optimization of Pre-filtration of Surface Water for Quantification and Size Characterization of Engineered Nanoparticles E.M. Siska, Student Contractor to the USEPA, USEPA; E.M. Heithmar, US Environmental Protection Agency, Office of Research and Development, National Exposure Research Laboratory, USEPA, Research Chemist. As quantities of metal and metal oxide based engineered nanomaterials (ENMs) in consumer products increase, higher loadings of released nanoparticles in wastewater and ultimately surface water will follow. Understanding their potential risk to human health and ecosystems requires information on both potential exposure and effects. To evaluate potential exposure, the concentration and size distribution of the nanoparticles in surface water is a critical piece of information. All existing analytical methods for quantifying and characterizing metal-bearing ENM particles require pre-filtration of most surface waters. Unfortunately, the nominal size cut-off of filtration media is a poor predictor of the recovery of nanoparticles from surface water. Previous results in this laboratory indicated good recovery of 50 nanometer silver and gold nanoparticles from reagent water, using a filter of 5 µm cut-off. However, recovery of the same nanoparticles from urban stream water resulted in < 10% recovery. Filtration of nanoparticles from surface water can also potentially alter the size distribution. Here we report using single particle-inductively coupled plasma mass spectrometry to study the factors influencing recovery and size-distribution artifacts produced by filtration of surface water. The effects of nanoparticle composition, filtration media type, size cut-off, sample volume to filter surface area ratio, and other factors are investigated. Experimental conditions and expected data-quality for optimized pre-filtration of metal-bearing ENMs will be presented.

TP205 Measuring the Bioconcentration of DOSS in Pacific Oysters H. Boorse, Oregon Episcopal School, Science, Oregon Episcopal School, Columbia Analytical Services. The oil dispersants Corexit 9527® and 9500 A® were used in mass quantities in treatment of the Deep Water Horizon Gulf of Mexico oil spill of 2010. (Boxall, 2011) There has been much concern and controversy over the effect and toxicity of these oil dispersants to marine biota. Studies were conducted by EPA in 2010 on the toxicity of various oil dispersants and their oil mixtures. Primary active ingredients in oil dispersants are surfactants. To date, very little research has been conducted on the affect, toxicity or bioaccumulation of these surfactants on marine organisms. This investigation focused on the short term bioconcentration of Dioctyl Sulfosuccinate Sodium Salt (DOSS), the primary surfactant found in Corexit® products, in the Pacific oyster Crassostrea-Gigas. DOSS is water soluble and fat soluble and has the potential to accumulate in the fatty tissues of organisms. Oysters were exposed to low-level concentration (ug/L) of Corexit 9500 A® over an approximate 60 hour period of time. Oyster and water samples were taken at approximately six hour intervals, frozen and shipped to the laboratory for DOSS analysis by liquid chromatography

tandem mass spectroscopy (LC/MS/MS). The results of this biconcentration study are discussed.

TP206 A Comparison of Patterns of PCB Congeners and Aroclor Mixtures in Sediments and Fish Tissues in the River Raisin, Monroe, MI, USA S. Roark, CH2M Hill, Ecotoxicology & Risk Assessement; M. Loomis, USEPA, Great Lakes National Program Office. Bioaccumulation of polychlorinated biphenyls (PCBs) varies among congeners, with congeners of intermediate chlorination (4 to 7 chlorines) generally accumulating in fish tissue more than those of greater and lesser chlorination. Consequently, the profile of PCBs in fish tissue typically differs from that of sediments from the same location. Furthermore, reported congener profiles in fish tissue are only an approximate match for theoretical congener profiles based on proportional technical mixtures of Aroclors. Data available from the USEPA Great Lakes National Program Office for River Raisin (RR) indicated that Aroclor 1242 is the predominant Aroclor mixture in RR sediment, with Aroclors 1254 and 1260 infrequently detected or representing only a small percentage of the total PCB. Consistent with the technical mixture of Aroclor 1242, congeners with 3 or fewer chlorines composed approximately 60 percent of total PCB, and congeners with 4 or fewer chlorines composed approximately 90 percent of the total PCB in RR sediment data reported from 2001. Despite consistent profiles in RR sediments, reported PCB Aroclor profiles in fish tissue were variable, and congeners with 4 or fewer chlorines represented a lesser proportion of the total PCB than was reported in sediments. Fillet data reported from the Michigan Dept of Environmental Quality Fish Contaminant Monitoring Program indicated (FCMP) that in 1998 smallmouth bass, freshwater drum, and carp tissues from RR contained only Aroclor mixtures 1248 and 1254. PCB congener analyses from the FCMP for several fish species analyzed in 2008 indicated that PCB congeners with 4 or fewer chlorines represented 23 to 40 percent or less of the total PCB in RR fish tissues, although only 73 congeners (or coelution groups) were reported. Additional contemporaneously collected sediment and fish tissue data, including Aroclors and congeners, will further elucidate these patterns. An understanding of the differential bioaccumulation of PCB congeners may be important in ecological risk assessments for fish and consumers of fish, because congeners of intermediate chlorination include those of greatest toxicological significance and are accumulated disproportionately in fish tissues.

TP207 Accumulation and Depuration of Polychlorinated Biphenyls from Field-collected Sediment in Three Freshwater Organisms J. Van Geest, Univ of Guelph, School of Environmental Sciences, Intrinsik Environmental Sciences Inc; D. Poirier, Ontario Ministry of the Environment, Laboratory Services Branch; P. Sibley, Univ of Guelph, School of Environmental Sciences, Univ of Guelph, Dept of Environmental Biology; K. Solomon, Univ of Guelph, School of Environmental Sciences, Univ of Guelph, Centre for Toxicology, School of Environmental Sciences. As laboratory-based bioaccumulation methods are standardized and expanded to include other test species, kinetic studies assessing the major classes of contaminants with these species are needed to support and/or improve the selection of standard duration for bioaccumulation tests. In the present study we measured the uptake (28-d exposure) of polychlorinated biphenyls (PCBs; total and selected congeners) from field-contaminated sediment in the oligochaete *Lumbriculus variegatus*, the mayfly nymph *Hexagenia* spp., and the fathead minnow *Pimephales promelas*. Depuration (25 d) of PCBs was measured in organisms that had been transferred to clean sediment and water after the 28-d exposure. Uptake and elimination of PCBs was rapid in both *L. variegatus* and *Hexagenia* spp. and tissue residues reached steady-state concentrations within 28 d. Elimination rates and biota-sediment accumulation factors (BSAFs) of the PCB congeners were not correlated with K_{OW} in these invertebrates. Uptake and elimination rates of PCBs were slower in *P. promelas* and it is not clear whether steady-state was reached in the tissues of fish. Elimination rates of the PCB congeners significantly decreased with increasing K_{OW} in fish. The present study confirms the appropriateness of a 28-d exposure for measuring steady-state concentrations in tissue of the invertebrates, but further study is required for fish.

TP208 Bioaccumulation of PCBs across Concentration Gradients in Sediments L.P. Burkhard, USEPA, Mid-Continent Ecology Division; D.R. Mount, US Environmental Protection Agency, ORD; T.L. HighLand, US-Environmental Protection Agency, NHEERL, MED; J.R. Hockett, US-Environmental Protection Agency, NHERRL, MED; T.J. Norberg-King, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; N. Billa, US-Environmental Protection Agency, NHEERL, MED; S.B. Hawthorne, Univ of North Dakota, Energy & Environmental Research Ctr; D.J. Miller, C.B. Grabanski, Univ of North Dakota, Energy and Environmental Research Center. Sediment bioaccumulation tests with *Lumbriculus variegatus* quantify the relationships between the chemical residues in sediments and benthic invertebrates, and these relationships are expressed as biota-sediment accumulation factors (BSAF). At some field sites, BSAFs decrease slightly with increasing concentrations of the chemicals in the sediment, and this behavior has been attributed to the presence of black carbon in the sediment. In this study, 28-day sediment bioaccumulation tests were performed with PCB contaminated sediment samples from Fox, Hudson, and Grasse Rivers Superfund sites. Sediments tested had widely varying total PCB concentrations (0.5 to 150 ppm), total organic carbon contents (0.5 to 25%), black carbon contents (0.1 to 4.4%), and freely dissolved chemical concentrations (measured using polyoxymethylene (POM) coupons) in the sediment interstitial water (0.02 to 65 ng/L). For PCB 118 (2,3',4,4',5-pentachlorobiphenyl), the slopes of geometric mean regressions of the log transformed concentration in the *L. variegatus* (µg/g lipid) against log transformed concentration in the sediment (µg/g organic carbon) were 0.87 (±0.16, n=10) and 1.10 (±0.14, n=10) for the Fox and Hudson Rivers, respectively, and neither slope was significantly different from 1.0 (α=5%). Slopes less than 1.0 imply that the BSAF decreases with increasing concentration in the sediment. Similarly, the slopes of geometric mean regressions of the log transformed concentration in the *L. variegatus* (µg/g lipid) against log transformed concentration in the sediment interstitial water were 0.99 (±0.07, n=10) and 0.78 (±0.06, n=10) for the Fox and Hudson Rivers, respectively, and only the slope of the Hudson River regression was significantly different from 1.0 (α=5%). Slopes less than 1.0 imply less accumulation in the *L. variegatus* with increasing concentration in the interstitial water. The BSAFs for PCB 118 ranged from 1.3 to 11.7 and from 0.8 to 2.7 for the Fox and Hudson Rivers, respectively. Assuming $K_{lipid} = K_{ow}$, prediction of residues in the *L. variegatus* from the measured concentrations in the interstitial water resulted in a median ratio of 0.11 predicted to measured residues for tri- through hepta-PCB congeners (n=801). Potential influences of black carbon on accumulation are discussed, along with the implications of this study for predicting chemical residues in the *L. variegatus*. This abstract does not necessarily reflect USEPA policy.

TP209 Bivalve Shells as Long-term Archives of Trace Metals: The Autoregression Approach W.A. Shoults-Wilson, Roosevelt Univ, Biological, Chemical and Physical Sciences; L. Seymour, Univ of Georgia, Statistics; J. Unrine, Univ of Kentucky, Plant and Soil Sciences; M. Black, Univ of Georgia, Environmental Health Sciences. Past attempts to utilize the annual rings of bivalves as long-term archives of environmental conditions have met with mixed success. While intensive spatial resolution of trace metal concentrations is possible, it can then be difficult to match this data to specific dates and thus validate by environmental monitoring. In this study, we used laser ablation inductively coupled plasma-mass spectrometry (LA ICP-MS) to analyze trace elements (Cd, Cu, Mn, Pb and Zn) on a transect perpendicular to the growth annuli of the freshwater bivalve *Elliptio hopetonensis*. Concentrations of Mn from multiple shells at each site were correlated and average Mn data series were calculated. Periodicity of Mn data was determined and sampling errors removed using an autoregression model. The data series at each site exhibited regular periodicity of high and low concentrations. Periods correlated between the shells from within the same site but were not correlated between shells from different sites. Using Mn correlations to offset Pb series from the same site aligned Pb peaks from multiple shells. This study demonstrates that Mn deposition in the shells of *E. hopetonensis* is a regular, seasonal process. However, this process differs in rate between sites with different environments. It also demonstrates that Mn series can be used to align Pb peaks between multiple shells. This suggests that by using autoregression models to remove sampling error, bivalve shells have the potential to be used as archives of both essential (i.e., Mn) and potentially toxic (i.e., Pb) trace elements uptake by the organism.

TP210 Comparative Pharmaceutical Metabolism with Rainbow Trout (*Oncorhynchus mykiss*) S9 K.A. Connors, Baylor Univ, Institute of Biomedical Studies, Baylor Univ, Dept of Environmental Science; B. Du, Baylor Univ, The Institute of Ecological, Earth, Environmental Sciences, Baylor Univ, Dept of Chemistry and Biochemistry; Dept of Environmental

Science; P.N. Fitzsimmons, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; C.K. Chambliss, Baylor Univ, Dept of Chemistry and Biochemistry; J.W. Nichols, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; B.W. Brooks, Baylor Univ, Environmental Science and Biomedical Studies, Baylor Univ, Dept of Environmental Science. The occurrence of pharmaceuticals in the environment represents an area of emerging concern. Chemical and biological properties of therapeutics present unique challenges to ecological risk assessment. An important component of risk characterization is understanding bioaccumulation of a chemical. Unlike other industrial chemicals, existing pharmaceutical safety data and pharmacology information may be leveraged through biological "read-across" to aid environmental assessments. However, few approaches and robust empirical datasets exist, particularly for comparative pharmacokinetic applications. For many pharmaceuticals, the primary CYP enzymes responsible for their metabolism have been identified in humans. The purpose of this novel study was to employ a comparative metabolism approach to determine whether rainbow trout possess similar cytochrome P450 (CYP) isozyme-type activity as humans. Test compounds were selected based on their known metabolism in humans by CYP3A4, CYP2D6, or CYP2C9. Metabolism by rainbow trout liver S9 fractions was evaluated using a substrate depletion approach which provides an estimate of the intrinsic clearance rate (CLIN VITRO,INT). An isotope dilution liquid chromatography tandem mass spectrometry (LC-MS/MS) method was employed for quantitation of parent chemical concentrations. Initial studies suggested that trout possess a limited ability to metabolize the putative CYP3A4 substrates diltiazem and carbamazepine. This observation is important given the accumulation of diltiazem and carbamazepine previously reported from fish in the field by our group. Further results from this effort will help inform the advantages and limitations of cross-species extrapolations of comparative metabolism and pharmacokinetics during risk assessments of pharmaceuticals.

TP211 Development of an Abbreviated In Vivo Fish Bioconcentration Test D. Hala, Univ of North Texas, Dept of Biological Sciences; T. Springer, Wildlife International Ltd.; D.B. Huggett, Univ of North Texas, Dept of Biological Sciences. Laboratory bioconcentration studies are becoming an integral part of global hazard and risk assessment paradigms. Experimental measurement of the bioconcentration factor (BCF) is often required for any chemical with log KOW greater than 3, if it is produced in quantities greater than 100 t/year. Currently, the expectation is that a BCF will be experimentally determined for any such chemical by performing a fish bioconcentration study according to Organization for Economic Cooperation and Development (OECD) test guideline 305 or US Environmental Protection Agency (USEPA) guideline 850.1730. These standardized guideline studies are demanding of resources and require the use of large numbers of animals. In an attempt to develop an in vivo screening level test, common carp were exposed to chlorpyrifos, methoxychlor, DDT or musk xylene for 7 d, at which point fish were placed in chemical free water for 7d. During this period, liver and muscle tissues were sampled on days 1, 3,7, 10 and 14. 14 d BCF values for all chemicals were similar to those values obtained using standard protocols and timelines, suggesting that a reduced design may be helpful in screening chemicals that warrant a more robust bioaccumulation assessment. Statistical and modeling approaches will be applied to these data sets to optimize the experimental design for a robust screening test.

TP212 Development of In Vitro Assays for Assessing Bioaccumulation Potential of Commercial Chemicals F. Chen, National Univ of Singapore; B.C. Kelly, X. Liu, S. Bayen, National Univ of Singapore, Dept of Civil and Environmental Engineering. The Stockholm Convention on Persistent Organic Pollutants (POPs) aims to reduce or eliminate the production of persistent, bioaccumulative and toxic (PBT) chemicals. PCBs and DDTs are well-established PBT chemicals, which can cause reproductive failures and cognitive dysfunction in wildlife and humans. Brominated flame retardants (BFRs) and perfluorinated chemicals (PFCs), which have likewise emerged as potentially hazardous PBT chemicals. There is a current need to develop effective in vitro and in silico tools for identifying commercial chemicals that can persist in the environment, bioaccumulate in food chains and cause adverse effects in wildlife and humans. The main objective of the present study was to develop in vitro assays for assessing the toxicokinetics and bioaccumulation potential of commercial chemicals. In particular, we developed a Parallel Artificial Membrane Permeability Assay (PAMPA) to assess passive, transcellular permeability of lipophilic organic chemicals. We also developed in vitro hepatic microsomal assays utilizing microsomes isolated from liver tissue of two tropical marine fish species (Tiger grouper and Coral trout) to assess metabolic transformation of organic contaminants in marine fish. Test chemicals included several polychlorinated biphenyls, organochlorine pesticides and synthetic musk compounds. The developed PAMPA assays, which involved 96 hour controlled chemical transport between stationary donor and acceptor PDMS disks in solution, were successfully used to quantify apparent permeability (LogPapp) of test compounds. Observed LogPapp values were negatively correlated with chemical Log Kow, consistent with previous reports. The developed in vitro hepatic microsomal assays were successfully used to quantify biotransformation of several PCB congeners and synthetic musks. The extent of chemical biotransformation was variable among compounds and between fish species. Interestingly, Musk Xylene, a nitro musk fragrance compound, exhibited the least amount of metabolic transformation, with only 1-10% of the compound being degraded in these fish liver microsomes. The developed PAMPA and hepatic microsomal biotransformation assays provide a simple and cost-effective approach for eliciting key toxicokinetic data, which can be further incorporated into in silico predictive models to better forecast bioaccumulation potential of commercial chemicals.

TP213 GIS Based Source Estimation of Cu Pollution in Lake Itezhi-tezhi and Cu Accumulation Profile in *Oreochromis* sp. from the Field and Laboratory Studies S.M. Nakayama, Graduate School of Veterinary Medicine, Hokkaido Univ, PhD. Student; Y. Ikenaka, Graduate School of Veterinary Medicine, Hokkaido Univ; K. Muzandu, K. Choongo, Univ of Zambia; J. Yabe, T. Muroya, Graduate School of Veterinary Medicine, Hokkaido Univ; S. Ijiri, Faculty of Fisheries Sciences, Hokkaido Univ; T. Umemura, M. Ishizuka, Graduate School of Veterinary Medicine, Hokkaido Univ. [Field study] We reported that concentrations of Cu in sediment and fish liver (*Oreochromis* sp.) from Lake Itezhi-tezhi (ITT) were high, most likely due to the discharge of Cu wastes from the Copperbelt mining area, located 450 km northern of the Kafue River in Zambia. However, it is still not clear whether Cu wastes from the Copperbelt area actually reach Lake ITT. Another question was why *Oreochromis* sp. had higher concentrations of Cu than other fish species. Our objectives were to: (1) clarify the metal distributions in the lake sediment to predict the source of Cu pollution using GIS analysis; (2) reveal if diet is related to Cu accumulation in fish. In this study, GIS analysis suggested that northern part of the lake could be the Cu pollution source. *Oreochromis* sp. showed significantly higher concentrations of Cu than those in other fish species, while concentrations of Cu in the stomach contents among the fish species were not significantly different. [Laboratory experiment] *Oreochromis niloticus* and Japanese medaka (*Oryzias latipes*) were exposed to Cu in order to reveal the species differences in the Cu accumulation or excretion ability. Both species were exposed to Cu (0.2 ppm, waterborne) for 4 days and checked recovery phase up to 14 days. *O. niloticus* showed significantly higher concentrations of Cu compared with medaka at all sampling points.[Conclusions] Northern part of the lake, probably Copperbelt mining area, could be the source of Cu pollution in Lake ITT. Both field and laboratory studies imply that *Oreochromis* sp. contains high concentration of Cu under their physiological condition.

TP214 Heavy Metal Bioaccumulation in Bivalve Mollusc (*Perna perinea*) in the Coastal Marine Environment Adjacent to Arcelormittal Tubarão F. Passamani, ARCELORMITTAL TUBARÃO, Environment, ArcelorMittal Tubarão, Environment; J.O. Santos, ARCELORMITTAL TUBARÃO, Environment. ArcelorMittal Tubarão, one of the biggest world supplier of steel slabs, is located 14km north of Vitoria (ES- Brazil). Its domestic and industrial effluents are previously treated and mixed with the sea water used to cool the equipment and structures to be later on thrown into the marine environment. Among the several types of pollutants in the waste generated by a steel making industry are heavy metals which must be carefully considered as they are not biodegradable, are toxic to man in certain concentrations and can be incorporated by the trophic chain. Besides that, heavy metals have already been detected in analysis of the water, the biota and sediments collected in areas adjacent to place where ArcelorMittal Tubarão effluent is thrown into the sea. Bivalve molluscs, especially mussels, are filtering organisms which accumulate composites present in the environment. Therefore, they are constantly used as pointers in environmental monitoring programs throughout the world as they are widely distributed, sedentary or sessile, present on the first levels of the food chain, relatively tolerant to an extensive range of environmental conditions, filter large

volumes of water and bio-accumulate several composites in their tissues. The present study chose one species of mussel to be used as bio-monitor of heavy metals; the *Perna perna* was chosen for meeting all the requirements above, which qualifies the species as a good bio indicator of the area. Thus, the concentrations analysed from 1998 to 2009 for each metal were compared with other works carried out in Brazil and other countries, using the *Perna perna* species as bio-monitor, and classified the areas in two categories: natural or slightly contaminated and contaminated.

TP215 Occurrence and Bioaccumulation of Pharmaceuticals in a Wastewater Impacted Watershed B. Du, Baylor Univ, The Institute of Ecological, Earth, Environmental Sciences, Baylor Univ, Dept of Chemistry and Biochemistry; Dept of Environmental Science; J. Berninger, Baylor Univ, Institute of Biomedical Studies; K.A. Connors, Baylor Univ, Institute of Biomedical Studies, Baylor Univ, Dept of Environmental Science; S.B. Junot, T. Conry, Waco Regional Water Quality Laboratory; K. Chambliss, Baylor Univ, Dept of chemsitry and biochemistry; B.W. Brooks, Baylor Univ, Environmental Science and Biomedical Studies, Baylor Univ, Dept of Environmental Science. Trace level of pharmaceuticals, considered as contaminants of emerging concern, have already been identified in various environmental matrices globally. Effluent-dominated systems in rapidly urbanizing watersheds represent the worst-case scenarios for waterborne exposure to human pharmaceuticals. Evaluation of environmental exposure and impacts of active pharmaceutical ingredients (APIs) is critical for performing an appropriate assessment of ecological risk for effluent dominated aquatic systems. A recently developed isotope dilution liquid chromatography tandem mass spectrometry (LC-MS/MS) methodology was applied to examine 23 target human and veterinary pharmaceuticals, several metabolites, and other effluent associated contaminants (e.g., sucralose) in surface water samples collected throughout the North Bosque River watershed of central Texas, which receives discharges from six municipal wastewater treatment plants and is severely impacted by dairy Confined Animal Feeding Operations. Surface water concentrations ranged from 0.38 ng/L for diphenhydramine to 3.5 µg/L for sucralose. During dry periods, such as the record setting drought of 2011, stream flow of this watershed is effluent dominated, particularly in the upper reaches of the river basin. Subsequently, we examined bioaccumulation of these target analytes in fish collected from downstream from the first effluent discharge. We furthered measured and predicted plasma tissues and bioconcentration factors (BCFs), based on actual concentration in organisms' tissue and plasma, water concentration of target analytes and accounted for site-specific pHs, which are important to consider during ecological risk assessments of ionizable pharmaceuticals.

TP216 PCB Spatial Patterns in San Francisco Bay Forage Fish R.M. Allen, B.K. Greenfield, San Francisco Estuary Institute. Forage fish are frequently employed as biosentinels to evaluate mercury contamination, but spatial surveys of other pollutants are less common. The San Francisco Estuary Regional Monitoring Program (RMP) analyzed polychlorinated biphenyls (PCBs) in forage fish to determine spatial patterns in PCB food-web uptake. Topsmelt (*Atherinops affinis*) or Mississippi silverside (*Menidia audens*) were sampled at 17 randomly chosen sites throughout San Francisco Bay and 12 targeted sites near historically polluted locations. The average sum of 40 PCB congeners in fish from targeted stations (357 ppb, SD = 339) was significantly higher than probabilistic stations (115 ppb, SD = 78). In probabilistic stations, concentrations in topsmelt (154 ppb, SD = 69) were higher than silverside (75 ppb, SD = 68), likely due to elevated lipid content in topsmelt. Both species concentrations were comparable to those of high lipid sport fish in the Bay, and well above a local regulatory threshold for forage fish (10 ppb). Fish PCB concentrations followed spatial patterns in sediment contamination. The highest concentration samples were from targeted Central Bay locations, including Hunter's Point Naval Shipyard (1130 ppb; topsmelt), Stege Marsh (970 ppb; silverside), Oakland Inner Harbor (590 ppb; topsmelt), and Richmond Inner Harbor (340 ppb; topsmelt). Some targeted sites exhibited distinct congener profiles, suggesting local source contributions. These findings indicate that spatial patterns in PCB food web exposure correlate with historical sediment contamination due to industrial activity.

TP217 Seasonal Changes in the Oxidative Stress Indicators and Heavy Metal Levels in Macroalgae of the Genus: *Gracilaria* in Bahia Magdalena, B.C.S., Mexico P.T. Rodriguez, Centro de Investigaciones Biológicas del Noroeste, S.C., Laboratorio de Biomedicina y Salud Ambiental; L.M. Rodriguez, E.S. Zaragoza, T.Z. Savin, Centro de Investigaciones Biológicas del Noroeste, S.C. Marine organisms, such as algae, have been successfully used as sentinels in evaluating the health status of aquatic ecosystems. *Gracilaria vermicullophyla* and *G. textorii* are red algae that are common and abundant in Bahia Magdalena, Mexico. Due to their distribution and ability to accumulate heavy metals in their tissues, they can be used as indicators in environmental health studies. These algal species are an important constituent of the diet of many herbivorous animals influencing their chemical element content with potential consequences in their health. In this study, we compared the levels of Zn, Cd, Cu, Pb and Fe, as well the activities of four antioxidant enzymes: superoxide dismutase, glutathione reductase, glutathione peroxidase, and glutathione S-transferase, and two indices of oxidative damage lipid peroxidation (TBARS) and protein carbonyl levels in the algae *G. vermicullophyla* and *G. textorii*. Macroalgae were collected at Bahia Magdalena, México, in November 2009, and February, May and June, 2010. Seasonal variability of heavy metal concentrations and antioxidant enzyme activities was observed in both species. The metal distribution pattern in marine algae was as follows: *G. vermicullophyla*- Fe > Zn > Pb > Cu> Cd; *G. textorii* Fe > Zn > > Cd > Pb > Cu. Both species showed, in general, higher enzymatic activities and lower TBARS and carbonyl protein levels in June, when Pb concentrations were higher. Lower enzymatic activities in algae were found in the seasons with lower Pb, Cd and Cu content. No trend was found for levels of Zn and Fe. This study provides information on the seasonal variations of heavy metal concentrations and oxidative stress indicators in two species of the genus *Gracilaria*, and its potential as sentinel in monitoring marine ecosystems.

TP218 Translating from Passive Sampling and Passive Dosing to Lipid Based Concentrations in Organisms P. Mayer, S.N. Schmidt, Aarhus Univ, National Environmental Research Institute; K. Maenpaa, M. Leppanen, Univ of Eastern Finland, Dept of Biology; M.S. McLachlan, A. Jahnke, Stockholm Univ, Dept of Applied Environmental Science (ITM). Equilibrium sampling into various formats of the silicone polydimethylsiloxane (PDMS) is increasingly used to measure the exposure of hydrophobic organic chemicals in environmental matrices, and passive dosing from silicone is increasingly used to control and maintain their exposure in laboratory experiments. Both these equilibrium partitioning approaches are normally calibrated to freely dissolved aqueous concentrations (Cfree), which often are considered the effective concentration for partitioning, bioconcentration and toxicity. In the present studies we extend the calibration of such methods towards equilibrium partitioning concentrations in lipids (Clipid,partitioning). Three case studies will be presented that complement each other: (1)Equilibrium in tissue sampling in three different fish yielded lipid based PCB concentrations in good agreement with those determined using total extraction and lipid normalization. These results support the validity of the in tissue sampling technique, while at the same time confirming that the fugacity capacity of these lipid-rich fish tissues for PCBs was dominated by the lipid fraction. (2)Equilibrium sampling of PCB contaminated lake sediments with PDMS coated vials and with Head Space Solid Phase Microextraction (HS-SPME) yielded lipid based concentrations that were in good agreement with each other. These measurements were about a factor of two higher than actually measured lipid-normalized concentrations in native sediment larvae. (3) Passive dosing was applied to bioconcentration and toxicity studies of several PAHs with the terrestrial springtail Folsomia candida. Within the bioconcentration study, equilibrium partitioning concentrations in lipids served as a well defined reference for the evaluation of measured concentrations in the springtails. In the toxicity tests of naphthalene, phenanthrene and pyrene, lethal concentrations were determined also on a Clipid,partitioning basis and were in good agreement with the typical range of lipid membrane burdens for baseline toxicity (40-160 mM). This demonstrates that these new calibration principles also can be applied within a toxicological context.

TP219 Biodegradable and Low Antimicrobial and Antifungal Toxicity Chiral Ionic Liquids N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences; M. Ghavre, Dublin City Univ, School of Chemical Sciences and National Institute for Cellular Biotechnology. Synthesis of enantiomerically pure compounds is of great importance in organic chemistry. Especially in the pharmaceutical industry the synthesis of chiral pharmaceuticals as a single enantiomer by the most economical method is desirable. Hence various methods, including asymmetric synthesis, the chiral pool strategy, classical

resolution and either kinetic or dynamic kinetic resolution may be employed to obtain an enantiopure product. Use of chiral ionic liquids as solvents for asymmetric synthesis is a new method to obtain enantiomerically enriched products. ILs are often described as 'green solvents'; mainly due to their negligible vapour pressure. However, assessment of their environmental impact is also a requirement, ILs must not persist in the environment and should be non-toxic or of limited toxicity to the environment and all life within. This is a challenging goal for ionic liquid research today. In our present work a library of CILs has been synthesized from methyl imidazole and readily available chiral starting materials in three steps followed by anion exchange. A range of different anions were incorporated into the CILs in order to modulate their physical, chemical properties. When the CILs were tested against seven strains of bacteria they generally displayed low toxicity, and also exhibited favourable biodegradability in a CO_2 headspace test.

TP220 Green Chemistry Principles Applied to the Synthesis of Novel Opiate Analogues N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences; J. Phopase, Dublin City Univ, School of Chemical Sciences and National Institute for Cellular Biotechnology. The constant pressure to prepare compounds in a more efficient manner has placed the process by which traditional synthetic chemistry is conducted under scrutiny. Pharmaceutical companies desire short, efficient and environmentally friendly synthetic methods. One way that offers this prospect is the minimization of the use of protecting groups in synthesis. A protection/deprotection strategy introduces at least two steps, incurring costs of reagent and waste disposal, and leads to a reduced overall yield. We herein wish to report our short two step synthetic approach with high yields leading to diverse library of novel analgesic compounds. Binding data to the mu opioid receptor is also presented.

TP221 Green Friedel-Crafts Reaction of Aromatic Compounds with Glyoxamides N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences. The Friedel-Crafts reaction of aromatic compounds with carbonyl compounds is one of the fundamental reactions in organic chemistry. Numerous examples of addition reactions of aromatic compounds to activated carbonyl and alpha-dicarbonyl compounds, such as glyoxylate, trifluoropyruvate, and phenylgloxyal, in the presence of Lewis acids and organocatalysts are known. It provides a simple procedure for the preparation of optically active mandelic acid derivatives, which are important building blocks for many biologically active compounds. Herein, we present the catalytic Friedel-Crafts reaction of aromatic compounds including dimethylaniline to a series of glyoxamides catalyzed by various catalyst systems. We found that the reaction led to the formation of double addition products in the presence of Lewis acid catalysts. Further study of the Friedel-Crafts reaction between N-methylpyrrole and glyoxamides in aqueous $NaHCO_3$ demonstrated that the reaction selectively produced mono-addition products. Our work provides a 'greener' synthesis of bioactive α-hydroxyamides and α-hydroxyamino cores via green Friedel-Crafts type methodology. A detailed study including expanded reaction scope, catalyst optimization and solvent effect will be presented.

TP223 Ain't No Mountain High Enough: Persistent Organic Pollutants in Remote Irish Lake Catchments H.E. Scott, Trent Univ, Environmental & Life Sciences, Trent Univ, Environmental and Life Sciences; J. Aherne, C.D. Metcalfe, T.L. Metcalfe, Trent Univ. Long-range atmospheric transport of persistent organic pollutants (POPs) has become an increasing concern on a global scale as evidenced by the enactment of the Stockholm Convention on Persistent Organic Pollutants in 2001. This concern has been driven by the seemingly ubiquitous nature of POPs and their presence in the most remote locations around the world. Ireland is positioned on the western edge of Europe and assumed to be 'pristine' owing to the dominant prevailing Westerlies bringing in 'clean' Atlantic air. As such, it may be considered as a 'background' or reference environment to other European regions. During 2009, POPs were measured in six remote lakes suited around the circumference of Ireland using Semi-Permeable Membrane Devices (SPMDs). The headwater lake catchments were located in high elevation regions (500 to 800 meters above sea level) to avoid influences from local emissions. All study sites were situated in close proximity to the north Atlantic Ocean and Irish sea, thus, receiving inputs solely via rainfall (1200-2200 mm). As anticipated, the concentrations of POPs were low at each of the study lakes. Nonetheless, polychlorinated biphenyls (PCBs) were present across all of the sites, particularly those bordering the west coast. Additionally, several types of organochlorine pesticides, including Endosulfan, were detected in some or all of the lakes. Concentrations of dichlorodiphenyltrichloroethane (DDT) were highest at sites on the east coast of Ireland possibly due to the influence of national sources or contributions from eastern European airsheds. Moreover, benzene hexachloride (BHC) concentrations were highest in the lake catchment located on the northwest coast. Notably, polybrominated diphenyl ethers (PBDEs), recently listed under the Stockholm Convention annex, were also identified at a number of the study lakes. In general, the lakes were dominated by lighter POPs, more prone to long-range atmospheric transport. Despite the low concentrations measured, the lakes have received a wide range of contaminants from national and 'global' emission sources.

TP224 An Overview of the Programs Implemented to Assess Shoreline Impacts as a Result of the MC252 Incident C. Fay, BP, Gulf Coast Restoration; G. Harmon, Cardno Entrix. This poster will describe the studies implemented to determine the spatial extent and degree of impacts of MC252 Incident on the GOM shoreline habitats. In response to the Deepwater Horizon Oil Spill, three programs were implemented to delineate the spatial extent of shoreline oiling in the Gulf of Mexico (GOM): Shoreline Cleanup Assessment Teams (SCAT) overseen by Response organization; rapid pre-assessment mapping by Shoreline Natural Resource Damage Assessment (NRDA) teams; and pre-assessment point evaluation by NRDA teams. The following activities were implemented to assess impacts to shoreline habitats. These programs include: coastal wetland vegetation sampling and monitoring; marsh recession; high-resolution aerial imagery; inter-tidal sediment and soil sampling. These studies will be used to determine the amount of restoration to offset the impacts from the MC252 Incident.

TP225 Assessment of Perfluorinated Compounds in Fish from US Rivers L.L. Stahl, J.B. Wathen, USEPA Office of Water, Office of Science and Technology; A.R. Olsen, USEPA, Office of Research and Development, Western Ecology Division, ORD/National Health and Environmental Effects Laboratory; B.D. Snyder, Tetra Tech, Inc., Center for Ecological Sciences; H.B. McCarty, CSC. EPA's Office of Water and Office of Research and Development are collaborating to conduct a national study of fish contamination in US rivers, which includes an assessment of contaminants of emerging concern (CECs) in urban waters for potential impacts to human health. The CEC assessment includes analysis of perfluorinated compounds (PFCs) in fillet tissue from fish composite samples collected at about 150 urban river locations (>5th order based on 1:100,000-scale Strahler order) throughout the lower 48 states. This national-scale urban river study is EPA's first broad assessment of CECs in fish using a statistically-based sampling design. It is being conducted under the framework of EPA's National Rivers and Streams Assessment (NRSA), a probability-based survey designed to assess the condition of the Nation's streams and rivers. The 150 urban river sites form a statistical subset of the 900 sampling locations selected for the NRSA. Samples were collected for the study in 2008 and 2009 during June through October sampling seasons. Field teams across the country applied consistent methods to collect one fish composite sample at every sampling location. Each composite sample consisted of five similarly-sized adult fish of the same species, and the field teams targeted species that are commonly consumed by humans. Largemouth and smallmouth bass were the primary species collected for the study, accounting for 34% and 24% of all fish composites, respectively. Fillets from fish composite samples were analyzed for 13 PFCs, including perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS). PFCs, and PFOA and PFOS in particular, are heat stable chemicals that repel water and oil, and are commonly used in stain repellants, non-stick cookware, and a variety of other industrial and commercial applications. They are very persistent in the environment and in biota where they bind to blood proteins. Analytical results from this study of US urban rivers indicated that 6 of the 13 target PFCs were detected in fish fillet composites. Frequency of occurrence was dominated by PFOS, which was detected in 76% of all samples.

TP226 Assessment of Polybrominated Diphenyl Ethers in Fish from US Lakes and Reservoirs L.L. Stahl, USEPA, Office of Water, Office of Science and Technology, Office of Science and Technology; A.R. Olsen, USEPA, Office of Research and Development, Western Ecology Division, ORD/National Health and Environmental Effects Laboratory; B.D. Snyder, Tetra Tech, Inc., Center for Ecological Sciences; L. Walters, CSC. The US Environmental Protection Agency's Office of Science and Technology

(within the Office of Water) and Office of Research and Development collaborated to conduct a national study of a broad suite of contaminants in freshwater fish. This collaborative effort included analysis of polybrominated diphenyl ethers (PBDEs) in fillet and whole-body tissue samples from lakes and reservoirs throughout the US as part of the National Study of Chemical Residues in Lake Fish Tissue (or National Lake Fish Tissue Study). This was the first national freshwater fish contamination study with sampling sites selected according to a probabilistic (random) sampling design, and it included data on the largest set of persistent, bioaccumulative, and toxic (PBT) chemicals studied in fish to date. An unequal probability design was used to initially develop national estimates for 268 PBT legacy chemicals in fish tissue from lakes and reservoirs of the conterminous United States (excluding the Laurentian Great Lakes and Great Salt Lake). The National Lake Fish Tissue Study also provided the first opportunity to determine PBDE levels in fish tissue on a national basis. Sampling teams collected two five-fish composites from 500 randomly selected lakes throughout the country: a predator (e.g., bass or trout) and a bottom-dweller (e.g., carp or catfish). About one-third of the fillet composites from predator samples and whole-body tissue composites from bottom-dweller samples (which consisted of a statistical subset of samples from 166 of the 500 lakes) were analyzed for 46 PBDE congeners using EPA Method 1614: Brominated Diphenyl Ethers in Water, Soil, Sediment, and Tissue by HRGC/HRMS. Six of the 46 PBDE congeners (PBDE 10, 12, 13, 30, 35, and 166) were not detected in any of the samples. Percent occurrence was dominated by eight congeners (PBDE 28, 33, 47, 49, 99, 100, 153, and 154), accounting for 95% of the total PBDEs measured in the samples. Congener 47 alone accounted for more than 50% of the total detected PBDEs. Total PBDE concentrations were higher in bottom-dweller whole body composites than in predator fillet composites, and maximum concentrations were 125,070 and 58,185 ng/kg (ppt) wet weight for the whole-body and fillet samples, respectively.

TP227 Comparison of Passive Samplers for Monitoring Dissolved Organic Contaminants in Water Column Deployments M. Perron, Brown Univ, School of Engineering; R.M. Burgess, USEPA, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, USEPA, USEPA; M. Cantwell, USEPA, Atlantic Ecology Division; E.M. Suuberg, Brown Univ, School of Engineering. Nonionic organic contaminants (NOCs) are difficult to measure in the water column due to their inherent chemical properties resulting in low water solubility and high particle activity. Traditional sampling methods require large quantities of water to be extracted and interference from colloids and/or small particles often exists. In recent years, passive samplers have been used to measure dissolved nonionic organic contaminants. The technique relies upon contaminant partitioning between the aqueous phase and the organic polymer of the passive sampler. The sampler accumulates NOCs resulting in greater analytical detection and measured contaminant concentrations in the sampler can then be used to calculate dissolved contaminant concentrations. In North America, several passive sampling materials are commonly used for NOCs, including solid phase microextraction (SPME) fibers, polyethylene devices (PEDs), and polyoxymethylene (POM). In this study, the utility and effectiveness of these sampling materials for monitoring water column concentrations of several contaminants were compared. Samplers were deployed in galvanized cages in Narragansett Bay, RI (USA) and solvent extracted to analyze for contaminants of concern. For each contaminant, sampler-water partition coefficients (Ksampler-water) needed to calculate dissolved NOC concentrations from measured passive sampler concentrations were determined in the laboratory. Differences observed between the three samplers and Ksampler-water values will be presented for polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), and the emerging contaminant triclosan. Results from this work will provide useful information for monitoring legacy and emerging contaminants in natural waters.

TP228 Degradation Patterns of High Molecular Weight PAHs Provide Evidence of Photolysis in Surfaced MC252 Crude Oil L. Cook, Exponent; P. Boehm, Exponent, Environmental & EcoScience Group, Exponent, Environmental Group, Exponent, Inc., Environmental & EcoScience sGroup; R. Barrick, ENTRIX, Inc. Crude oil samples collected on the water surface from the Deepwater Horizon oil spill showed depletion patterns for the 3- and 4-ring parent and alkylated PAHs that varied from the expected PAH losses associated with dissolution, evaporation, and biodegradation. PAHs in MC252 surface oil showed greater levels of compound-specific depletion with increasing number of aromatic rings and alkylation levels. Increased levels of depletion were most apparent for the 4-ring PAHs with 3 and 4 methyl groups. Depletion was calculated for individual PAHs using the conserved biomarker hopane with comparison to fresh MC252 crude oil. Based on initial observations of the PAH depletion profiles, the hypothesis that exposure to ultra-violet (UV) light increased the depletion of the alkylated 4-ring PAHs benzo[*a*]anthracene/chrysenes and fluoranthene/pyrenes in MC252 (and hence the degradation of the surface oil and tars) oil was tested using available: field oils and tars as well as surface and deep water samples. Weathering of oil slick samples collected by the USCG Rapid Assessment Teams (RAT) during this spill showed depletion profiles for the alkylated 4-ring PAHs consistent with published information of photodegradation patterns. A sample of the MC252 oil collected immediately after surfacing showed PAH profiles consistent with weathering from dissolution alone, eliminating the transport to the surface as the mechanism for the alter depletion profiles. Oil-impacted water samples collected from the 0-1 meter (m) depth range showed indications of photolysis, likely associated with entrainment of surface oil. Water samples ranging in depth from 1 to 1500 m in depth have PAH depletion profiles that are consistent with PAH losses only from dissolution and biodegradation without any effect from UV exposure. The results of controlled, laboratory UV exposure study of MC252 oil confirm the field observations. Thus analysis of available field data and laboratory studies support the hypothesis that UV exposure increased the depletion of the alkylated 4-ring PAHs in surfaced MC252 oil.

TP229 Determination of Bisphenol A, Alkylphenols and Alkylphenol Ethoxylates in Human Serum Using a Two-step Solid Phase Extraction and GC-EI/MS/MS I. Kosarac, C. Kubwabo, Health Canada, Environmental and Radiation Health Sciences Directorate. Bisphenol A (BPA), alkylphenols and related ethoxylates are widely used industrial compounds. Lately, BPA, especially, has been the centre of the attention in the media and general public. In order to contribute to filling the gaps with regards to the lack of information on the levels of human exposure to these emerging contaminants, a new method was developed for the analysis of bisphenol A, alkylphenols and related ethoxylates in human serum. The method consisted of a two-step extraction on Florisil and Oasis HLB cartridges. Target analytes' elution was achieved using dichloromethane and acetone in the first step and methanol and acetone for solid phase extraction on Oasis HLB cartridges. Following the concentration and derivatization with N-methyl-N-trimethylsilyltrifluoroacetamide (MSTFA), the final extract was analyzed by gas chromatography-tandem mass spectrometry (GC/EI-MS/MS). The following compounds were analyzed in this study: bisphenol A, 4-nonylphenol (technical branched isomers mixture, NP), 4-tert-octylphenol (4-(1,1,3,3-tetra-methylbutyl)phenol, OP), 4-n-nonylphenol (linear form), 4-octylphenol (linear form), branched nonylphenol monoethoxylate (NP1EO) and branched nonylphenol diethoxylate (NP2EO). This novel method, unlike many currently available ELISA based methods, offers greater specificity and sensitivity at sub-parts-per-billion levels. Preliminary results show that the concentrations are in the range of 0.936 ng/mL, 10.070 ng/mL, 1.179 ng/mL, 4.030 ng/mL, and non-detected for BPA, NP, OP, NP1EO and NP2EO, respectively. The recoveries for all target compounds ranged between 60 and 115%.

TP230 Determination of Inorganic Mercury in Fish Liver Using a Direct Mercury Analyzer-80 B. Barst, Université du Québec, INRS-ETE; C. Hammerschmidt, Wright State Univ, Dept of Earth & Environmental Sciences; M.M. Chumchal, Texas Christian Univ, Biology Dept; J. Smith, Univ of North Texas, Dept of Biological Sciences and Institute of Applied Sciences; T. Rainwater, Medical Univ of South Carolina, Dept of Obstetrics and Gynecology, Hollings Marine Laboratory; P. Drevnick, Université du Québec, INRS-ETE. Mercury is found in the environment in elemental, inorganic, and organic forms. Methylmercury, the predominant organic form, compromises the majority of mercury in fish muscle tissue (≥90%). For this reason total mercury analysis is often substituted for the more time consuming and expensive methylmercury analysis in fish muscle, while mercury speciation is reserved for analysis of organs like the liver. The percentage of methylmercury in fish liver is more variable and could be dependent on species-specific physiology. Past research from our laboratory and others has linked hepatic damage in fish with elevated hepatic inorganic mercury concentrations. Knowledge of methylmercury and inorganic mercury concentrations is therefore essential when studying hepatic mercury toxicity in fish. Here, we present a quick and relatively inexpensive method

for inorganic mercury determination in fish liver. This method involves microwave acid digestion, removal of the methylmercury from the acid (with toluene) and analysis of inorganic mercury in a diluted aliquot of the acid by Direct Mercury Analyzer (DMA-80). We have demonstrated good reproducibility and recovery of inorganic mercury. Methylmercury can also be analyzed by DMA-80, after it is transferred from toluene to an aqueous phase (L-cysteine solution), but recovery is low (< 70%). Instead, methylmercury concentrations can be calculated by subtracting the determined inorganic fraction from total mercury in the same sample. We are currently validating the method by comparison with accepted techniques (GC-CVAFS and Thiourea Complex IC-CVAFS).

TP231 Environmental Fate of Decamethylcyclopentasiloxane (D5) Predicted by the Quantitative Water Air Sediment Interaction (QWASI) Fugacity Model J. Kim, Dow Corning Corporation, Health and Environmental Sciences; D.E. Powell, Dow Corning Corporation, Health & Environmental Sciences, Dow Corning Corporation, Health & Environmental Sciences (C03101); D. Mackay, Trent Univ. Due to the unique characteristic properties of decamethylcyclopentasiloxane (D5), airborne D5 remains in the compartment until it is oxidized by OH radicals. In contrast, when D5 is released to water, multiple processes including volatilization, sedimentation, advection and hydrolysis are expected to take place competitively in the water compartment. Since a better quantitative assessment on the fate, distribution and transport of D5 in a real water body system is needed, this study evaluated the environmental behavior of D5 in the aquatic environment of Lake Ontario at a realistic range of water temperature. Additionally, the assessment included sensitivity and uncertainty analyses to determine the most probable range of the model outcome and the most influential input parameters using a new Excel-spreadsheet version of the Quantitative Water Air Sediment Interaction (QWASI) model. The QWASI model predicts that water concentration of D5 decreases quasi-linearly from 0.31 to 0.05 ng/L due to increase in hydrolysis rate as temperature is increased from 1 to 20°C, whereas sediment concentration of D5 decreases slightly from 1.0 to 0.7 ng/g dry weight. In the same range of temperature, the reaction rate increases from 53% to 93% of the total emission rate while the volatilization rate decreases from 41% to 6%. The effect of changes in rates of sedimentation and advection are relatively small compared with the effects of hydrolysis and volatilization. Both sensitivity and uncertainty analyses indicate that half-life in water and Koc are the most influential input parameters to the outcome of the QWASI model predictions for D5 concentrations in water and sediment. Variances of sediment concentration of D5 and the sedimentation rate are contributed by uncertainties of KOC and half-life in water, whereas variances of water concentration and rates of hydrolysis, volatilization and advection are exclusively influenced by half-life in water. The variance of the model outcome becomes smaller at higher temperature. Thus, the study suggests that Koc and half-life in water as well as emission rate of D5 must be precisely specified in the QWASI model for a better understanding of the fate, distribution and transport of D5 especially in the water environment.

TP232 Excitation-Emission Matrix Fluorescence Characterization of Dissolved Organic Carbon Leached from Leaves from Various Tree Species J. Hauri, Assumption College, Natural Sciences Dept; K. Wirzbicki, Assumption College. Dissolved organic carbon (DOC) is an operationally defined parameter that encompasses a variety of chemical structures dependent on the specific allochthonous or autochthonous carbon source. The type of DOC has a significant impact on both the chemical and biological processes that occur in natural waters, as well as the disinfection by-product formation during drinking water treatment. Excitation-emission matrix (EEM) fluorescence spectroscopy has become a more common technique used to characterize the variety of DOC. We investigated DOC leached from different species of leaves collected from trees adjacent to the stream on campus. The leaves were leached in lab using different experimental methodologies to compare the impact of using deionized water versus synthetic moderately hard culture water as the solvent. The samples of leached water containing DOC were analyzed via EEM. Our experimental furthers our knowledge on how DOC derived from different leaves differ from each other, as well as how leaching methods influences the DOC obtained.

TP233 Field Comparison of Grab Sampling and Time-integrating Passive Sampling Methods for Organic Contaminants in a Freshwater System J. Croskrey, J.P. Hassett, R. Oakes, M. Giardono, State Univ of New York College of Environmental Science and Forestry, Dept of Chemistry. Many hydrophobic organic contaminants (HOCs) exist in aquatic environments at very low concentrations due to low water solubility and high affinity for the particle or gas phase. However, even at low concentrations, many HOCs are potentially harmful to both humans and wildlife due to their persistence in the environment and ability to bioaccumulate. Onondaga Lake in Syracuse, New York is a natural, freshwater lake that is known to have elevated levels of several potentially harmful HOCs, including chlorinated benzenes, polycyclic aromatic hydrocarbons (PAHs), and alkyl benzenes. Due to the potential harm of such contaminants, it is important to accurately monitor their concentrations in freshwater systems like Onondaga Lake and to understand how HOC concentrations may vary with time. Concentrations of several HOCs were measured in Onondaga Lake using passive, in situ, concentration/extraction samplers (PISCES) during the summer and fall of 2009 and 2010. The samplers were filled with hexane and suspended in the water for 7–14 days at three sites. Using an effective sampling rate, the average water concentrations for the compounds of interest were determined during the sampling period at each site. Grab samples were also taken in 2010 for comparison and to refine the effective sampling rate of the PISCES. Significant variation in the concentration of contaminants, in particular the PAHs, was observed during both the 2009 and 2010 field seasons with the passive samplers. Comparison of the passive and grab sample methods shows good agreement for concentrations of most contaminants being monitored, but not for the PAHs. This deviation is due to large, short-term (daily) fluctuations in PAH emissions from a nearby source. The passive samplers capture these fluctuations as composites of the contaminant concentrations during the entire sampling period, whereas weekly grab samples do not reliably capture these fluctuations.

TP234 Gulf Waters: Protective Enough for Pescetarians? G. Greenberg, Gradient. In light of the BP oil spill in the Gulf of Mexico, concerns of health risks from fish and shellfish consumption from affected waters have surfaced. In June 2010, the Food and Drug Administration (FDA) released a two step protocol using sensory testing and chemical analyses for reopening federal and state fishers after the BP oil spill. Areas that pass the sensory test are then sampled for fish, shellfish and bivalves. The edible tissue are tested and tissue concentrations are compared against FDA risk based criteria. FDA calculated public health levels of concern using the 90th percentile seafood consumers only consumption rate (13 g/day shrimp and crabs, 12 g/day oysters, 49 g/day finfish) from the 2005-2006 NHANES survey. However, there is a wide array of ingestion rates, which could alter the current FDA levels of concern. In addition, FDA's risk based criteria do not account for the higher ingestion rates among subpopulations (e.g., subsistence populations, native American populations, Asian communities) as well as regions (e.g., Michigan, Louisiana). Consequently, federal and state waters where fish tissue concentrations were below the screening levels may be improperly screened out due to a liberal ingestion rate. Calculations of more conservative ingestion rates and how it could alter FDA's fish residue screening levels will be presented, compared and contrasted with the current standard.

TP235 Investigation of the Binding of Perfluoroalkyl Acids to Human Serum Albumin Through 19F Nuclear Magnetic Resonance and Fluorescence Spectroscopy M.P. O'Connor, Union College, Chemistry; L.A. MacManus-Spencer, Union College, Dept of Chemistry. Perfluoroalkyl Acids (PFAAs) are used in the manufacture of a wide variety of consumer and household products, and their presence in the environment is a growing environmental and toxicological concern. PFAAs have been shown to bioaccumulate in the liver and blood stream of many organisms, as well as competing with endogenous ligands when binding to proteins. In this study, the binding of PFAAs to human serum albumin (HSA) over a range of differing pH and ionic strength values was investigated using two experimental approaches. Fluorescence spectroscopy and ^{19}F nuclear magnetic resonance (^{19}F NMR) spectroscopy were used to qualitatively and quantitatively describe the binding of PFAAs with varying chain length and ionic head group to HSA as a function of pH and ionic strength.^{19}F NMR experiments were used to probe the binding of PFAAs to HSA by using the distinct signal arising from the fluorocarbon tails of the PFAAs. Fluorescence spectroscopy was used to monitor the native fluorescence of HSA as a function of PFAA binding, monitoring conformational changes in the protein and subsequent changes in the fluorescence spectrum. Fluorescence results indicate that ionic strength (over a physiologically relevant range) has little effect on the binding, while pH has a greater effect. Estimated binding constants from

these studies are on the order of 10^4 M^{-1}, varying with fluorocarbon chain length, ionic head group, and pH. The results of this study illustrate the relative effectiveness of these two complementary experimental approaches in estimating PFAA-HSA binding constants and contribute to a better understanding of the role of HSA in the bioaccumulation and pharmacokinetics of PFAAs.

TP236 Monte Carlo Uncertainty Analysis of a Level III Multimedia Fugacity Model for Decamethylcyclopentasiloxane (D5) J. Kim, Dow Corning Corporation, Health and Environmental Sciences; D.E. Powell, Dow Corning Corporation, Health & Environmental Sciences, Dow Corning Corporation, Health & Environmental Sciences (C03101); D. Mackay, L. Hughes, Trent Univ. Among several multimedia models, the Equilibrium Criterion (EQC) fugacity multimedia model has been widely used for the assessment of the fate, distribution and transport of a chemical of interest in the environment. Since the model requires partitioning and reactivity properties of the chemical as input data, it is very important to understand how much the uncertainties of the physicochemical properties affect the model outcomes. Thus, this study focused on the uncertainty analysis of the EQC Level III model for decamethylcyclopentasiloxane (D5) to quantify the confidence ranges of mass distribution, persistence and intermedia transport rates based on pre-determined dispersion factors of physicochemical properties of the chemical. For the uncertainty analysis, the Monte Carlo simulation technique was employed using Oracle Crystal Ball as an Excel Add-in program to a new spreadsheet platform of the EQC model. The uncertainty analysis showed that once it is released or vaporized to air, D5 stays in the compartment until it is removed at a relatively fast rate via OH radical oxidation and advection, resulting in relatively short overall persistence and no intermedia transport from air to other compartments. These model outcomes are virtually unaffected by the uncertainties of physical properties of D5. On the contrary, when D5 is released to water, a major fraction is distributed in sediment due to sorption of the compound to organic matter in sediment where the degradation rate is very small. In this case, the model outcome is predominantly influenced by the uncertainty of Koc. Under a realistic emission scenario (94.5% to air, 0.8% to water and 4.7% to soil), the 95%-confident ranges of the mass distribution in air and sediment are 47%~78% and 19%~49%, respectively, whereas the overall persistence varies from 3.2 to 5.8 days with the same confidence. The variances are predominantly affected by Koc. Overall, the EQC model results are strongly dependent on the mode of emission. Since the mass distribution in sediment is sensitive to the emission to water, accurate measurement of Koc and half-life in sediment is expected to afford a better understanding of the fate, distribution and transport of D5 in the environment.

TP237 New Standard Reference Materials (SRMs) for Environmental Contaminant Analysis J. Hoguet, M. Schantz, National Institute of Standards and Technology (NIST), Analytical Chemistry Division; J.R. Kucklick, National Institute of Standards and Technology (NIST), Analytical Chemistry Division, National Institute of Standards & Technology, Hollings Marine Laboratory; J.M. Keller, S. Vander Pol, R. Pugh, A. Moors, S. Wise, National Institute of Standards and Technology (NIST), Analytical Chemistry Division. For the past 30 years, the National Institute of Standards and Technology (NIST) has developed Standard Reference Materials (SRMs) in response to a growing demand for natural environmental matrices with certified values for organic contaminants. The first environmental SRM issued in 1980, SRM 1580 Organics in Shale Oil, had certified concentrations for five polycyclic aromatic hydrocarbons (PAHs), three phenols, and benzo[*f*] quinoline; however with declining interest in alternative fuel development, SRM 1580 became outdated. In response, NIST has developed a number of environmentally relevant matrix SRMs over the years, including whale blubber, fish and mussel tissues, human blood, house dust, sewage sludge, air particulate material, and a variety of sediments, with a broader range of individual organic contaminants characterized to better suit the needs of the environmental community. Regarding the marine environmental community, NIST has issued several new SRMs, including SRM 2974a Organics in Freeze-Dried Mussel Tissue (*Mytilus edulis*), and SRM 1588c Organics in Fish Oil. NIST has also replaced SRM 1941a Organics in Marine Sediment with SRM 1941b and has begun production of SRM 1974c Organics in Mussel Tissue (*Mytilus edulis*), to replace SRM 1974b. These SRMs have been characterized for a suite of organic contaminants, including polychlorinated biphenyl (PCB) congeners, PAHs, polybrominated diphenyl ether (PBDE) congeners, and organochlorine pesticides. This presentation will summarize the development and certification of these SRMs.

TP238 Partitioning of Polybrominated Diphenyl Ethers to Dissolved Organic Matter M. Wei-Haas, The Ohio State Univ, School of Earth Sciences; Y. Chin, The Ohio State Univ, Dept of Geological Sciences; K. Hageman, Univ of Otago, Dept of Chemistry, Univ of Otago. Polybrominated diphenyl ethers (PBDEs) are a class of brominated flame-retardants (BFRs) that are ubiquitous in the environment and undergo long-range atmospheric transport to the Arctic. Recent research indicates that PBDEs, particularly the lower brominated congeners, bioaccumulate and cause liver, thyroid, and neurotoxic effects. The large reported octanol-water partition coefficients (K_{OW}) of PBDEs (> 10^5 for tribromodiphenyl ethers to > 10^9 for decabromodiphenyl ether) make these substances highly susceptible to partitioning to dissolved organic matter (DOM). This process would increase the apparent aqueous solubility of PBDEs and alter their transport, bioavailability, and transformation in aqueous environments. The DOM partition coefficients (K_{DOM}) for these compounds also vary with organic matter properties such as molecular weight, polarity, and aromaticity. These processes are especially important in the Arctic where PBDE bioaccumulation and phototransformation is highly dependent upon the ability of PBDEs to interact with DOM. DOM partition coefficients for BDE-153 and BDE-99, two commonly detected congeners in environmental samples, were measured by the solubility enhancement method for organic matter collected from Toolik Lake and Oksrukuyik Creek, located on the North Slope in Alaska, and an International Humic Substance Society standard, Suwannee River humic acid. Based on previously derived linear free energy relationships (LFER) between DOM and octanol-water partition coefficients, estimates of log K_{DOM} for BDE-153 range from 7.4 to 6.6. Our measured partition coefficients were somewhat lower than the calculated values, with a log K_{DOM} of 6.17 and 5.92 for BDE-153 in Suwannee River humic acid and Oksrukuyik DOM, respectively. We attribute these differences to the different types of DOM used in our analysis and those used to establish the LFER. Partition coefficients derived for BDE-153 and BDE-99 will be compared to the composition of each type of organic matter as determined by spectroscopic methods and mass spectrometry as part of our ongoing research examining the role of DOM composition on K_{DOM}. We believe that this study will yield insights into both the photolytic fate of PBDEs (via photosensitization reactions with DOM) and their transport, distribution, and bioavailability in the environment.

TP239 Update to the USEPA's Guidelines for (Human) Exposure Assessment and Monitoring N.S. Tulve, US Environmental Protection Agency, Office of Research and Development, National Exposure Research Laboratory; M. Olsen, US Environmental Protection Agency – Region 2, Emergency and Remedial Response Division; M. Broder, US Environmental Protection Agency, Office of the Science Advisor, Risk Assessment Forum. The goal of the USEPA is to protect human health and the environment by understanding, characterizing, and reducing risks to environmental agents. Exposure science evaluates and predicts exposures and provides information for developing exposure and risk assessments as well as the most effective strategies for reducing risks. When conducting a risk assessment, the assessor needs to understand whether an agent may cause an adverse health effect and how exposure to that agent may be reduced. The increasing number and complexity of risk assessments conducted by the Agency presents new challenges. Advances in the field of exposure science require updated resources for conducting exposure and risk assessments. The Guidelines for (Human) Exposure Assessment and Monitoring has been prepared to provide an updated resource for exposure and risk assessors both within and outside the Agency. This document builds on the solid foundation of the 1992 Guidelines, incorporating advances in the field that have occurred since the Guidelines were originally published. It reflects the best science currently conducted across the Agency. This updated document describes the principles of exposure assessment, provides guidance on approaches to conduct an exposure assessment, presents references for more detailed information, and supplies hyperlinks to exposure assessment tools and technical documents. The Guidelines are arranged into chapters, each of which explores a component of the exposure assessment process, including: basic concepts and principles in exposure science; planning and scoping; collecting and using data; using models; planning an observational exposure measurement study; incorporating lifestages, vulnerable groups, and populations of concern into an assessment; evaluating uncertainty and variability; and presenting and

communicating results. This presentation will highlight and showcase many of the updates in the document.

TP240 Using Octanol-Air Partition Coefficient (KOA) to Screen Chemicals for Terrestrial Bioaccumulation Potential M. Kawa, SRC, Inc.; C. Baier-Anderson, US Environmental Protection Agency, Office of Chemical Safety and Pollution Prevention, Design for the Environment Program; R. Boethling, US Environmental Protection Agency, Office of Chemical Safety and Pollution Prevention, Exposure Assessment Branch; M. Citra, SRC, Inc.; J. Costanza, US Environmental Protection Agency, Office of Chemical Safety and Pollution Prevention, Antimicrobials Division; E. Lavoie, E. Sommer, US Environmental Protection Agency, Office of Chemical Safety and Pollution Prevention, Design for the Environment Program; J. Tunkel, SRC, Inc. Bioconcentration factors (BCF) obtained from experimental studies and estimated using quantitative structure activity relationships (QSAR) are widely used to screen chemicals for potential to bioaccumulate in fish. With the introduction of the BCFBAF™ model in EPA's EPI Suite version 4, aquatic bioaccumulation factors (BAFs) can be estimated for three trophic levels of fish using a set of QSARs that incorporate an estimate of the rate of metabolism. A recent investigation (Costanza et al., in press) determined the impact of using upper trophic BAF from BCFBAF™ instead of BCF in screening 4,566 high and medium production volume chemicals for bioaccumulation potential. The results indicate that for nonionic species, most chemicals would retain the same concern level in binning for high/medium/low concern, but approximately 10% of the chemicals would be assigned a higher hazard concern using BAF over BCF. We have extended this work by investigating the potential of chemical substances to bioaccumulate in air-breathing species. It has been suggested that the log octanol/water partition coefficient (Kow) can be used in conjunction with the log octanol/air partition coefficient (Koa) for this purpose, for chemicals that do not metabolize. This work arose from initial results from chemical review under EPA's Design for the Environment (DfE) Alternative Assessment initiative. These chemicals were evaluated using Koa and Kow instead of experimental or estimated BCF, estimated BAF, and available monitoring data. For brominated flame retardant alternatives to decabromodiphenyl ether, bioaccumulation hazard concerns were generally assigned consistently using the predictors described above. For alternatives to Bisphenol A in thermal papers, the concern level for 12 of 14 low bioaccumulation hazard materials could increase using the evaluated Kow and Koa approach, a result that was not entirely consistent with the anticipated metabolism potential of these compounds. We then estimated Kow and Koa for the 4,566 high and medium production volume chemicals evaluated previously with BCFBAF™. A sensitivity analysis of the hazard classifications relative to bright line criteria will be presented, along with the utility of this methodology for screening chemical compounds for potential to bioaccumulate in air-breathing species.

TP241 Adsorption and Remediation of 17β-estradiol and Bisphenol A Using an Activated Carbon Solution J. Wang, Univ of Pennsylvania School of Medicine, Teen Research and Education in Environmental Science, Dept of Pharmacology, Center for Excellence in Environmental Toxicology; J. Field, Univ of Pennsylvania School of Medicine, Dept of Pharmacology, Center for Excellence in Environmental Toxicology. The presence and effects of endocrine-disrupting chemicals (EDCs) such as natural and synthetic estrogens on animal and human populations has become a cause for concern not only within the scientific community but also in the public sphere. EDCs present in the environment have caused increased incidences of intersex marine vertebrates and elevated vitellogenin levels in male fish, as well as various malformations and adverse health effects in humans, such as hypospadias and cryptorchidism. It is imperative that methods of filtering or otherwise removing endocrine disruptors be created and implemented. One such promising method is that of activated charcoal filtration. In this study, the bioluminescent yeast estrogen screen (BLYES) developed by Sanseverino et. al was used to determine the estrogenicity of standard and experimental solutions. Experiments using a 10% activated charcoal solution achieved 99.1% and 79.3% reductions, respectively in the concentration of two known natural and synthetic estrogens, 17β-estradiol and bisphenol A. Activated charcoal holds great potential for reusable and highly effective EDC filtration, but more experiments must still be performed to optimize this method and to enact its widespread application.

TP242 Ambient Thermal Desorption Ionization for Rapid Mass Spectrometric Analysis of Contaminants G. Cleland, J. Burgess, Waters Corp.; K. Rosnack, Waters Corporation; D. Shaw, C. Mallet, M. Twohig, Waters Corp. To ensure the safety of consumers following an oil spill, a rapid screening method is required to analyze food for compounds of concern. Of the many compounds found in oil, a subset of major concern is the polyaromatic hydrocarbons (PAHs). These compounds are known to be carcinogenic and the US Environmental Protection Agency has defined these compounds as priority pollutants. The application of ambient desorption techniques for sample introduction into mass spectrometers is an emerging technology that has applicability in many areas of contaminants analysis. The atmospheric-pressure solids analysis probe (ASAP) is a unique mass spectrometry technique for direct analysis of volatile, semi-volatile, solid and liquid samples. In ASAP, samples are introduced to the mass spectrometer on a glass capillary and vaporized with heated nitrogen desolvation gas. Ionization is achieved using a corona discharge. While conventional analytical tools, such as LC or LC/MS, require time-consuming sample preparation procedures, ASAP can provide mass spectra within seconds of sampling. The use of ASAP coupled to a tandem quadrupole mass spectrometer for the detection of PAHs in seafood samples was investigated. Spiked samples of fish and shrimp were homogenized and then sampled directly with the glass capillary. PAHs were screened using multiple reaction monitoring (MRM) mode. In addition, PAHs were extracted from the samples using a simple QuEChERS protocol and the extract sampled directly using the capillary. Results from both approaches will be presented. This work provides an interesting example of the potential applications of ASAP for the analysis of environmental contaminants and will discuss the benefits and challenges of the technique.

TP243 Comparing Total Hg, 'Reactive' Hg and Speciated Hg in Natural Waters B. Jackson, Dartmouth College, Dept ofEarth Sciences; V. Taylor, Dartmouth College. Here we compare total Hg, determined by BrCl oxidation, $SnCl_2$ reduction, gold trapping and pyrolysis and AFS detection, reactive Hg, determined as for total Hg but without the BrCl step, and speciated Hg determined by speciated isotope dilution, automated purge and trap-ICP-MS on natural waters collected from ponds, rivers and vernal pools. The water samples were filtered at 0.45μm, 0.2 μm and 10KDa to assess the effect of dispersed colloids and nanoparticles on the comparison. We hypothesize that incompete isotopic equilibrium of inorganic Hg with the particle bound Hg causes underestimation of total dissolved Hg by the speciatied isotope dilution method. Furthermore particle-bound inorganic Hg is not $SnCl_2$ reducilble and this operationally defined fraction records the lowest concentration of dissolved Hg.

TP244 Coupling Asymmetrical Flow Field Flow Fractionation with ICP-MS for Characterization of Silver Nanomaterials in Aqueous Samples E. Hoque, Trent Univ, E. & R. S.; C.D. Metcalfe, Trent Univ, Environmental & Resource Studies, Trent Univ, Dept of Environmental & Resource Studies. Silver nanomaterials (nAg) are widely used in consumer products, such as textiles, personal care products, food storage containers, laundry additives, home appliances and paints, because of its antibacterial properties. According to a 2009 report from 'The Project on Emerging Nanotechnologies', there are 259 listed consumer products containing nAg. It is likely that nAg enters into the aquatic environments from discharges of domestic and industrial wastewater. Hence, it is important to develop proper analytical tools to quantify nAg in water to assess exposures to aquatic organisms. In this study, we developed an analytical method using asymmetrical flow field flow fractionation (FFF) and inductively coupled mass spectrometry (ICP-MS) to determine the size and concentration of nAg in aqueous samples. Analysis of a mixture of 20, 40, 60 and 80 nm nAg standards suspended in water resulted in a well resolved fractogram. Retention times of nAg were correlated with nanomaterial sizes. The current limit of quantitation of FFF-ICP-MS method is ~ 1.0 ng/mL nAg, which is within the range of predicted concentrations of nAg in wastewater. Using this method, nAg was detected in an untreated wastewater (i.e., influent). The estimated size and concentration of nAg in the influent of a wastewater treatment plant (WWTP) were 10 – 20 nm and ~ 2.0 ng/mL, respectively. This result is being validated by transmission electron microscopy investigation. In addition, the developed method is being utilized to evaluate the fate of nAg in WWTP and characterize nAg in exposure water to support aquatic toxicology studies.

TP245 Determination of Tamoxifen and its Major Metabolites in Exposed Fish S. Jayaraman, M. Simoneau, R. Pruell, R. Gutjahr-Gobell,

G. Zaroogian, L. Mills, USEPA. Tamoxifen (TAM), (Z)-1-(p-dimethylaminoethoxyphenyl)-1, 2-diphenyl-1-butene, is a nonsteroidal agent that has been used in breast cancer treatment for decades. Its major metabolites are 4-hydroxytamoxifen (4-OHT), N-desmethyltamoxifen (DMT), and endoxifen. While TAM and metabolites have been measured in humans, rats, and chickens, we know of no studies conducted in fish, although fish are likely to be exposed to these chemicals through wastewater effluent entering aquatic environments. The purpose of this study was to develop and validate an analytical method for quantifying TAM and metabolites in fish plasma. We tested and modified the published analytical methods of Zhu et al. (2008, J Pharmaceut Biomed, 46: 349-355), which use UV exposure to convert TAM and metabolites to fluorescent derivatives for HPLC detection. We evaluated mexiletine, propranol, methoxytamoxifen, clomiphene and tormifene for internal standards. To determine optimal extraction and analytical methods, plasma samples from untreated fish were spiked with TAM and metabolites. Different solvents for extraction were evaluated, including diethyl ether (DEE) and various hexane/butanol mixtures. We varied combinations of mobile phase to optimize the separation, settling on an 82:18, methanol: 1% aqueous triethylamine solution. The optimal time for photochemical conversion of TAM and metabolites to phenanthrene derivatives, using a 4-watt UV lamp, was assessed. Chromatographic separations were carried out on a Waters HPLC with a 2690 Alliance separation module, 996 photodiode array detector, and 474 scanning fluorescence detector. The column was an Agilent Zorbax Extend C18 maintained at 60_C preceded by a matching guard column. A flow rate of 0.75 ml/minute was found to maximize separation of all analytes. The method detection limit was 1 ng/mL. Cunner (Tautogolabrus adspersus) were given a single 25 mg/kg dose of TAM by oral gavage, then approximately 0.5 ml of plasma was drawn from a caudal vein 1, 4, 8, 16, 20, 24, 48 and 72 hours later. Three fish were sampled at each time point, and each fish was sampled twice during the study. The analytical method that we developed is being utilized to evaluate TAM and metabolites in the plasma of these fish.

TP246 Development and Validation of Silicone Passive Samplers to Examine Oxygenated-PAHs in the Portland Harbor Superfund, OR S.G. O'Connell, Oregon State Univ, Environmental and Molecular Toxicology; T.A. Haigh, Oregon State Univ, EMT Dept; S.E. Allan, Oregon State Univ, Environmental and Molecular Toxicology, Oregon State Univ, Graduate Researcher; G. Wilson, Oregon State Univ, EMT Dept; L. Tidwell, K.A. Anderson, Oregon State Univ, Environmental & Molecular Toxicology. Passive samplers have been deployed to examine bioavailable fractions of contaminants in many matrices including air, water, and sediments. New deployment devices and materials have been developed in the last decade to sample contaminants with wide ranges of physiochemistry properties, including non-polar and polar organic compounds. Silicone polymers have been increasingly used as passive sampling devices in laboratory and field studies, mostly concentrating on polycyclic aromatic hydryocarbons (PAHs). Due to the intramolecular forces inherent in this material, silicone may preferentially sequester semi-polar organic compounds such as Oxygenated-PAHs (OPAHs) over other polymers used as passive sampling devices. OPAHS are characterized in recent publications as an emerging class of contaminants with environmental concentrations and toxicities similar to those of comparable PAHs. Early work supports our hypothesis by comparing silicone and lipid-free polyethylene tubing using GC-MS Automated Mass Spectral Deconvolution and Identification System (AMDIS). Several semi-polar organic compounds (log K_{ow} 2.0-4.8) were identified exclusively in the silicone polymer, including 9,10-Anthraquinone at the Portland Harbor Superfund Site, OR. Current work will quantify any additional OPAHs present in the extracts, and the results of these analyses will be compared to those values found in lipid-free polyethylene tubing deployed in tandem at the same field site.

TP247 Development of a Sample Preparation Procedure for the Determination of 17alpha-ethinylestradiol in Whole Fish Tissues A. Alansari, A. Saleem, L. Kimpe, V. Trudeau, J. Blais, Univ of Ottawa, Biology. Analysis of whole fish tissue extracts containing steroidal estrogens can be a challenging task to accomplish mainly due to the presence of co-extracted lipids and proteins that can hinder the analysis. The purpose of this study was to develop and optimize a targeted method for the sample preparation and analysis leading to a successful determination of 17a-ethinylestradiol (EE2) in whole fish tissues at $ng.g^{-1}$ levels. The procedure includes the extraction of whole fish tissue by pressurized liquid extraction (PLE), followed by lipid removal using gel permeation chromatography. Then, a crucial acetonitrile precipitation cleanup step was applied to facilitate the removal of cholesterol. The analysis was performed on a gas chromatograph/mass spectrometer (GC/MS) in selected ion monitoring (negative polarity). The method was developed using high lipid content wild fish spiked with EE2 ranging from 12.5-50 $ng.g^{-1}$. The recovery of the analyte ranged from 74.5-93.7% (RSD of 2.3-6.2%). The method detection limit was 0.68 $ng.g^{-1}$ dry weight (dw). The developed method was applied to determine EE2 levels in goldfish (*Carrasius auratus*) after a 72h dietary exposure. EE2 was detected in all of the seven exposed samples averaging 2.07±0.85 $ng.g^{-1}$ with method detection limits of 0.68 $ng.g^{-1}$. Funded by NSERC-Canada and King Abdulaziz Univ, Saudi Arabia.

TP248 Development of Modified QuEChERS Extraction Methods for the Analysis of PAHs in High Fat Content Fish and Smoked Salmon N.D. Forsberg, G. Wilson, Oregon State Univ, Environmental and Molecular Toxicology; K.A. Anderson, Oregon State Univ, Environmental & Molecular Toxicology. The QuEChERS extraction methods are popular techniques for extraction of bio-matrices because they are seen as Quick, Easy, Cheap, Effective, Rugged and Safe. However, we found that traditional QuEChERs methods were ineffective at recovering polycyclic aromatic hydrocarbons (PAHs) from high fat fish. Specifically, we demonstrated the poor performance of the traditional method in recovering (often < 60%) a large number of PAHs from fatty salmon samples. To fill this knowledge gap, modified extraction methods were developed and validated for 33 PAHs in smoked salmon with 3-11 % fat content. Sample preparation for the modified methods includes extraction of PAHs into a (2:2:1, v/v/v) solution of ethyl acetate, acetone and iso-octane followed by cleanup with dispersive SPE and analysis by GC-MS in SIM mode. Spike recoveries of some 2, 3 and 5-ring PAHs were improved 50 – 200% over traditional methods, while average recovery across all PAHs was improved 67%. Method precision and sensitivity were good with replicate extractions typically yielding relative standard deviations < 10% and detection limits in the low ng/g range. Results of the current work add to the understanding of QuEChERS sample preparation applications, specifically for extracting hydrophobic contaminants from high fat bio-matrices, and demonstrate limitations of traditional extraction schemes.

TP249 Diffusive Flux of Nanoparticles Through Porous Membranes with Chemically Modified Surfaces J.R. Stephens, The Pennsylvania State Univ, Chemistry; M.E. Williams, The Pennsylvania State Univeristy, Chemistry. Diffusive transport of nanoparticles through mesoporous materials are examined using a diffusive cell with two compartments separated by either a porous alumina or polycarbonate membrane. The initial experiments were conducted as a function of pore size, particle diameter, and solvent. Rates of transport were monitored by a change in absorbance of nanoparticle solutions in the receiving cell. Flux (J) of 3, 8, and 14 nm diameter $CoFe_2O_4$ particles were determined using the measured extinction coefficients and change in absorbance of the solution as a function of time as the particles were translocated across porous membranes with diameters of 30, 50, 100, and 200 nm in hexane and aqueous solutions. In all cases, J was slower through pores than in bulk solution and decreases as pore diameter decreases, however flux is inversely related to particle size. J values were larger in for aqueous solutions than in hexane, which is thought to result from the hydrophilic nature of the unmodified membranes. Pore surface chemistry plays an important and complementary role determining particle flux through pores, and ultimately in achieving selectivity in separation of nanoparticles and nanoarchitectures. These studies have used nanoparticles of 4, 8.5, and 14 nm diameter $CoFe_2O_4$ particles and alumina membranes with specific surface chemistries. The membranes are modified by the direct attachment of siloxanes with varying chains of varying length and terminal functionality. The results show that flux is greater when a hydrocarbon chain lines the interior pore wall compared to the initial studies of untreated membranes. Also, by altering the terminal head group of the attached siloxanes, flux of the $CoFe_2O_4$ nanoparticles is affected. These experiments allow us to explore the role of intermolecular interactions between the pore and particles and the impact on particle transport.

TP250 Distribution of Selected Wastewater Derived Pharmaceuticals in the Grand River Watershed L. Bragg, R. Tanna, Univ of Waterloo, Dept of Biology; G.R. Tetreault, Univ of Waterloo, Biology; M.E. McMaster, Environment Canada, National Water Research Institute; M.R. Servos, Univ of

Waterloo, Dept of Biology and Canadian Water Network, Univ of Waterloo, Dept of Biology. There has been increasing interest in pharmaceuticals and personal care products (PPCPs) in the environment over the past decade as technology continues to advance and detection of more compounds becomes possible. As populations continue to increase these chemicals are continuously added into the river systems since our waste water treatment plants (WWTPs) are not designed to remove PPCPs from the treated effluent. The Grand River watershed hosts a large population (~925,000) which is expected to increase substantially in the next decade. In the Upper Grand River, the major contributing WWTPs are in the cities of Waterloo, Kitchener, and Guelph. Waterloo and Kitchener have only secondary treatment whereas Guelph has tertiary treatment. We have completed a survey of selected emerging contaminants in the river water plus the WWTP effluent to coincide with other fish population and intersex studies completed in 2010. Samples were collected, preserved, transported to the lab prior to extraction with solid phase extraction (Oasis HLB 6cc, 500 mg cartridges). All samples were spiked with isotopically labeled standards to compensate for possible losses and matrix effects in the analysis. Analysis was completed by liquid chromatography-tandem mass spectrometry (LC-MS/MS) using an Agilent 1200 LC with an ABSciex 3200 Qtrap MS with electrospray ionization in both positive and negative modes. A wide range of emerging contaminants were analyzed such as ibuprofen, carbamazepine, diclofenac, fluoxetine, naproxen and venlafaxine with detection limits all below 10 ng/L Atrazine, a pesticide used frequently in the watershed, was also monitored in the analysis. The concentration of this pesticide remained relatively consistent throughout the watershed. Pharmaceutical concentrations, on the other hand, varied widely through the watershed increasing downstream of each WWTP. Distinct differences were observed between the effluents of the treatment plants with different treatment processes.

TP251 Effect Directed Assessment: Evaluating Estrogenic Activity of Municipal Wastewater Effluents B.M. Smith, K. Oakes, H.E. Engelhardt, L. Bragg, Univ of Waterloo, Dept of Biology; W. Parker, Univ of Waterloo, Dept of Engineering; M.R. Servos, Univ of Waterloo, Dept of Biology. Municipal Wastewater Effluents (MWWE) are potential anthropogenic sources of estrogenic substances. Fish exposed to these substances have shown estrogenic responses at various biological levels including estrogen receptor (ER) activity, elevated circulating vitellogenin (Vtg) and the occurrence of intersex within testes. An Effects Directed Assessment (EDA) was applied to three MWWE and three municipal wastewater pilot plant effluents to evaluate estrogenic activity using the yeast (*Saccharomyces cerevisiae*) estrogen screen (YES). Each effluent was also analyzed for Vtg using an indirect competitive enzyme linked immunosorbant assay (ELISA) in Rainbow Trout (*Oncorhynchus mykiss*) exposed for 8 or 14 d to each MWWE. The MWWE represent a range of treatment from conventional activated sludge to tertiary processes that discharge into the Grand River (Ontario, Canada). The pilot plant wastewater effluents represent three different processes: conventional activated sludge (CAS), nitrifying CAS (CAS-N), biological nutrient removal CAS (CAS-BNR). Effluent samples were collected, extracted by solid phase extraction (SPE) and fractionated by high performance liquid chromatography (HPLC) to separate potential estrogenic compounds and assayed for ER agonists using YES. All of the fish exposed to the MWWE showed no physiologically significant induction of circulating Vtg within or between treatments. However, preliminary results using YES show the presence of ER agonists in whole effluent extracts. Known estrogenic compounds including the natural hormone estrone have been isolated and identified at biologically active concentrations. Further comparisons among the treatment plant processes and pilot plant effluents are being conducted to elucidate and isolate other potential estrogenic substances.

TP252 Endocrine Disrupting Compounds and the Horseshoe Crab Populations of Delaware E.S. Maung, Univ of Delaware, School of Marine Science and Policy, Univ of Delaware; A.K. Aufdenkampe, Stroud Water Research Center; D.C. Miller, Univ of Delaware, School of Marine Science and Policy. The American horseshoe crab, *Limulus polyphemus*, is one of several horseshoe crab species, but the only one found along the coast in North America. With a range from northern Maine to the Yucatan peninsula in Mexico, this species has its highest spawning densities in Delaware and is of great importance to the fishing, biomedical and ecotourism industries. Because horseshoe crabs spend the first 3 weeks to few months of life buried in coastal beach sediments, they are susceptible to endocrine disrupting compound (EDC) exposure from sources such as runoff and groundwater. Little is known about what endocrine disrupting compounds may accumulate in the tissues of horseshoe crabs, or how those contaminants will impact larval development. Furthering our understanding of these parameters is critical to understanding chemical problems in the Delaware estuaries, as horseshoe crabs hold a key role in the food web and thus in maintaining ecosystem integrity and biodiversity. We took a novel approach to examine these unknowns by modifying a pre-existing gas chromatography mass spectrometry method to identify which EDCs horseshoe crabs accumulate while developing in beach sediments. This method was implemented on eggs, embryos and larvae collected from a total of 6 sites from within the Delaware and Inland Bays. These samples were examined for accumulation of pesticides, surfactants, antimicrobials, as well as estrogens. Nonylphenol and triclosan were among the most ubiquitously found compounds. Alachlor and 17α-ethinylestradiol had the highest tissue concentrations (0.24 and 0.73 µg/kg respectively). Experiments are currently underway to determine the impact of chronic exposure to these compounds on larval development.

TP253 Enrichment of Chromium, Nickel and Cobalt in Sediments, Water, Mussels and Fucus Influenced by Natural Mineral Sources M. Caetano, INRB IP/IPIMAR; R. Prego, N.O. Alvarez, Marine Research Institute (CSIC); J. Raimundo, INRB-Ipimar, Biogechistry & Environmental Impact; C. Vale, INRB IP/IPIMAR. Geological complex close to the shoreline could be significant contributors of trace metal to the coastal environment. This is a key question poorly considered that could be blend with anthropogenic contamination events. Therefore, the aim was to research the influence of chromium (chromite and chromospinel) and nickel (gersdorfite and pentlandite) minerals associated with ultrabasic rocks of Cape Ortegal and pirrotites of Herbeira Massif, on its adjacent coastal area of north Galicia. In order to achieve this objective (a) the tributary rivers Mera, Landoi and Lourido that flow from Ortegal hillside to the Ortigueira Ria were fortnightly sampled during 2008; (b) the surface sediment of Northern Galician Rias and their adjacent shelf was sampled in July 2008; (c) samples of mussels and fucus were seasonally collected during 2008 inside the Ortigueira Ria. Dissolved Cr and Ni was analysed by ICPMS while particulate samples and organisms were mineralized in a microwave following EPA procedures and metals analyzed by GFAAS. Levels of Cr in surface sediments ranged 200-930, 230-1340 and 290-1660 mg•kg-1 in inner and outer ria and shelf, respectively. Results confirm enrichment of Cr, five to forty times, higher than background levels of other Galician rias. Using Mg as a particle tracer it maybe concluded that Ortegal Cape was the Cr source. Moreover, rivers indicate the same pattern: Landoi and Lourido in Ortegal area had 7-48 and 5-81 nM of dissolved Cr and 0.2-0.8 and 0.2-1.3 g•kg-1 of Cr in SPM while out of Ortegal complex Cr in Mera River was < 0.2nM and < 0.3 g•kg-1. In biota, Cr levels (2.0-3.5 mg•kg-1) were similar to mussels of other coastal rias whilst in fucus higher levels were found in Ortigueira (7-16 mg•kg-1). The Ortegal Cape was also identified as the main Ni source using Mg as a particle tracer. Levels of Ni in coastal surface sediments ranged 100-620, 140-470 and 160-1360 mg•kg-1 in inner and outer ria and shelf of Ortigueira, respectively; these concentrations decreased to 5-160 and 4-87 mg•kg-1 in the neighbouring rias of Barqueiro and Viveiro. Results pointed to a high sedimentary Ni enrichment, four to twenty times respect to usual rias background concentrations, in the coastal environment of the Ortegal Cape. Fluvial discharges also indicated the same geological source: Lourido and Landoi transport 190±95 and 80±30 nM of DNi and 24±17 and 95±90 nM of PNi while out of Ortegal complex Mera River had 15±7 nM of DNi and 4±3 nM of PNi. In biota, Ni levels (3.4-6.9 mg•kg-1) were similar to mussels of other rias whilst in fucus the highest concentrations were found in Lourido mouth (46 mg•kg-1), decreasing to ria mouth (8.5 mg•kg-1). Coastal enrichment in trace metals can also occur due to natural contributions apart from anthropogenic contamination. It is the observed case of Cr and Ni in the fluvial, estuarine and marine environment close to Cape Ortegal as result of the presence of chromium and nickel minerals.

TP254 Environmental Fate of Glyphosate in Broom-infested Mt. Tamalpais Soil H. Hwang, Univ of California, Davis, Dept of Civil and Environmental Engineering, Univ of California, Dept of Civil and Environmental Engineering. Glyphosate is a post-emergent and non-selective organophosphorus herbicide, which is the most commonly used in the US for weed control in residential, commercial, agricultural, and forestry settings. The present study investigated environmental decay of glyphosate in surface soil and on the broom leaves as well as lateral and vertical transport

by stormwater runoff and soil infiltration. Environmental half-life in the surface soil was 44 days, while concentrations of glyphosate in broom leaves didn't exhibit significant changes over 84 days of study period. Significant fractions of leaves were still remained on the stems at the end of the study period and thus the slow degradation on leaves needs to be combined together with relatively faster degradation in soils to calculate overall degradation of glyphosate. Glyphosate was not found in two stormwater runoff collected at a site about 50 feet from an application site. Glyphosate was detected in core soils up to 30 cm deep with the highest concentrations in the top layer. Laboratory infiltration simulation study showed that glyphosate can further move down through the soil layers up to 54 cm, though water infiltration rate used for the laboratory study was not realistic.

TP255 Environmental Quality in Recreational Beaches in Campeche, Mexico L. Alpuche Gual, Campeche Autonomous Univ/EPOMEX Center, Centro Epomex; M. Lara-Flores, Y. Sulub-Palafox, G. Poot-Cruz, B. Ramirez-Vargas, Campeche Autonomous Univ/EPOMEX Center. Campeche coastal tourism depends on clean beaches, unpolluted water, well-planned coastal areas and coastal and marine ecosystems preserved. Despite the importance that the beaches are in coastal development in the zone, have become the receptacle of contaminated water collected by the urban sewer systems or storm drains – often without treatment – water courses, maritime areas adjacent to their coasts, or even directly to the beach. The aim of this study was to evaluate the environmental quality of coastal waters from several beaches in Campeche, Mexico through the measurement of water quality parameters and determination of pollutants identified by the Mexican standards. Water and sediment samples were collected on a network of sampling sites in five public beaches and adjacent coastal every month during an annual cycle. Using a multiparameter sonde we measured in situ pH, conductivity, temperature, salinity, TDS, LDO and %LDO. The results indicate poor water quality especially in Campeche and Carmen beaches to good in Champoton beaches. Measured levels of faecal coliforms were above the limits established by Mexican law. This, besides a deficiency in dissolved oxygen and a high organic matter concentration (as COD), reflects eutrophication processes in some areas of the coastal zone in Campeche and Carmen. Multivariate analysis was used to regionalize the beaches in Campeche as a function of the behavior of all measured parameters. It was concluded that discharges of untreated wastewater, impact the environmental quality of these shores in some seasons, particularly total and fecal coliforms, which are hazardous to the health of recreational users of these sites.

TP256 HPLC-ESI/MS/MS Method for the Determination of Endogenous Estradiol and Testosterone in Fish Plasma M. Fleischer, S. Devellis, Smithers Viscient; R. Biever, Smithers Viscient, Dept of Environmental Toxicology; P. Riebach, Smithers Viscient. Estradiol and testosterone are two key steroids of the endocrine system, which can be measured as optional endpoints in the Fish Short-Term Reproduction Assay. The levels in plasma can be used as in indicator of disruption in endocrine system functions. An HPLC-ESI/MS/MS method was developed and validated for the simultaneous determination of both estradiol and testosterone in fish plasma. Whole blood was collected manually from fathead minnows (*Pimephales promelas*). Plasma was generated by centrifugation. Analyses were performed on small volume plasma samples (generally ≤ 10 µL). Plasma proteins were removed by either centrifugation or using a 96 well filtration format plate. Estradiol was derivatized with dansyl chloride. Testosterone was determined without modification. Deuterated internal standards for both were utilized. The LOQ for the analysis is 0.3 ppb for estradiol and 0.15 ppb for testosterone. Endogenous levels for control fish generally agreed with published values. This method will be used in conjunction with Tier 1 Endocrine Disruptor Screening Program (EDSP) assays.

TP257 Metabolic Activation of Halogenated Bisphenol A by Rat Liver S9 and Their Thyroid Hormone Activity M. Terasaki, Univ of Shizuoka, Institute of Environmental Sciences; Y. Seki, M. Makino, Univ of Shizuoka. The thyroid hormone (TH) agonist/antagonist activities of halogenated derivatives of bisphenol A (BPA) were assessed using a yeast two-hybrid assay incorporating the human thyroid hormone α (TRα), both with and without possible metabolic activation by rat liver S9 preparation. In the absence of the rat liver S9 preparation, 3,3',5,5'-tetrabromobisphenol A (TBBPA), 3,3',5,5'-tetrachlorobisphenol A (TCBPA), and 3,3',5-trichlorobisphenol A (3,3',5-triClBPA) exhibited agonist activity, whereas 3-chlorobisphenol A (3-ClBPA), 3,5-dichlorobisphenol A (3,5-diClBPA), 3,3'-dichlorobisphenol A (3,3'-diClBPA), and BPA did not. In the presence of the rat liver S9 preparation, three halogenated BPAs showed an increase in agonist activity. The activities of TBBPA and TCBPA increased markedly after their metabolic activation with the rat liver S9 preparation (7.6-fold and 3.1-fold, respectively). With regard to the biotransformation of halogenated BPA, TBBPA undergoes oxidative cleavage near the central carbon of the molecule, leading to the production of hydroxylated bromophenol by liver S9 fractions. Several halogenated phenols are capable of acting as TH-like compounds in in vitro assays and are more active than TCBPA or TBBPA. Some yeast strains are also able to degrade dibenzofuran or biphenyl up to ring cleavage in the presence of the co-metabolic substrate. The activity of the metabolites of halogenated BPA may contribute to the elevation of the observed TH activity by exposure to the S9 preparation or yeast strain. TBBPA, TCBPA, and 3,3',5-triClBPA inhibited the binding of triiodothyronine (T3) to TRα at 20,000 nM without rat liver S9 treatment and 4,000 nM with rat liver S9 treatment, demonstrating their T3 antagonist activity. These antagonist activities were enhanced by exposure to S9 metabolic activation at the same concentration level. In this study, we showed the agonist/antagonist activities of some halogenated BPAs, as well as their assumed effects in humans, and their metabolic activities with respect to TH when exposed to the rat liver S9 preparation. Interestingly, the results also revealed that metabolic activation by rat liver S9 significantly increased their agonist/antagonist potential.

TP258 Method Development for the Analysis of DDT, DDeE, DDD in Cow Milk A. Parra, Univ of Texas at El Paso, 330 Emerald Rise; B. Rocha, Univ of Texas at El Paso; W. Lee, Univ of Texas-El Paso. Organochlorine Pesticides (OCs) are classified as persistent organic pollutants (POPs). They have been found to bioaccumulate in organisms. These chemicals tend to attach to fatty tissues in animals and humans, remaining in them for long periods of time. OCs may be responsible for a vast number of health conditions including neurological disorders, endocrine disruption, reproductive dysfunctions, and possible linkage to cancer. OCs such as DDT, DDE and DDD are banned, however, they have still been detected in environmental samples worldwide. The main objective of this study is to investigate a new extraction method to determine the presence of DDT, DDE and DDD in milk using an innovated and environmental friendly technique, called Stir Bar Sorptive Extraction (SBSE). SBSE coupled with thermal desorption Gas Chromatography and Mass Spectroscopy will be applied in the analysis of OCs in samples. Different solvent system and additive effects were tested with SBSE process to determine OC recovery in milk samples. It was discovered that a 30% mixture of acetonitrile/ water and sodium hydroxide as an additive yielded the most OC recovery after extraction.

TP259 Miniaturized Matrix Solid Phase Dispersion Extraction for the Analysis of Pesticides in *Chironomus dilutus* Y. Ding, Southern Illinois Univ; A. Hartmann, Southern Illinois Univ, Fisheries and Illinois Aquaculture Center; M. Lydy, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology. A miniaturized method using disposable glass Pasteur pipettes (5.75") was developed based on matrix solid phase dispersion extraction to measure seven pesticides and their degradation products in the aquatic invertebrate, *Chironomus dilutus*. The target pesticides included the organochlorine pesticide dichlorodiphenyltrichloroethane (*p,p'*-DDT), and its major degradation products, dichlorodiphenyldichloroethane (*p,p'*-DDD) and dichlorodiphenyldichloroethylene (*p,p'*-DDE); pyrethroid insecticides, permethrin, bifenthrin, and tefluthrin; and organophosphate pesticide, chlorpyrifos. The method compared Florisil and silica gel as dispersants for extraction and cleanup of biological samples. Analyses were performed by gas chromatography with micro-electron capture detection (GC-µECD) with 4, 4'-dibromooctafluorobiphenyl and decachlorobiphenyl as spike surrogates. Silica gel (0.5 g) was selected as the dispersion absorbent to blend with midge larvae (0.05 g wet weight) and anhydrous sodium sulfate, while 4 ml ethyl acetate was used as the elution solvent. Mean recoveries ranged from 57.2 to 127.6% at spiked levels between 20 and 1000 µg kg^{-1}, with relative standard deviations below 15% for most target analytes. The method detection limits ranged from 3.1 µg kg^{-1} for *p,p'*-DDD to 19.6 µg kg^{-1} for permethrin. The proposed method was used to measure *C. dilutus* residues of tefluthrin, chlorpyrifos, and *p,p'*-DDD in laboratory-exposed toxicity tests. The developed method was easier and less time consuming than the conventional extraction procedure and reduced the amount of sample, dispersant and solvent used.

TP260 National Rivers and Streams Assessment Survey: Evaluating the Extent of Selected Human Prescription Pharmaceuticals in US Surface Waters A.L. Batt, USEPA Office of Research and Development, National Exposure Research Laboratory; J. Lazorchack, L. Stahl, J. Wathen, USEPA. The Ecological Exposure Research Division (EERD) has prioritized a list of the most prescribed active pharmaceutical ingredients (API) in the US based on the potential of their wastewater residues to cause biological effects. A method using selective solid phase extraction and liquid chromatography in combination with tandem mass spectrometry was developed for the analysis of the top rated APIs from that process, which includes 48 APIs and 6 selected metabolites. The National Rivers and Streams Assessment (NRSA) is a statistical survey of flowing waters of the US designed to assess the condition of the Nation's rivers and streams. EERD from the Office of Research and Development (ORD) is working with the Office of Water (OW) on the current NRSA Survey, which consists of approximately 700 sites where fish were collected over the course of summer 2008 and 2009. A portion of these sample collection sites (180) have been identified as Urban Rivers, due to their proximity to urban areas. Surface water samples were collected from each of these Urban River sites and analyzed for the presence of over 50 human prescription pharmaceuticals. Several of the target analytes were detected, with concentrations ranging from low ng/L up to 500 µg/L. Results from this study will be presented and used by ORD and OW to assess the extent of contamination of these emerging contaminants in our nation's urban rivers.

TP261 Occurrence and Environmental Distribution of Artificial Sweeteners in the Aquatic Ecosystems in Japan T. Orishikida, H. Nakata, Univ of Kumamoto, Graduate School of Science and Technology; T. Hosono, Univ of Kumamoto, Priority Organization for Innovation and Excellence; M. Ono, T. Tokunaga, M. Kagabu, J. Shimada, Univ of Kumamoto, Graduate School of Science and Technology. In recent years, large amounts of low-calorie sweeteners have been used in a wide variety of soft drinks and foodstuffs in the world. These compounds are less degradable during wastewater treatment process, and detected in the aquatic environment in European countries. However, there are little data of the occurrence, concentrations and distribution of artificial sweeteners in Japan. In this study, we developed simultaneous analytical method of five artificial and two natural sweeteners in liquid samples and it was applied to wastewater treatment plant (WWTP), river water, and groundwater samples collected in Japan. As for the method development, the solid phase extraction (SPE) cartridge, Oasis HLB (500 mg, 6 cc), was used for the extraction of samples. When the eluate of SPE was applied to 40% acetonitrile/water (v/v), the recoveries of artificial and natural sweeteners were 92 and 87%, respectively. The artificial sweeteners, such as acesulfame K (AK) and sucralose (SUC), were detected in WWTP influents and effluents at the concentrations of > 1 µg/L. High concentrations of saccharin Na (SA) was also found in the influents of WWTPs, which suggests the large amounts of productions and usage of these compounds in Japan. AK, SUC and SA were detected in river water samples at the levels ranging from several tens to hundreds of ng/L. AK and SUC showed higher concentrations in river water samples at the stations proximal to downstream of WWTPs. AK and SA were also detected in groundwater samples, at the levels of

TP262 Occurrence of Perfluorinated Compounds in the Ground and River Water of the Tama Region in Tokyo, Japan T. Suzuki, Tokyo Metropolitan Institute of Public Health, Division of Water Quality; Y. Kosugi, M. Hosaka, K. Yaguchi, D. Nakae, A. Ogata, Tokyo Metropolitan Institute of Public Health; T. Nishimura, National Institute of Health Sciences. Perfluorinated compounds (PFCs) in the environment have been concerned by their persistence, bio-accumulation and toxicity. PFCs were detected in many kinds of samples from aquatic and atmospheric environment, food, human, and marine life. Perfluorooctane sulfonate (PFOS) and perfluorooctane sulfonyl fluoride were added to a list of persistent organic pollutants (POPs), by the Stockholm Convention in 2009. In this study, the monitoring of PFCs in the urban river water and groundwater at the Tama region in Tokyo, Japan was conducted. The analytes in this study were 10 perfluoro carboxylic acids (PFCAs, C5 – C14) and 4 perfluorosulfonates (PFCSs, C4 – C10). The river water samples of the Tama River, a typical urban river in the Tokyo area, were collected in 2008. The groundwater samples at the Tama region were collected from shallow and deep wells used as the drinking water from 2007 to 2010. The analysis was performed by a solid-phase extraction and a liquid chromatography-tandemmass spectrometry (LC/MS/MS). PFCs in the river water samples obtained at the upper reaches ranged at the concentrations of 0.7 – 5.1 ng/L for PFCAs and 0.2 – 30.4 ng/L for PFCSs. Those obtained at the lower reaches of the river increased to 14 – 60 ng/L for PFCAs and 17 – 168 ng/L for PFCSs. The composition of PFCAs and PFCs were as follows: PFNA (43%) > PFOA (32%) > PFHxA (9%), and PFOS (77%) > PFHxS (18%) > PFBS (4%), respectively. The increase of the PFCs concentration in the river water was due to the inflow from sewage treatment plants (STPs) located by the river. The total inflow amount from the STPs ranged from 20 to 30 g/day. The higher concentrations of PFCs were detected in the groundwater samples than in the river water samples. The composition of PFCs in the groundwater samples (n=326) were as follows: PFOA (67%) > PFOS (57%) > PFHxS (55%) > PFNA (44%) > PFHpA,PFPeA,PFBS, PFHxA (35-42%) > the others (0-15%). PFCs in the groundwater samples ranged at the concentrations of 0.5 – 200 ng/L for PFCAs and 1.6 – 5800 ng/L for PFCSs. According to a cluster-analysis, PFOS and PFHxS were predominant in the groundwater in this region. The concentration of PFOS in the 16 wells exceeded the USEPA's provisional drinking water guideline value of 200 ng/L, whereas, the concentrations of PFOA in all wells were lower than the guideline value of 400 ng/L.

TP263 Partitioning of a Suite of Chlorobenzenes to Aldrich Humic Acids and Primary Effluent Colloidal Organic Matter from a Sewage Treatment Plant K. McPhedran, R. Seth, Univ of Windsor, Environmental Engineering; K.G. Drouillard, Univ of Windsor, Great Lakes Institute for Environmental Research. Municipal sewage treatment plants (STPs) can be a source of exposure to human and ecological receptors for many contaminants of concern through loadings via STP effluent discharges to receiving waters or land application of sludges. These loadings depend on the fate and transport of contaminants through the stages of the STP process. Submicron size or colloidal organic matter (COM) possess large surface areas that can facilitate binding of hydrophobic organic compounds (HOCs). Municipal sewage has a significant concentration of COM that can impact the HOC fate. HOC sorption to colloids has been well studied in natural environments; however, few studies have investigated their sorption to STP colloids. The objective of the current study is to improve understanding of HOC fate during the STP process and ensuing environmental loadings. In this study, the sorption of three chlorobenzenes (1,2,4,5-tetrachlorobenzene, pentachlorobenzene, and hexachlorobenzene) to COM in 1.5 µm filtrate of primary settling tank STP effluent was examined using the long-column sparging technique. Six spargers were used in parallel which allowed for concurrent replication of control and treatment spargers. Chlorobenzenes (CBs) are a diverse chemical suite with widely varying physico-chemical properties, presenting an ideal choice for better understanding of partitioning behaviour. Sorption of CBs to standard Aldrich humic acids (AHA) was conducted for comparison. Results show significant sorption of all three CBs to primary settling tank COM. The sorption behaviour was different as compared to AHA when normalized to the organic matter content. AHA sorption behaviour was similar to literature values and followed expected trends based upon physico-chemical properties of the three CBs. In contrast, no clear trends of sorption behaviour with effluent COM was observed. Implications of the results will be discussed.

TP264 Persistent Organic Pollutants and Trace Elements Associated to Sedimentary Processes in the Colorado River Delta, Baja California, México K. Lugo-Ibarra, Universidad Autonoma de Baja California, Instituto de Investigaciones Oceanologicas; L. Daessle Heuser, J. Macias-Zamora, N. Ramirez-Alvarez, Universidad Autonoma de Baja California. Polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs) and trace elements (As, Cu and Pb) were studied in sediments cores from two distinctive modern channels of the Colorado River (CR) delta. Their abundance and temporal changes are associated with flood-flows of the CR across the Mexico-USA border. The CR channel is directly exposed to river flood-flows. The Hardy River (HR) is a local channel derived mainly from agricultural runoff, geothermal effluents and treated urban wastewater. Different headwater compositions and degrees of exposure to flood-flows appear to be the factors controlling the composition of persistent organic pollutants (POPs) and trace elements. Enrichment of OCPs (46 ng g-1 dwt in HR and 4.37 ng g-1 dwt in CR) occurred during, or a few years after flooding. PCB-138 (4.2 ng g-1 dwt) is enriched in HR suggesting its origin in dielectric oils from the geothermal power plant. PCB-28 (2.1 ngg-1 dwt) in CR maybe related with atmospheric input and/or re-deposition of upstream sediments. Only HR with 4, 4'- DDE (8.16 ng g-1 dwt) and ΣDDT (8.34 ng g-1 dwt)

exceed some of the international sediment quality guideline criteria. As, Cu and Pb suggest the most likely sources for these element enrichment especially As are the arsenate based pesticides used intensively in the area during the first half of the 20 th century. Arsenic in the buried clay units of the HR has concentrations above the probable toxic effect level (PEL) for dwelling organisms, with maximum concentrations of 30 lg g-1.

TP265 Photochemical Fate of Organic Ultraviolet Filter Chemicals in the Aquatic Environment L.A. MacManus-Spencer, S. Bercovici, S. Suhag, A. Kracunas, Union College, Dept of Chemistry. One class of pharmaceuticals and personal care products of current environmental concern comprises the organic ultraviolet filter chemicals (UVFCs) used in sunscreen lotions, lip balms, and other personal care products to protect the skin from harmful UV radiation. In addition to indirect inputs (e.g., showering and washing clothes, leading to discharges to wastewater treatment plants), these chemicals also enter the aquatic environment by direct routes (e.g., swimming). Given the ever-increasing use of sunscreen products and their multiple routes to the environment, it is important to understand their environmental fate in order to make educated decisions about their regulation and remediation. In this study, the photochemical fates of two commonly used organic UVFCs, octyl dimethyl para-aminobenzoic acid (padimate O) and octyl methoxycinnamate (octinoxate), have been investigated. In previous studies, we have shown that octinoxate degrades readily by direct photolysis (half-life less than one hour), and we have identified several degradation products. In recent research, we have investigated the effects of sorption to suspended particles on the photolysis kinetics and product distribution of octinoxate. In addition, we have investigated the kinetics of padimate O photolysis under a variety of conditions. Padimate O degrades only slightly slower than octinoxate, with an estimated half-life of just over one hour, and is characterized by a direct photolysis quantum yield similar to that of octinoxate ($\sim 10^{-3}$). Using liquid chromatography-mass spectrometry (LC-MS), several padimate O photodegradation products have been identified, including demethylation products and a methylation product. We have also obtained evidence of products formed by the reaction of two padimate O molecules, and some evidence points to the photochemical production of para-aminobenzoic acid (PABA), a previously used sunscreen chemical that is no longer approved by the FDA due to its ability to cause allergic reactions and its potential carcinogenicity. Finally, we have investigated the photolysis of mixtures of organic UVFCs in order to more accurately represent conditions both in the aquatic environment and in the sunscreen products themselves. For example, oxybenzone (another of the most commonly used organic UVFCs) acts to slow the photolysis of octinoxate, thought it does not appear to affect all photolytic pathways equally.

TP266 Rapid Screening for Polyaromatic Hydrocarbons in Seafood Using LC-Fluorescence J. Burgess, Waters Corp.; M. Benvenuti, K. Rosnack, Waters Corporation. Major oil spills such as the *Exxon Valdez* in 1989 and the recent Gulf of Mexico spill of April, 2010 have raised concerns over the quality of seafood harvested from these regions. Fish, crustaceans and mollusks may come into contact or ingest the oil thereby introducing potential health risks to consumers. PolyAromatic Hydrocarbons (PAHs) are an important subset of compounds present in oil that have been classified as priority pollutants. The USFDA has established levels of concern ranging from 0.035 mg/kg Benzo[*a*]pyrene in finfish to 2000 mg/kg combined phenanthrene and anthracene in oysters. To prevent consumption of contaminated seafood and minimize the impact on the seafood industry, a fast screening method is required to analyze these compounds of concern at the stated levels. Here we demonstrate that, following a simple extraction using a QuEChERS technique, an analysis of PAHs can be achieved in less than 4 minutes using the ACQUITY® H-class with fluorescence detection. Results show that dispersive sample preparation provides a fast and effective method for extracting PAHs from different seafood matrices. The method provides advantages over other sample preparation techniques as accurate results can be achieved with less sample preparation and in a shorter time. With sample preparation times reduced, a rapid chromatographic separation is critical to manage the samples, standards and QCs generated using this approach. The ACQUITY H-Class separation, which was achieved in less than 4minutes, is able to address this demand. This solution allows laboratories to screen for PAHs in seafood, providing results in a timely manner.

TP267 Sorption of Two Growth Promoters Used in Livestock to Midwestern Soils A. Kreinberg, The Ohio State Univ, School of Earth Sciences; Y. Chin, The Ohio State Univ, Dept of Geological Sciences. The environmental fate of synthetic and naturally produced hormones/growth promoters is not well understood. Tylosin is a macrolide antibiotic that is used both to treat bacterial infections in humans and more commonly as a growth promoter for swine production. As of 2000, over 90% of swine production facilities in the United States used antibiotics, of which tylosin was the most widely applied. Progesterone, an estrogenic steroid produced naturally by both genders, is also used (in conjunction with other steroids and steroid-like compounds) as a growth promoter in feedlot cattle. Both of these compounds are mostly metabolized by the target organism, but residual levels can enter the environment by waste products. Thus, sorption to soils by these compounds is a potentially important attenuation process. We conducted batch sorption experiments to measure the sorption of these two compounds to several different soils with different sorbent properties, such as soil organic matter content, cation exchange capacity, and soil pH. Our results show that tylosin sorption is linear to all soils with a soil organic matter partition coefficient (K_{OC}) ranging from 446 to 1130 L/kg. Our K_{OC} values are consistent with values reported in the literature and are higher than the compound's octanol/water partition coefficient (K_{OW} = 316). Tylosin has a pK_a of 7.7 and is positively charged at pH values less than its pK_a. We suspect that the higher than anticipated K_{OC} values reflect adsorption of the charged tylosin species to specific sites on the sorbent. Conversely progesterone sorption is non-linear and is best described by the Freundlich equation with slopes varying from 0.82 to 0.98. The degree of nonlinearity is strongly dependent upon the sorbent used. We are currently studying how both the sorbate and sorbent properties are influencing the sorptive behavior of our target compounds.

TP268 Synthesis and Evaluation of Natural Product Halogenated Bipyrroles as Heme Oxygenase-1 Inhibitors K. Foster, R. Smith, Univ of Mississippi, Dept of Medicinal Chemistry; D. Stec, Univ of Mississippi Medical Center, Dept of Physiology and Biophysics; J. Rimoldi, Univ of Mississippi, Professor of Medicinal Chemistry, Univ of Mississippi, Dept of Medicinal Chemistry. Naturally occurring halogenated bipyrroles have recently been discovered in seabird eggs bioaccumulating in trophic organisms. These compounds are suspected to be biogenic in nature from evidence of marine natural products persistent in the environment and widespread in the Pacific and Atlantic Ocean. These compounds exhibit chlorinated and brominated substitution patterns that closely resemble anthropogenic pollutants like the polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and polybrominated diphenyl ethers (PBDEs). In 2003, environmental health concerns surfaced regarding these naturally occurring bipyrrole compounds since several of these analogs were shown to induce the cytochrome P4501A (CYP1A) gene through activation of the AhR signaling pathway and also resulted in porphyrin accumulation in chicken embryo hepatocytes. Based on these studies, we have focused our efforts on examining the effects of halogenated bipyrroles to inhibit heme oxygenase (HO), the enzyme responsible for the catalytic oxidation of heme, which may account for the accumulation of porphryrins in hepatocyte models. Within the current study we have synthesized and characterized several natural product halogenated bipyrroles, and examined their effect on heme oxygenase-1, utilizing assays performed on liver lysates obtained from mice treated with the heme oxygenase-1 inducer, cobalt protoporphyrin. The ability of the halogenated bipyrroles to inhibit HO was evaluated by measuring the amount of bilirubin formed from the HO-catalyzed oxidation of hemin. Several of the analogs were found to be potent inhibitors of HO, and these results suggest that porphyrin accumulation from halogenated bipyrrole exposure may be mediated by the direct inhibition of heme oxgyenase-1.

TP269 Uptake Kinetics and Long-term Monitoring of Persistent Organic Pollutants Using SPMD and High Volume Water Sampler G. Han, Korea Ocean Research and Development Institute, Oil & POPs Research Group; S. Hong, Korea Ocean Research & Development Institute, Oil and POPs research group, Korea Ocean Research & Development Institute; U. Yim, S. Ha, J. An, W. Shim, Korea Ocean Research and Development Institute. Passive sampling in environmental research is getting increasing attention as an alternative to expensive and more laborious active sampling. It can provide time-integrated samples for air and water. Uptake kinetics and characteristics of persistent organic pollutants (POPs) in seawater was investigated using passive and active water sampling. Semipermeable membrane devices (SPMDs) and high volume water sampler was deployed at a coastal station, Jangmok, Korea. Performance reference compounds

including PCB14, PCB50, PCB188, and _-HCH-d6 were used to estimate the sampling rate of SPMD. Accumulation characteristics of POPs were monitored monthly basis by both sampling methods. In general, the POPs concentration in seawater tends to increase at high temperature season. Concentrations of POPs estimated by the SPMDs were comparable to those detected by active sampling. However, significant difference was observed in some volatile compounds such as HCHs, where active sampler accumulated relatively higher amount of the residues than SPMD. The isomer profiles of target compounds were similar between active and passive samples. The highest uptake rate of hydrophobic compounds by SPMDs was observed for analytes with log KOW between 5.0 and 6.5.

TP270 Environmental Risk Assessment of Selected Human Pharmaceuticals in Urban Rivers in Japan T. Nishimura, National Institute of Health Sciences, Division of Environmental Chemistry, National Institute of Health Sciences, Environmental Chemistry; A. Hirose, National Institute of Health Sciences, Risk Assessment, Biological Safety Research Center; T. Kawamoto, Hyogo Prefectural Institute of Public Health and Consumer Sciences Public Health Science Research Center, Life science division; M. Yano, Hyogo Prefectural Institute of Public Health and Consumer Sciences Public Health Science Research Center; Y. Kosugi, T. Suzuki, Tokyo Metropolitan Institute of Public Health, Water Quality. Recently, the environmental risk assessment (ERA) has been conducted in Japan. In EU and USA, the ERA of pharmaceuticals has been already introduced in order to develop a pharmaceutical with low potential environmental risk. The objective in this study was to investigate whether it is adjusted to apply the European Medicines Agency (EMEA) guideline to Japanese situation by evaluating measured (MECs) and predicted (PECs) environmental concentrations of selected human pharmaceuticals in urban rivers receiving discharge from sewage treatment plants (STPs). This case studies were conducted at the urban river basins in Tokyo Metropolitan and Hyogo Prefecture in Japan. The MECs of the selected pharmaceuticals in water samples were measured by reverse-phase LC/MS(/MS) after solid-phase extraction. The PECs for aquatic environment of pharmaceuticals were calculated by according with Phase I of the EMEA guideline. The PECs of the selected 101 pharmaceuticals in raw sewage of STPs were calculated from 0.10 to 300 _g/L. 38 pharmaceuticals have been detected in raw sewage of six STPs. Their MECs ranged from 0.04 to 16.9 _g/L, and all of them were lower than those PECs. As for the river basins, the PECs of 101 pharmaceuticals in the river water receiving discharge from STPs were calculated from 0.015 to 30 _g/L. 41 pharmaceuticals have been detected in the river water. Their MECs ranged from 0.003 to 3.23 _g/L and were in the same range of the PECs. In the river water at the sampling site, where approximately half of the river water consists from drainage of STPs, however, the MECs of epinastine (antiallergic drug), candesartan (drug for high blood pressure), and lorazepam (psychotropic drug) were higher than their PECs. Epinastine is mainly excreted unchanged in human. Candesartan, principle active metabolite of candesartan cilexetil in human, is excreted unchanged in urine and feces. Lorazepam is mainly excreted as the glucuronide. The removal rates of these active gradients at six STPs ranged from 0 to 30%. The pharmaceuticals, which have maximum dose lower than several dozen mg/kg/day, high excretion ration in human, and low removal rate at STPs, could be underestimated in urban river in Japan at the dilution factor (DF) = 10 in Phase I of the EMEA guideline. However, it was prevent when the DF of real field condition at the sampling sites in the river were applied.

TP271 Optimizing Scientific and Social Attributes of Pharmaceutical Take Back Programs to Improve Public and Environmental Health K.I. Stoddard, Univ of North Texas, Institute of Applied Sciences, Univ of North Texas, Research assistant; D. Huggett, Univ of North Texas, Institute of Applied Sciences. Scientific data indicate that pharmaceuticals are present in water, sediment, and aquatic biota here in the US and in many other countries. Research continues to provide evidence that these contaminants may cause adverse environmental effects with the most studied response being feminization of fish associated with oral contraceptives. Excess pharmaceuticals also pose a threat to public health due to the increased risks of accidental poisoning and prescription medicine abuse. The two main routes by which pharmaceuticals enter the environment are improper disposal of excess or unwanted pharmaceuticals and post-consumer excretion. Pharmaceutical take-back programs (TBP) have emerged as a promising method for addressing these public and environmental health concerns; however, to date oversights of scientific and social elements of TBPs have limited their full potential to address these concerns. A semi-annual TBP called Denton Drug Disposal Day (D4) has been developed in Denton, Texas in response to these oversights. The objectives of D4 include providing a safe pharmaceutical disposal method, determining the public and environmental health benefits of a TBP, and using survey analysis and Geographic Information Systems (GIS) to optimize TBPs. Prior to the first D4 event, a phone survey of Denton County residents was conducted to gather baseline information on disposal practices, public risk perception, and identify barriers to TBP participation. Data from this survey were analyzed using logistic and linear regression models to identify factors that significantly influence an individual's willingness to participate and willingness to pay for TBPs. Additionally, data from D4 participant surveys were also analyzed to determine behavioral trends and the geographic distribution of D4 participants. Knowledge gained from these analyses will be applied to future D4 events to improve event participation and effectiveness. Environmental health benefits of D4 events are currently being assessed through bimonthly monitoring of a target pharmaceutical in local wastewater effluent using LC-MS/MS. Public benefits of TBPs will be determined by comparing poison data before and after D4 events to determine if human drug poisonings have been reduced. These latter analyses will provide critical data necessary to determine if D4 events can improve both public and environmental health.

WP001 Quantification of Manufactured TiO_2 Nanoparticles in UK Natural Water Systems G. Raza, J. Lead, Univ of Birmingham, School of Geography Earth and Environmental Sciences. Titanium dioxide (TiO_2) nanoparticles are excessively used in a wide range of consumer products, mounting a big concern on ultimate fate of these materials in aquatic environment. The current research focuses on behaviour of some of the smallest TiO_2 nanoparticles (5-30 nm in diameter), in a range of UK river waters having different chemistry. Different phase distribution of such nanoparticles has been synthesized in School of Geography, Earth and Environmental Sciences Univ of Birmingham and Natural History Museum London. River water samples (with different water chemistry) to be analysed are collected from different parts of United Kingdom with help of Centre of Ecology and Hydrology. All samples are being analysed for any initial amount of TiO_2 present. In next phase effect of manufactured nanoparticles (NP's) on overall water chemistry will be analysed by spiking known quantity of NP's. The parameters which need to be addressed are pH, zeta potential, electrical conductivity, total organic carbon (TOC), dissolved oxygen (DO) and different cations & anions within natural waters. The ultimate fate of TiO_2 nanoparticles as a function of above mentioned parameters will be studied in depth.

WP002 Assessment and Source Modeling of Bioavailable Contaminants in Gulf of Mexico Coastal Waters Before, During and After the Deepwater Horizon Oil Spill S.E. Allan, Oregon State Univ, Environmental and Molecular Toxicology, Oregon State Univ, Graduate Researcher; B. Smith, Oregon State Univ; K.A. Anderson, Oregon State Univ, Environmental & Molecular Toxicology. Following the fatal explosion of the Deepwater Horizon oil rig, lipid free tubing, low-density polyethylene passive sampling devices (PSDs) were deployed in coastal marine waters of four states in the Gulf of Mexico; Louisiana, Mississippi, Alabama and Florida. A pre-impact baseline was obtained prior to shoreline oiling in May, 2010 followed by 13 months of sampling during and post shoreline oiling. Samples were analyzed for unsubstituted polycyclic aromatic hydrocarbons (PAHs), methylated PAHs and oxygenated PAHs, and screened for over 1200 chemicals of concern using Deconvolution Reporting Software (Agilent Technologies). PSDs sequester and concentrate the freely dissolved, and therefore bioavailable, fraction of hydrophobic organic contaminants, providing a time integrated measure of their concentration in the environment. This research is a follow-up to 5 months of data that was presented at the SETAC NA 2010 meeting. Since then, sampling continued through June, 2011 and the samples have been analyzed for a wide range of chemicals associated with crude oil and its breakdown products. The highest concentrations of PAHs in coastal marine waters were observed at the site in Louisiana during June and July; demonstrating a more than 40 fold increase over pre-impact levels. The other sites showed maximum concentrations up to 10 times above baseline levels and a west-to-east temporal trend in the timing of peak concentrations. The bioavailable concentration of PAHs in coastal waters was not significantly elevated above pre-oiling baselines at any of the sites by May, 2011. Other organic contaminants assessed in this study demonstrated temporal changes that suggest an association with crude oil contamination events and analysis of PAH degradation products provides insight into the fate of certain chemicals of concern in the environment. Chemical data was modeled to elucidate changes in chemical profiles associated with unique source inputs. Among other models, principal component analysis discerned three distinct groups of samples based on chemical profile. Pre-oiling samples from all four sites were separated from two "oiling" groups, where the Louisiana site had a distinct profile from the three eastern sites. Samples from spring, 2011, had chemical profiles that associated them with the pre-oiling group, demonstrating an attenuation of the input from the unique Deepwater Horizon spill source.

WP003 Desorption and Bioavailability of Organic Contaminants in Biosolids H. Hwang, Univ of California, Davis, Dept of Civil and Environmental Engineering, Univ of California, Dept of Civil and Environmental Engineering; H. Kim, Univ of California, Civil and Environmental Engineering. Biosolids contain variety of toxic chemicals, including legacy and emerging organic compounds and trace metals. Toxic chemicals in biosolid amended surface soils are subject to wash off by stormwater runoff, which transports toxic chemicals into adjacent creeks, rivers, and estuaries. Toxic chemicals desorbed from biosolids can be also taken up by plants and worms and eventually may be transferred to higher trophic level wildlife such as birds and mammals. It is important to know desorption rates of toxic chemicals in biosolids to predict their wash off rates and bioavailability. We conducted batch tests to investigate desorption of PAHs in biosolids with an aid of ethyl vinyl acetate (EVA) as adsorbent added to accelerate desoprtion. Vials (50 mL) containing bioslolid (1 g), EVA (1 g), and water were tumbled for 0, 3, 6, 9, 12, 24, 48, 72, and 96 hours. EVA collected at each time point was extracted with hexane to quantify the mass of desorbed PAHs. PAH desorption rates negatively correlated with their hydrophobicity (Kow). Acenaphthene and fluorene reached equilibrium within 48 hours but 4-ring PAHs such as fluoranthene, pyrene, benz[a]anthracene, and chrysens didn't reach equilibrium during the study period. Desorption of 5- and 6-ring PAHs was negligible compared to smaller PAHs. Additional tests with longer mixing time (e.g., weeks or months) will be conducted to obtain more accurate desorption rates and equilibrium time of high molecular weight PAHs. Batch test samples will be also analyzed to verify whether the results of the present study can be used to predict other hydrophobic organic contaminants having similar Kow values.

WP004 Direct and Indirect Photochemistry of Sulfapyridine and Sulfamethoxazole in the Aquatic Environment J.K. Challis, Univ of Winnipeg, Richardson College for the Environment; J.C. Carlson, Univ of Winnipeg, Richardson College for the Environment, Univ of Manitoba, Dept of Environment and Geography; K.J. Friesen, Univ of Winnipeg, Richardson College for the Environment; M.L. Hanson, Univ of Manitoba, Dept of Environment and Geography; C.S. Wong, Univ of Winnipeg, Richardson College for the Environment, Richardson College for the Environment, Environmental Studies Program and Dept of Chemistry. The averaged direct photolytic quantum yield of the sulfonamide antibiotic, sulfapyridine, was characterized over a 290-300 nm wavelength range as a function of pH, to assess the ability of sulfapyridine to undergo direct photolysis, an important contributor to its degradation in the aquatic environment. Time-based direct photochemical rate constants and quantum yields were determined using a merry-go-round photochemical reactor for this chemical in singly deprotonated (pH 5) and doubly deprotonated (pH 11) states, as well as at an environmentally relevant pH of 7. The second pKa of sulfapyridine was measured via spectrophotometric titration to be 8.58±0.02, a result previously unreported. The photochemical reactivity of sulfapyridine increased with pH, despite a reduction in its molar absorption coefficient. The quantum yields at pH 5, 7, and 11 were 0.002 ± 0.001, 0.003 ± 0.001 and 0.02 ± 0.01 respectively. This increase in quantum yield with pH has been observed with other sulfonamides, but not sulfapyridine. The relatively large quantum yields at environmentally relevant pH values and the significant light absorption (molar absorption coefficient > 100) at near-UV wavelengths suggest that sulfapyridine will be quickly photodegraded in surface waters. Significant indirect photolysis was suggested by field experiments in sewage lagoons with significant amounts of dissolved organic matter.

WP005 Levels of PBDEs and Hexabromobiphenyl (BB 153) in Surface Water and Bottom Sediment of Diep River, Cape Town, South Africa A.P. Daso, Cape Peninsula Univ of Technology, Cape Town, South Africa., Environmental And Occupational Studies, Cape Peninsula Univ of Technology, Environmental And Occupational Studies; O.S. Fatoki, Cape Peninsula Univ of Technology, Cape Town, South Africa., Dept of Chemistry; J.P. Odendaal, O.O. Olujimi, Cape Peninsula Univ of Technology, Cape Town, South Africa., Dept of Environmental and Occupational Studies.; H.K. Okoro, B.O. Opeolu, Cape Peninsula Univ of Technology, Cape Town, South Africa., Dept of Chemistry. Polybrominated diphenyl ethers (PBDEs) and polybrominated biphenyls (PBBs) are important brominated flame retardants that have attracted global attention in the past two decades. Unfortunately, there is still paucity of environmental data with respect to these widely studied contaminants in Africa and in most developing countries around the world, hence, concerns on how to bridge this knowledge gap necessitate this study. In this study, river water (n=51) and bottom sediment (n=54) samples were analysed for the concentrations of the commonly investigated PBDE congeners (BDE 28, 47, 100, 99, 154, 153, 183 and 209) as well as BB 153. Samples were collected bi-monthly between May 2010 and March 2011 from three sampling locations. These locations correspond to the upstream, point of discharge and downstream regions of a wastewater treatment plant, which discharges its effluents into the river. The routine analysis of these samples was carried out using GC-ECD technique while the structural elucidation and confirmation of target compounds were done using gas chromatography (time-of-flight, TOF) mass spectrometry. The overall mean values of all the eight PBDE congeners in the sediment

and river water samples are as follows: 0.69, 0.34, 0.45 ng/g (dw) and 1869.90, 4051.77, 116.07 ng/L for upstream, point of discharge and downstream samples, respectively. Surprisingly, BB 153 was detected at a relatively high level than expected with overall mean values of 103.83, 284.33, 116.93 ng/L and 0.12, 0.09, 0.19 ng/g for river water and sediment samples, respectively. BDE 47 was the most dominant congener in the river water contributing more than 95% to the total PBDE concentrations, except for the samples collected at the downstream region where it ranked second next to BDE 153 contributing 19.0% to the total PBDE concentrations. In sediment samples, BDE 209, 47, 183 and 99 were the dominant congeners. Due to the lower concentrations of BDE 209 found at the upstream regions with correspondingly higher values further downstream, it thus implied that discharges from the WWTP might be a significant source of BDE 209 into the Diep River. The trend observed in this study revealed that there could be other notable sources of PBDEs into the river other than from the WWTP.

WP006 Levels, Removal Trend and Health Risk of Metals (As, Cd, Pb, Hg, Ni, Cr, Co, Zn, Cu) from Wastewater Effluents in Cape Town, South Africa O.O. Olanrewaju, Cape Peninsula Univ of Technology, Environmental And Occupational Studies, Univ of Agriculture, Environmental Management & Technology; O.S. Fatoki, Cape Peninsula Univ of Technology, Cape Town, South Africa., Dept of Chemistry; J.P. Odendaal, Cape Peninsula Univ of Technology, Cape Town, South Africa., Dept of Environmental and Occupational Studies.; A.P. Daso, Cape Peninsula Univ of Technology, Cape Town, South Africa., Environmental And Occupational Studies, Cape Peninsula Univ of Technology, Environmental And Occupational Studies; H.K. Okoro, B.O. Opeolu, Cape Peninsula Univ of Technology, Cape Town, South Africa., Dept of Chemistry. This study focused on one year monitoring campaign of occurrence and removal of endocrine disruptive metals (EDMs) from selected wastewater treatment plants (WWTPs) in Stellenbosch and Cape Town. Water samples were collected from the WWTPs from January 2010 to December 2010 on quarterly basis and metals concentration determined using Inductively Coupled Plasma-Mass Spectrometry (ICP-MS) after open beaker. A total of 432 water samples consisting of raw, primary effluent, secondary effluent and final effluents were collected. The general abundance distribution pattern for metals is Zn > Cu>Pb>Cr>N i>As>Co>Cd>Hg. The removal efficiency ranged from 1.5% for Hg at Zandvliet WWTP plant during winter to 98.27% for Cu at Athlone WWTP treatment plant during summer. The final effluent concentration for most of the metals were within South Africa water quality guidelines while As, Hg, Cd and Pb concentration were higher than maximum limits set by Canadian council of ministers of the environment. Potsdam WWTP plant proved to be more effective at heavy metals removal as compared to the other five treatment plants investigated in this study. The effluent metal concentration over time could pose health risk if used for vegetable watering.

WP007 Occurrence of Bisphenol A in Paper Currencies from Several Countries and Implications for Dermal Exposures C. Liao, K. Kannan, New York State Dept of Health, Wadsworth Center. Bisphenol A (BPA) is one of the highest production volume chemicals and has been widely used in industrial and commercial products. In this study, paper currencies (n = 156) collected from 21 countries from March 2010 to January 2011 were analyzed for the presence of BPA. Three circle punches (19 mm diameter) were taken from the lower left corner, middle, and upper right corner of each paper currency. Samples were cut into small pieces, spiked with $^{13}C_{12}$-BPA as an internal standard, and then extracted with methanol 3 times and subjected to high performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS) analysis. BPA was found in all currencies at concentrations ranging from 0.001 to 82.7 (mean 5.21; median 1.13) μg/g. BPA concentrations in samples taken from the middle portion of the currencies were higher than those taken from the peripheral portions. Transfer of BPA from thermal receipt paper to currencies was also examined by placing currencies in contact with thermal receipt papers for 24 h in a wallet. Concentrations of BPA increased by 2-3 orders of magnitude after 24 h of contact with thermal receipt papers (mean ± SD, 18.0 ± 11.1 μg/g after contact versus 0.068 ± 0.077 μg/g before contact; paired t-test, p < 0.01). This result clearly suggests the transfer of BPA from receipt paper to currency bills and that thermal receipt paper is a major source of BPA found in paper currency bills. Estimation of daily intake of BPA through dermal absorption from handling of paper currencies showed that exposures from currencies is a minor pathway, although high levels of BPA were measured. Since the paper currency is frequently handled in daily life, exposure doses of BPA can be elevated under occupational settings.

WP008 Perfluorinated Compounds in Human Blood, Water, Edible Freshwater Fish and Seafood in China: Daily Intake and Regional Differences in Human Exposures T. Zhang, Nankai Univ, China, and Wadsworth Center, USA, Key Laboratory of Pollution Processes and Environmental Criteria, Ministry of Education, Nankai Univ; H. Sun, Y. Lin, L. Wang, X. Zhang, Y. Liu, MOE Key Laboratory of Pollution Processes and Environmental Criteria, Nankai Univ; X. Geng, Waters Technologies (Shanghai) Ltd; F. Li, L. Zhao, MOE Key Laboratory of Pollution Processes and Environmental Criteria, Nankai Univ; K. Kannan, Wadsworth Center, New York State Dept of Health and Dept of Environmental Health Sciences, School of Public Health, State Univ of New York at Albany. Despite the growing public interest in perfluorinated compounds (PFCs), very few studies have reported the sources and pathways of human exposure to these compounds in China. In this study, concentrations of 10 PFCs were measured in human blood, water (tap water and surface water), freshwater fish and seafood samples collected from China. Based on the data, we calculated daily intakes of PFCs, regional differences in human exposures, and potential risks associated with ingestion of PFCs from diet, drinking water, and indoor dust for the Chinese population. Perfluorooctane sulfonate (PFOS) was the most predominant PFC found with a mean concentration of 12.5 ng/mL in human blood from Tianjin, and 0.92 ng/g wet wt in freshwater fish and seafood; perfluorooctanoic acid (PFOA) was the major PFC found in drinking water at a concentration range of 0.10 to 0.92 ng/L. The estimated daily intake of PFOS and PFOA via fish and seafood consumption (EDIfish&seafood) ranged from 0.10 to 2.51, and 0.13 to 0.38 ng/kg bw/d, respectively, for different age groups (i.e., toddlers, adolescents and children, and adults) from selected locations (i.e., Tianjin, Nanchang, Wuhan, Shenyang). The EDIfish&seafood of PFCs decreased ($p < 0.05$) with age. The estimated daily intake of PFOS and PFOA via drinking water consumption (EDIdrinking water) ranged from 0.001 to 0.009, and 0.002 to 0.027 ng/kg bw/d, respectively. Comparison of EDIfish&seafood, and EDIdrinking water values with the modeled total dietary intake (TDI) of PFCs by adults from Tianjin, Nanchang, Wuhan, and Shenyang showed that contributions of fish and seafood to TDI of PFOS varied depending on the location. Fish and seafood accounted for 7%, 24%, 80%, and 84% of PFOS intake in Nanchang, Shenyang, Wuhan, and Tianjin, respectively, suggesting regional difference in human exposure to PFOS. Drinking water was a minor source of PFOS (< 1%) exposure in adults from all the study locations.

WP009 Relationship Between Soil Sorption Coefficient (KOC) and Octanol/Water Partition Coefficient (KOW) for Methylsiloxanes S. Xu, Dow Corning Corporation, Health and Environmental Sciences; G. Kozerski, Dow Corning Corporation, Health & Environmental Sciences. In environmental modeling, organic carbon normalized soil/water sorption coefficients (K_{OC}) of nonionic organic compounds by natural organic matter are often estimated from their octanol/water partition coefficients (K_{OW}) using an empirical single-parameter linear relationship. When this approach was used for cyclic methylsiloxanes (cVMS) such as octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5), the measured log K_{OC} values for cVMS were found to be much smaller than those estimated based on the empirical model optimized using data for non-siloxane organic compounds as the training set. In order to better understand the relationship between K_{OC} and K_{OW}, the measured room temperature values of log K_{OC} and log K_{OW} from literature were analyzed in this study for nonionic (neutral) organic compounds, including volatile methylsiloxanes (VMS). It was found that the aforementioned discrepancy for siloxanes arose from two factors. First, relative to wet n-octanol, wet organic carbon is a more cohesive matrix, stronger H-bonding donor, and more effective at inducing dipoles in polarizable molecules. Secondly, relative to the benchmark non-organosilicon compounds for which the correlation between K_{OC} and K_{OW} was derived, VMS have larger size, strong H-bonding basicity and low polarizability that signify the difference in solvation properties between organic carbon and octanol. Consequently, VMS follow the same scientific principles as other nonionic organic compounds in environmental partitioning, but may not obey the simplified single-parameter relationships.

WP010 Spiders and Spider Silk as Bioindicators for PCB-contaminated Sediments J. Dahle, Clemson Univ, Dept of Chemistry, 342 Computer Court; D. Delach, Clemson Univ, Environmental Toxicology; C.M. Lee,

Clemson Univ, Environmental. Engineering and Earth Sciences Dept; V. Dang, Clemson Univ, Environmental Engineering and Earth Sciences. Currently the USEPA and others employ expensive and time-intensive testing methods to quantify the concentrations of polychlorinated biphenyls (PCBs) in sediments of hazardous waste sites. In this study, spiders and spider webs from the Sangamo Weston/Twelvemile Creek/Lake Hartwell Superfund Site (SW/12MC/LH), SC, USA, were collected and tested to determine their accuracy as PCB bioindicators. Spiders and webs from both lotic and lentic systems were collected and their accuracy as concentration markers were compared and contrasted. Concentrations in spiders have recently been recorded as high as 1800 ppb and in webs 361 ppb. Low concentrations in spider webs versus the bodies of the spiders may indicate that webbing is not a highly efficient excretion pathway for PCBs. The derived relationship between PCB levels in sediment and the bodies of spiders and their webs will be presented. This study also seeks to quantify chiral preferences of PCB accumulation in spider webbing as an excretion pathway; this characteristic could be useful in further studies that investigate how the incorporation of PCBs and other contaminants into spider webbing affects properties of the silk. Thus far, spider webbing has been found to select chirally for most congeners, such as PCB 95 which exhibits an average enantiomeric fraction of 0.144. Previous research exists which indicates that spiders are an accurate model of PCB concentrations in the SW/12MC/LH area. The collection of spiders and spider webs is fast, inexpensive, and easy; these samples are also easy to extract and analyze, with extraction requiring less solvent (as little as 15 mL) and sample mass (as little as 10 g) than sediment testing. These benefits coupled with studies such as this one showing the accuracy of spiders and their webs as PCB concentration models could help lead to the development of less expensive, "greener" contaminant testing methods for contaminated sediments.

WP011 The Fate of Perchlorate in a Man-made Reflecting Pond Following a Fireworks Display in Albany, New York, USA Q. Wu, School of Public Health, State Univ of New York at Albany, Environmental Health Sciences, Wadsworth Center, New York State Dept of Health, New York State Dept of Health, Wadsworth Center; J. Oldi, Wadsworth Center and Dept of Environmental Health Sciences, SUNY at Albany; K. Kannan, New York State Dept of Health, Wadsworth Center. Perchlorate is a widespread contaminant in aquatic environments. Despite this, aquatic environmental fate of perchlorate released from fireworks displays is not well known. In this study, we examined the fate of perchlorate in man-made reflecting ponds, from 2008 to 2010, following three fireworks displays in Albany, New York. Immediately after the fireworks display, perchlorate concentrations in pond waters increased significantly, with concentrations 30 to 1480 times higher than the baseline values. Perchlorate concentration in pond water increased from 0.11 μg/L to up to 519 μg/L, following the fireworks display in 2008. Perchlorate concentrations in pond water decreased at a first-order kinetic degradation rate, with a mean k_{obs} value of 0.026 d^{-1} and an average half-life of 29 d. The rate of perchlorate deposition into water bodies following fireworks displays was estimated to range from 670 to 2620 g/ha. We also estimated the perchlorate ingestion rate by the inhalation of aerosols of pond water by people frequent near the pond. The estimated daily intake of perchlorate through the ingestion of aerosols was 32% (226 ng/kg bw), 13% (92 ng/kg bw), and 6% (42 ng/kg bw) of the US Environmental Protection Agency's reference dose for infants, children, and adults, respectively.

WP012 Toxicity of Manufactured CuO Nanoparticles in *Caenorhabditis elegans* Y. Zhang; B. Zhang, East Carolina Univ, Dept of Biology, East Carolina Univ, Biology, East Carolina Univ, Dept of Biology. Although manufactured metal oxide nanoparticles(NPs) have been widely used in various applications, limited information is available on the potential impacts of NPs on the human health and on the ecological systems. In this study, we use *Caenorhabditis elegans* (*C. elegans*) as an animal mode to assay the toxicological effects of CuO nanoparticles. The *C. elegans* L4 larvae was dosed with different concentrations (0, 0.001, 0.01 and 0.05 mg/mL) of CuO NP for three days. The growth and reproduction effects were investigated. In molecular level, we also dosed *C. elegans* L4 larvae for 24 hours to test the expression of egg-laying and oxidative stress related genes. Results showed CuO NP causes growth retardation and brood-size reduction in *C. elegans*. The gene expression of some egg-laying or stress related genes, such as acr-8, egl-9, egl-46, old-1 were also affected by CuO NP.

WP013 What Do We Know About What Is in Personal Care Products? R. Dodson, Silent Spring Institute; M. Nishioka, Battelle Memorial Institute; L. Standley, L. Perovich, J. Brody, R. Rudel, Silent Spring Institute. Despite concerns about endocrine disruption and other health effects from chemicals in household and personal care products, ingredient labeling and safety information is limited, making it difficult to evaluate products as exposure sources or make informed exposure reduction decisions. To help fill this data gap, we analyzed personal care, cleaning, and other household products for a range of endocrine disrupting compounds (EDCs) and chemicals associated with asthma. We also evaluated whether package labels can be used to identify products without these chemicals. We tested 213 commercial products composited into 85 samples and representing 50 product types, including cosmetics, personal care products, cleaners, sunscreens, and vinyl shower curtain and pillow protector. Analytes included parabens, phthalates, bisphenol A (BPA), antimicrobials, ethanolamines, alkylphenols, fragrances, glycol ethers, cyclosiloxanes and ultra-violet filters. We detected 55 compounds, indicating a wide range of exposures from common products. Vinyl products contained >10% bis(2-ethylhexyl) phthalate (DEHP) and could be an important source of DEHP in homes. In other products, the highest concentrations and numbers of detects were in perfume, air fresheners, dryer sheets, and sunscreens. Some products marketed as "green" did not contain the well-known EDC phthalates but contained other less-studied phthalates that are also EDCs, suggesting a substitution. Common products contain complex mixtures of EDCs and chemicals associated with asthma that are also found in environments relevant to human and ecological risk. Many detected chemicals were not listed on product labels, but some, including synthetic fragrances, BPA, and active ingredients, appear to be avoided using general purchasing criteria. Findings have implications for human and ecological risk assessment, since certain chemicals tend to co-occur and product composition varies within a product type.

WP014 Generating Screening-level Exposure Assessments of Personal Care Products in China at Multiple Spatial Scales C.M. Holmes, R. Vamshi, D. Mao, Waterborne Environmental, Inc.; J. Hodges, O. Price, Unilever. The development and application of models to predict in-river concentrations of ingredients used in personal care products are important to the environmental risk assessment process. While suitable models exist in the US and Europe, there are currently no available models to estimate exposure of personal care products in China. To this end, work was performed to create a GIS-based system that develops exposure estimates used to predict the emission of personal care products into freshwater ecosystems. Currently, many of the available inputs for the generation of environmental concentrations to be used in the exposure assessment are at a very coarse spatial scale, in some cases only a single value for the entire country is available. In this study, environmental concentrations in surface water were estimated at the province and county-levels (ca. 2,900 counties in China) based on both user supplied product/ingredient information, as well as other geographically-linked socio-economic and environmental information from official census and other data sources. Product information such as category (e.g., hair, skin, etc.), composition (e.g., ingredient fraction) and "take off" values (GDP threshold under which the product would not likely be purchased) were used to distribute total tons of individual ingredients based on product sales data in China. These data were combined with economic information, population density (including urban and rural separation), water use, disposal mechanism (e.g., STP, septic, direct discharge to river, etc.), and location-specific dilution factors to estimate ingredient-level concentrations in surface water at the county level. Results show that estimated concentrations vary considerably across the country when using more refined spatial data, and that economic information ("take off" values and population GDP) can have a significant influence on the resulting ingredient emission distributions. The method presented incorporates the inherent spatial variability of the model inputs so that patterns can be identified and used in the risk assessment. In other words, the ability to identify areas where existing combinations of model inputs may yield greater exposure estimates, i.e., the identification of realistic "worst case" scenarios. In addition, an understanding of where these "worst case" scenarios fit within the overall China-wide distribution is achieved.

WP015 Influence of Land Use on Ecological Risk Assessment of Municipal Wastewater Treatment Plant Discharges K. Kapo, Montani Run, LLC; S. Dyer, The Procter & Gamble Company, Central Product Safety, The Procter & Gamble Company, Miami Valley Innovation Center.

Ecological risk of consumer product ingredients associated with municipal wastewater treatment facility discharges may depend upon surrounding land use characteristics. A statistical comparison of biological condition (fish and invertebrate communities) between field monitoring sites (Ohio EPA) upstream and downstream of municipal wastewater treatment facility discharge points throughout the state of Ohio was conducted to evaluate potential impacts of chemicals and materials associated with municipal effluent. Land use-dependent relationships of upstream-downstream trends were delineated by comparing results between facilities located in areas of urban and rural land use, respectively (National Land Cover Dataset classifications). Comparisons of modeled effluent toxicity (consumer product ingredients and pharmaceuticals, respectively), other water chemistry parameters, habitat quality, and other landscape factors compiled from available data resources were also conducted between upstream and downstream sites. This study expanded upon a previous study (1996-1999 data) of major rivers ("RF1"), using updated data (2000-2008), additional environmental variables, and the National Hydrography Dataset stream network allowing for the inclusion of smaller tributaries. Evidence of a stronger influence of effluent in urban areas indicates that land use is a critical factor to consider in effectively characterizing the risk of effluent to receiving water ecosystems. The influence of urban vs. rural analysis on understanding the potential risks associated with domestic use of down-the-drain chemicals, such as those in consumer products will be highlighted. Understanding the importance of landuse is imperative in subsequent experimental approaches designed to obtain quantitative causal relationships of domestically used chemicals.

WP016 IFRA Environmental Standards: Risk and Hazard Assessment Update for 2011 A. Lapczynski, Research Institute for Fragrance Materials, Inc., Research Institute for Fragrance Materials, Inc, Environmental Specialist; D. Salvito, Research Institute for Fragrance Materials, Inc., Dept of Environmental Science; M. Vey, IFRA. The International Fragrance Association expanded the fragrance industry's self-regulatory safety program with the development of IFRA Environmental Standards for both risk and hazard in 2008. Fragrance material risk assessments for these Standards are incorporated in the Research Institute for Fragrance Materials' (RIFM) testing program in coordination with its Expert Panel. The development of this program was reported previously at SETAC (Seville, 2010). To identify materials for risk assessment refinement, fragrance materials were screened using the RIFM Environmental framework and 2008 IFRA volume of use survey as reported for both Europe and North America. The Framework for this evaluation was published in Environmental Toxicology and Chemistry (Salvito et al., 2002, 1301-1308). In addition, hazard assessment on these materials was also performed and reviewed. As a result nearly 3,000 materials were screened with preliminary risk quotients estimated to rank priority materials for risk assessment refinement. In an effort to provide greater transparency to the developing IFRA Environmental Standards, reported here are the results of these additional tests (for both risk and hazard assessments). These studies include persistence testing (ready biodegradation tests and die-away studies), bioaccumulation, and acute and chronic aquatic toxicity. Incorporating these new data in a second tier risk and hazard assessment for these materials will also be presented.

WP017 Aquatic Ecological Assessment for Shampoos: Sensitivity of the USETox Model to Parameter Uncertainty J.K. Saxe, M.L. Fleming, EcoSafety Sciences. The French Environment and Energy Management Agency (ADEME) is overseeing a new requirement for a comparative evaluation of the environmental performance of certain consumer products, including shampoos, to be provided to consumers. The USETox model was selected for this purpose. The aquatic environmental assessment in USETox is quantified as a single value, a characterization factor (CF). The quality of the model results and sensitivity of the model to three critical factors are presented. First, USETox requires a significant number of input parameters , many of which are not widely available for the range of ingredients used in shampoos. Specifically, the biodegradation rate is important in the model but adequate empirical data are often lacking for this parameter. Sensitivity of the model result to the use of empirical data vs. BIOWIN model results is examined. Second, surfactants are the are the most abundant non-water ingredient in shampoos, yet the environmental fate segment of the USETox model relies on a substance's octanol-water partition coefficient (Kow) – a parameter that is not meaningful for surfactants – to predict environmental partitioning. Two approaches for addressing the lack of a meaningful Kow for surfactants are compared. Third, aquatic toxicity is quantified using a distribution approach rather than selecting a single study as the point of departure for determining a predicted no effects concentration. This approach requires more toxicity data than are available for many shampoo ingredients, and requires that all quality studies conducted for an ingredient be evaluated and incorporated into the CF determination. The use of modeled versus empirical data, as well as the influence of study selection versus rejection on the data distribution (and hence on the model results), are presented. The result of this evaluation shows that the model results are most sensitive to uncertainty around the effects factor, which can span orders of magnitude, compared to uncertainty around biodegradability and octanol-water partition coefficient for surfactants. This suggests that clear guidance around selection and use of effects data, which are applied consistently across ingredients, is critical to achieving quality results in aquatic assessments for shampoos in USETox.

WP018 Toxicity of Decamethylcyclopentasiloxane (D5) to Aquatic and Terrestrial Environments A. Fairbrother, Exponent, EcoSciences, Exponent, Inc., EcoSciences; A. Burton, Univ of Michgan, School of Natural Resources & Environment and Cooperative Institute for Limnology & Ecosystem Research; S.J. Klaine, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX), Clemson Univ, Institute of Environmental Toxicology (ENTOX) Decamethylcyclopentasiloxane (D5) is undergoing regulatory review in Canada and Europe to ascertain its persistence, bioaccumulation, and inherent toxicity. In this paper, we focus on the question of ecotoxicity, specifically toxicity of D5 to pelagic (water column), sediment, and soil organisms. We specifically investigated the exposure concentrations in the tests in relation to the solubilities of D5 in those media. We concluded that below the solubility limit of D5 in water (17 *m*g/L), no adverse effects of D5 have been observed in any of the acute or chronic laboratory studies with fish, *daphnia*, or algae. Because the concentration of D5 in environmental media cannot exceed its solubility, it follows that there currently is no evidence to support a finding that D5 can cause immediate or long-term harmful effect to water-column biota in the environment. For soil organisms, D5 shows only minor effects to plants and invertebrates, with no-observed effect concentrations (NOEC = 77 mg/kg-dw barley and 377 mg/kg-dw springtails) several orders of magnitude higher than D5 residues measured in the environment (0.006–0.221 mg/kg-dw). The lowest NOECs for sediment organisms (62 mg/kg-dw *Hyalella*; 70 mg/kg-dw *Chironomus*) are ten times as high as the highest value measured in sediment at wastewater treatment plant outfalls (5.8 mg/kg-dw). Critical body burdens for benthic invertebrates were derived by multiplying lipid-normalized NOECs by the D5 biota-sediment accumulation factors [BSAF] from field-collected invertebrates and comparing those to measured tissue concentrations from field-collected organisms. Similar results were seen; field organisms are not able to accumulate toxic amounts of D5. Therefore, we conclude that D5 is not toxic to aquatic or terrestrial organisms at environmentally-realistic concentrations.

WP019 Environmental Assessment of D5 – Fate and Exposure C.E. Cowan-Ellsberry, CE2 Consulting, LLC, Central Product Safety, CE2 Consulting; D. Mackay, Trent Univ; B. Price, The Procter & Gamble Company. D5, cyclopentasiloxane-decamethyl, is one of several siloxanes that are used in a variety of personal care products, including hair care, skin care, cosmetics and antiperspirants and deodorants. Environment and Health Canada conducted a PBT categorization and screening assessment of the siloxanes, including D5, in 2008. They concluded that D5 meets the criteria for persistence and bioaccumulation and that D5 is entering the environment in a quantity that may have a harmful effect on the environment. Therefore, D5 should be listed on the Toxic Substances list and management actions taken to control D5's release to the environment, including potentially virtual elimination. The Silicones Environmental Health and Safety Council of North America recognized shortcomings in the evaluations that had been performed and requested that a Board of Review be constituted to conduct a de novo review of the nature and extent of the risk posed by D5 to the environment. As part of this process, we evaluated the D5 fate and estimated the exposure in various environmental media for Canada. D5 is a very unusual chemical in part due to its large size and molecular volume, low water solubility and high vapor pressure. As a result D5 does not partition among water, organic carbon, octanol and biological fluids like traditional non-polar substances resulting in very limited solubility in water, soil and sediment. Once released into the environment, a majority of the D5 will partition to air where it undergoes hydrolysis. A small amount will remain

in water and sediment. The primary pathway to the aquatic and sediment environments is through consumer product release to sewers, therefore, the fate and resulting exposure to these media from sewage plant effluent were estimated. Comparison of these estimated exposures to recent monitoring data for Canada showed that these estimated exposures were conservative and reasonable. These data also show that the current exposures are well below the maximum solubility in the media and well below any toxic level of concern.

WP020 Using a Novel Sediment Exposure to Determine the Effects of Triclosan on Marine Benthic Communities K.T. Ho, USEPA, Atlantic Ecology Division; L. Portis, USEPA; M. Perron, Brown Univ, School of Engineering; M. Pelletier, National Health and Environmental Effects Research Laboratory, USEPA, Dept: ORD NHEERL AED; M. Cantwell, D.R. Katz, USEPA, Atlantic Ecology Division; A. Chariton, CSIRO; S. Simpson, CSIRO Land and Water, Centre for Environmental Contaminants Research; D. Proestou, USEPA, Atlantic Ecology Division; R.M. Burgess, USEPA, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, USEPA, USEPA; J. Baguley, Univ of Nevada, Dept of Biology. Triclosan (5-chloro-2-(2,4-dichlorophenoxy)phenol), is an emerging contaminant commonly used as an antimicrobial compound in many personal care products such as softsoap, detergent, toothpaste, mouthwash, and is infused in many consumer products, such as kitchen utensils, toys, bedding, socks, and trash bags. Triclosan enters estuarine environments primarily via wastewater treatment plant effluent and has been found in sediment cores dating back to the mid 1960s. The objective of our research was to determine the effect of triclosan on intact estuarine benthic communities. We adapted a novel exposure method which brings intact sediment cores into the laboratory and then exposes the benthic community by addition of toxicant spiked sediments to the core surface. Treatments included: 1) field control – no added sediment, 2) laboratory control – clean sediment added, 3) low triclosan concentration (~20 mg/kg dry), and 4) high (~200 mg/kg dry) triclosan concentration. Macro- and meiobenthic communities were analyzed for differences after a two week exposure to either high or low concentrations of triclosan spiked sediments. Results from the triclosan sediment additions indicated a loss in total abundance and number of meiofaunal and macrofaunal taxa communities at the high triclosan concentration compared to the control. This high exposure concentration is similar to LC50s for amphipods and mysids exposed in the laboratory. We also noted a difference in the field control relative to the laboratory control, most likely due to a smothering effect of the added sediment. Differences in benthic communities were not noted between the low triclosan and laboratory control treatments. These data suggest that at elevated concentrations, triclosan can disrupt benthic communities while also indicating the exposure system does not completely emulate exposures in the field.

WP021 Determination of Cadmium Bioavailability of Winter Barley Through the Analysis of Guttation Water Droplets D. Schenke, Julius Kühn-Institute, Institute for Ecological Chemistry, Plant Analysis and Stored Product Protection; T. Strumpf, Julius Kühn-Institute; J. Krueger, Technische Universität Berlin. Guttation is known over hundred years, but this phenomenon was less considered in the system of soil/plant/atmosphere. The term guttation defines the exudation of water droplets through specific secretory organs at the edges of plant leaves in vascular plants. Guttation can be observed at high relative humidity when plants close their stomata and the transpiration suction is ceased in the order of 3 MPa. The smaller root pressure (0.3 MPa) caused by osmosis pushes the xylem-water droplets through the hydathodes (Schopfer u. Brennecke, 2006). In the guttation droplets mineral nutrients (Ivanoff, 1963), several amino acids (Pilot et al., 2004) and also active substances of plant protection products which may be applied as seed coating (Girolami et al., 2009, Schenke et al., 2010) were detected. This exposure by pesticide-containing guttation liquid may be relevant for water collecting bees and plant-settled non-target arthropods. Cadmium is transported with the transpiration stream up to the apical leaves in plants (Strumpf et al., 2009). In autumn 2010 winter barley (*cv. Naomi*) were sown in two slightly loamy soils with different cadmium content at the field station of JKI in Berlin. After emergence of winter barley coleoptiles guttation droplets were taken from the edges of leaves and analyzed. The concentration of cadmium in guttation droplets from barley at the contaminated soil (site A) exceeded clearly the concentration measured at the control site (B) with normal cadmium content. The cadmium concentration in guttation droplets in the early growth stages of barley (BBCH-code 10 – 11) were compared with cadmium content in soil measured with different methods (Tab.). The cadmium concentration in guttation water was found to be clearly lower than the content in the ammonium nitrate fraction which is the standard for assessment of metal bioavailability in Germany (BBod-SchV, 1999). Table: Cadmium in soil and guttation water droplets Method Conc. Site A Site B Soil/aqua regia digestion mg kg^{-1} 18.50 0.491 Soil/ammonium nitrate extraction 0.187 0.003 Soil/calcium chloride extraction 0.029 0.002 Guttation water (barley BBCH 10-11) mg L^{-1} 0.012 ± 0.005 0.0008 ± 0.0001

WP022 Trace Element Contamination Around the E-Waste Recycling Site at Agbogbloshie, Accra City, Ghana M. Otsuka, Ehime Univ, Center for Marine Environmental Studies; T. Itai, Ehime Univ, Center for Marine Environmental Studies (CMES); K.A. Asante, Ehime Univ, Center for Marine Environmental Studies (CMES), Ehime Univ, Center for Marine Environmental Studies; M. Muto, Center for Marine Environmental Studies (CMES), Ehime Univ; S. Tanabe, Ehime Univ, Center for Marine Environmental Studies. E-waste, obsolete electrical and electronic material, has become a subject of growing environmental concern in developing countries due to the large volume of illegal import from developed nations. Many toxic substances including BFRs, PCBs and heavy metals contained in e-waste are released into the environment during disposal and recycling. Furthermore, inappropriate thermal treatment and combustion processes widely employed by recyclers in developing countries to retrieve valuable metals have been known to generate unintentional but highly toxic chemicals such as PCDD/Fs, PBDD/Fs and mixed halogenated homologues. The lack of data is most glaring with regard to the e-waste recycling site in Asian and African developing countries, where the pollution has often been overlooked. In this study, we investigated level and speciation of trace metals around the largest e-waste recycling site, Agbogbloshie market in Accra city, Ghana. Concentrations of 15 elements in soil/ash mixture collected around Agbogbloshie markets were measured by handheld XRF analyzer. Accuracy of XRF measurement was preliminarily evaluated by measuring 19 certified geological materials distributed by Geological Society of Japan. In most of the cases, accuracy was within an order of magnitude. Concentrations of Cu (50 to 22000 mg/kg), Zn (200 to 160000 mg/kg), Pb (100 – 14000 mg/kg), and Sn (< 50 to 1000 mg/kg) were extremely high in residual ash derived from wire combustion, and Br (20 – 1500 mg/kg), As (< 50 to 1100 mg/kg), and Hg (< 20 to 150 mg/kg) were also at moderately high levels. Concentrations of these metals were positively correlated with darkness of soil color suggesting that these levels were simply controlled by dilution of residual ash by uncontaminated soil. Hence, it can be presumed that these metals were from e-waste products, and released into the surrounding environment through open burning. X-ray absorption fine structure measurements revealed that majority of Br was possibly in the inorganic salt rather than organic contaminants. As the Br concentration is the highest in black ash, the source of Br might be anthropogenic compounds, such as BFRs. Predominance of inorganic Br in soil/ash mixture might be attributed to the conversion of organic Br by thermal decomposition. Formation of dioxin like compounds is probably high in this area, and hence further comprehensive monitoring is needed to assess the health risk for the e-waste recycling workers.

WP023 Toxic Metal Contamination of Soil in Four Major Indian Cities P. Chakraborty, Savannah State Univ, Dept of Natural Science; K. Sajwan, Savannah State Univ, Natural Science. India being a tropical country, organic matter has a very high decomposition rate. With the rapid industrialization and urbanization, the anthropogenic wastes from heavy industries, electronic waste recycling units and ship breaking sites are found to be the key factors contributing toxic metal contamination of soil in major cities of India. Nevertheless, toxic metals accumulate in the soil and present a serious long-term hazard and are a source of danger to the health of the people. Hence present study was designed to assess Pb, Cu, Zn, Co, Ni, As, Cd, Hg and Cr in the soil samples from four major cities of India. Surface soil samples (0-20 cm) were collected from 15-20 locations based on urban rural and background transect from each city viz., New Delhi located in the north, Kolkata in the east, Mumbai in the west and Chennai in the southern part of India. Sampling was conducted during December 2006 through June 2009. Recoveries were nearly quantitative for all the metals studied. Comparison of the average metal concentration levels with world averages indicates an elevated value for Pb for certain locations. The applicability of this method was crosschecked with AAS and the results were in good agreement. The overall range of concentration in mg/kg were 30-390 for Cr,

167-4370 for Mn, 4-100 for Co, 13-300 for Ni, 10-1930 for Cu, 0.3-50 for As, BDL-15 for Cd, 1-80 for Hg and 5-2340 for Pb. The data reveals that soils from the sites close to the electronic waste dismantling sites in New Delhi and ship breaking yard in Mumbai are significantly contaminated, showing higher levels of these toxic metals from those urban sites than normal distribution in the background sites. The level of toxic metal contamination in Kolkata and Chennai were lower compared to New Delhi and Mumbai.

WP024 Trace Metals in Biosolids and Biosolid Amended Soils of Farm Land H. Hwang, Univ of California, Davis, Dept of Civil and Environmental Engineering, Univ of California, Dept of Civil and Environmental Engineering; H. Kim, Univ of California, Civil and Environmental Engineering. Large fraction of sludge from municipal wastewater treatment plants are being converted to biosolids to use as organic fertilizer. Most biosolids have been applied to farm lands to improve soil productivity and stimulate plant growth. Biosolids also contain very high levels of variety of toxic chemicals, including trace metals. This study investigated impacts of biosolid amendment on surface soil trace metal contamination. Surface soils were collected from farms in Solano County, California. These farms had received biosolids previously with different time interval (years). Biosolid analysis showed that concentrations of some trace metals such as copper, zinc, molybdenum, tin, and antimony were significantly higher in biosolids than in background surface soils. These metals in biosolid amended surface soils generally are up to 80-fold enriched. Among these metals, molybdenum, tin, and antimony can be used to indicators for biosolid application. Surface soils amended with biosolids more frequently had higher levels of metals, indicating biosolid application increases metal concentrations. Among measured metals, antimony and molybdenum in all biosolid amended soil exceed soil screening guideline values set to protect human health. Soil core data and plant bioaccumulation data will be added to the presentation.

WP025 PCBs, PBDEs, and OCPs in *Seriola lalandi* from the Subtropical Convergence Zone of the North Pacific Gyre S. Harwani, California Enviromental Protection Agency, Dept of Toxic Substances Control, Environmental Chemistry Laboratory, Dept of Toxic Substances Control, California Environmental Protection Agency; J. Park, California Environmental Protection Agency, Dept of Toxic Substances Control, California Environmental Protection Agency, Research Scientist; T.Y. Garcia, Environmental Chemistry Laboratory, Dept of Toxic Substances Control, California Environmental Protection Agency; M. Gassel, Office of Environmental Health Hazard Assessment, California Environmental Protection Agency; A. Neal, Jean-Michel Cousteau's Ocean Futures Society; B. La Belle, M. Petreas, Environmental Chemistry Laboratory, Dept of Toxic Substances Control, California Environmental Protection Agency. Over the last two decades the North Pacific Ocean has garnered much attention due to the noticeable amounts of mega-, macro- and micro-debris that has been found floating within it and being ingested by biota. The key portion of this marine debris is from plastics which do not generally biodegrade, but instead break down to smaller micro-plastic fragments. The ingestion of macro- and micro-plastics and the ensuing physical harm to biota has been a vital concern. More recent studies indicate that new and emerging persistent organic pollutants (POPs) have a high affinity for plastics and may adsorb onto them and get ingested by biota. Consequently it is even more important to further understand the dynamic role and impact that marine debris may have on the marine environment. In August of 2009, Project Kaisei launched its first expedition to the North Pacific Ocean with these objectives. During the early part of the expedition, 19 *Seriola lalandi* (Yellowtail amberjacks) fish samples were collected from the Subtropical Convergence Zone of the North Pacific Gyre. A simple and efficient methodology for the preparation, extraction, cleanup, and analysis of the fish sample extracts for polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), and polybrominated diphenyl ethers (PBDEs) was developed. In these remote ocean-surface fish, legacy OCPs were found to be at high concentrations (1480 ± 241 ng/g lipid weight), while total PCBs and PBDE levels were an order of magnitude lower on average with concentrations of 359 ± 56.1 ng/g lipid weight and 204 ± 9.1 ng/g lipid weight, respectively. The results from these studies warrant further investigation of various exposure pathways, including plastics, to these fish, and marine biota, in general. In addition to these studies, work focusing on PCB and PBDE metabolites in these fish will be pursued. "The views expressed herein are those of the authors and do not necessarily reflect those of Dept of Toxic Substances Control, California Environmental Protection Agency."

WP026 Accumulation Features of Halogenated Phenolic Contaminants in the Blood of Pinnipeds Along the Japanese Coastal Waters K. Nomiyama, C. Kanbara, H. Mizukawa, A. Eguchi, M. Ochiai, Ehime Univ, Center for Marine Environmental Studies (CMES); T. Isobe, Ehime Univ, Senior Research Fellow Center, Ehime Univ, Senior Research Fellow; T.K. Yamada, National Museum of Nature and Science, Tokyo, Dept of Zoology; S. Tanabe, Ehime Univ, Center for Marine Environmental Studies. Information on accumulation features of polychlorinated biphenyl metabolites (OH-PCBs) and hydroxylated polybrominated diphenyl ethers (OH-PBDEs) in the blood of marine mammals is limited. In this study, we determined the residue levels and patterns of PCBs (mono- to deca-, 62 isomers), PBDEs (mono- to deca-, 14 isomers), OH-PCBs (tri- to octa- 52 isomers), OH-PBDEs (tri- to octa-, 28 isomers) in the blood of pinnipeds [Northern sea lions (*Eumetopias jubatus*: male = 6, female = 4), Northern fur seals (*Callorhinus ursinus*: male = 3, female = 7), ribbon seals (*Phoca fasciata*: male = 1, female = 1) and spotted seals (*Phoca largha*: male = 6, female = 2)] along the Japanese coastal waters. Penta- through hepta-chlorinated PCB congeners were the dominant homolog groups in all species. The dominant PCB isomers found in all pinnipeds were CB153 and CB138. In contrast, specific differences in the distribution of dominant OH-PCB isomers and homologues were found among the species. The mean concentrations of ΣOH-PCBs were 180 pg g^{-1} in spotted seals, 160 pg g^{-1} in ribbon seals, 52 pg g^{-1} in Northern fur seals and 6.8 pg g^{-1} in Northern sea lions. The predominant OH-PCB isomers were para-OH-PCBs such as 4OH-CB107 and 4OH-CB187 in Northern sea lions. 4OH-CB107, 4OH-CB146, 4OH-CB162 and 4OH-CB187 were predominant in ribbon seals. 4OH-CB107 and 4OH-CB162 were predominant in ringed seals. In Northern fur seals, 4′OH-CB101/4′OH-CB120, 4OH-CB107, 4OH-CB162 and 4OH-CB97 were predominant. The differences in concentrations and profiles of OH-PCBs in the pinnipeds may suggest species-specific diets and metabolic capability. Characteristic differences found in the homolog patterns of OH-PCBs in pinnipeds suggest the need for further studies on the differences in exposure profiles, metabolic capacities and toxic effects. Of the 28 OH-PBDE isomers monitored, only two isomers (2′OH-BDE68 and 6OH-BDE47) could be consistently measured above the limit of quantification in all pinnipeds. The two abundant isomers accounted for about 41–99% (6OH-BDE47) and 1–48% (2′OH-BDE68) of the sum of all identified OH-PBDEs. These compounds have been reported as natural products present in red algae and cyanobacteria. It is probable that the many 6OH-BDE47 and 2′OH-BDE68 in cetaceans are not the metabolites of anthropogenic PBDEs.

WP027 Characterization and Quantification of PCB Metabolites in Riparian Spiders D. Delach, Clemson Univ, Environmental Toxicology; C.M. Lee, Clemson Univ, Environmental. Engineering and Earth Sciences Dept; D. Walters, USGS, Fort Collins Science Center, USGS, Ecologist. Many organisms can transform PCBs into various metabolites, such as hydroxylated PCBs (OH-PCBs). A variety of organisms ranging from polar bears to pinnipeds to fish have been examined; however, invertebrate metabolic capacity has only begun to be studied. It has been postulated that OH-PCBs can mimic edycsone hormone that stimulates exoskeleton shedding, but there has been little further investigation. Spiders have the important role of mediating trophic transfer from aquatic to terrestrial ecosystems, and may have the capacity to metabolize contaminants. Data from GC-MS-MS analysis provides qualitative evidence that the riparian orb weavers *Tetragnathidae* spiders have body burdens as high as 2400 ng/g, and may have the capacity to metabolize the contaminants. Hydroxylated PCB congeners with varying levels of chlorination are present, including di-, tri-, tetra-, and penta-chlorinated congeners. In an effort to determine the enzymatic detoxification pathway a suite of biomarkers was enlisted. Assays to assess activity of the most likely agents of detoxification were performed – namely, for cytochrome P450 isoforms 1A (EROD) and 2B (PROD), and for glutathione enzymes (GST assays). They were performed with spider tissue obtained along the contamination gradient. Preliminary results have indicated that CYP2B does not have a role in the detoxification process, unlike higher order organisms such as trout and birds.

WP028 The Immunologic Effects Aged Oil Sands-derived Naphthenic Acids on Rainbow Trout Co-exposed to Pathogen Associated Molecular

Patterns G.Z. MacDonald, Canadian Rivers Institute, Univ of Prince Edward Island; N.S. Hogan, K.L. Thorpe, L.J. Phalen, M.R. Heuvel, Canadian Rivers Institute, Univ of Prince Edward Island, Biology. Fishes in oil sands affected ponds and lakes have demonstrated an increase in disease prevalence which has been correlated with exposure to constituents of waters influenced by oil sands. Naphthenic acids are the major organic constituent in these waters raising questions regarding the potential of naphthenic acids to cause immune suppression in fishes. To investigate this potential, rainbow trout were injected with naphthenic acids extracted from 17-year-old oil sands tailings pond water using an acid precipitation method. Spectrophotometric analysis on this extract showed results consistent with the spectra of extracted naphthenic acids. Fish were injected with 0, 10, or 100 mg/kg dose of extracted naphthenic acids and sampled after either 5 or 21 days. The fish from the 21-day exposure were co-exposed to an injection of formalin inactivated *Aeromonas salmonicida* to induce an immune response. To assess the immune response, relevant immune parts including blood, spleen, and head kidney were removed from the fish at the end of the exposure and the constituent leukocytes, T lymphocytes, B lymphocytes, thrombocytes and myeloid cells were counted and typed via flow cytometry analysis using fluorescent antibodies specific for those cell types. In the 5-day exposure, there was a general depression in whole white blood cell populations and spleen thrombocyte populations with a significant depression at the 100 mg/kg dose. In the 21-day exposure white blood cell populations in both low and high doses showed some recovery from effects observed in the 5-day exposure, and spleen thrombocyte populations showed a general increase with dose with a significant increase at the 100 mg/kg dose. In the 21-day exposure, many cell types consistently showed a significant Dose x *A.s.* interaction at 100 mg/kg. Control fish cell numbers were consistently stimulated by *A.s.* injection while naphthenic acid injected fish usually showed a minor depression in numbers as compared to fish coexposed to *A.s.* From these results, it appears that naphthenic acids stimulate the immune response rather than suppress it. Overall, naphthenic acids are likely acting via a generally toxic mechanism in the short term, an immunostimulatory mechanism in the long term, and not via a specifically immunotoxic mechanism in either case.

WP029 Speciation of Vanadium in Coke and Oil Sands Process Water by HPLC-ICP-MS M. Jensen-Fontaine, Univ of Alberta, Chemistry; C. Le, Univ of Alberta, Dept of Laboratory Medicine & Pathology; X. Lu, Univ of Alberta, Laboratory Medicine & Pathology; P. Pourrezaei, Univ of Alberta, Civil and Environmental Engineering; M. Gamal El-Din, Univ of Alberta, Dept of Civil and Environmental Engineering. The Athabasca Oil Sands, found in Northern Alberta, Canada, produce over a million barrels of oil a day. The mining and upgrading process creates several by-products including petroleum coke and oil sands process water (OSPW). Most of the coke is stockpiled for use in future land reclamation projects. Some coke is slurried with OSPW to settling basins. Chemicals in the OSPW can sorb onto the coke or leach from the coke into the OSPW during the slurrying. Leaching of metals from coke during storage and after its use in land reclamation projects is also an environmental concern. Speciation and oxidation state affect a metal's toxicity, leaching potential and bioavailability. Of the six different oxidation states of vanadium, the common ones found in nature are V(III), V(IV), and V(V). The most toxic oxidation state is V(V). There are high levels of vanadium (640 ppm) in the Athabasca Oil Sands, mostly V(IV), that can potentially oxidize to V(V). To evaluate the severity of potential environmental contamination due to vanadium leaching and oxidation, we optimized an HPLC-ICP-MS method for vanadium speciation. The technique was applied to coke and OSPW samples. The limit of detection for both V(IV) and V(V) was below 1 ug/L. V(IV) rapidly oxidized in OSPW so a sample stability method was developed. Complexation with EDTA preserved the sample speciation and concentration for the duration of the study (56 days). The half-life of V(IV) in OSPW was determined by spiking OSPW with different concentrations of V(IV) and observing the conversion from V(IV) to V(V). In previous work, we had determined the speciation and concentration of vanadium in the supernatant when coke and OSPW were mixed for 12 hours. We therefore investigated the initial leaching profile of vanadium from the coke into OSPW. The supernatant was speciated at regular intervals during the first six hours of mixing. Over 60% of the vanadium leached in the first two hours. V(V) was the major species present in the supernatant as was the case with the 12 hour mixing tests. Future work will involve performing a bioaccumulation study of vanadium in *Hyallela azteca* by speciating the invertebrates and the water.

WP030 Are Oil Sands Sediments Toxic to Northern Pike (*Esox lucius*)? D. Turcotte, Environment Canada, Environment Canada; J.C. Raine, Toxicology Centre; L.K. Romanowski, V. Tumber, Environment Canada; J.L. Parrott, Environment Canada, Environment Canada, National Water Research Institute, Environment Canada. Northern pike (*Esox lucius*) are a commercially important fish species native to the northern hemisphere. In Alberta (Canada), these fish inhabit the Athabasca River, which flows through the Athabasca oil sands, and are exposed to natural sources of bitumen eroding from the McMurray formation. There is currently no information available to assess the early development of pike exposed to the bitumen present in the water of the Athabasca River. Pike are not easily cultured in a laboratory environment and no methods have been developed to assess the toxicity of oil sands to this fish species. Thus the current study describes the design and implementation of a daily-renewal bioassay that assesses the potential effects of sediments from the Athabasca oil sands area to the early stages of pike development. Eggs were collected and fertilized with milt from spawning wild pike captured from Lake Diefenbaker, SK. The fertilized eggs were exposed to treatments containing different concentrations of sediments from the oil sands area, reference sediments or strictly culture water until complete yolk absorption of control fish, approximately 15 days post-hatch. Brine shrimp were fed to the pike embryos daily at the initiation of exogenous feeding and continued to the conclusion the experiment. Developing fish were examined for morphological deformities, survival, hatching success, and changes in weight and length between treatments. Preliminary results suggest that the Northern pike is less sensitive than walleye and fathead minnow to the toxicity of oil sands sediments.

WP031 Characterization of Athabasca Oil Sands Process Water by Comprehensive Two-dimensional Liquid Chromatography M.S. Ross, Y. Wang, Univ of Alberta, Dept of Laboratory Medicine & Pathology; S.J. Rowland, Univ of Plymouth, School of Geography, Earth and Environmental Sciences; J.W. Martin, Univ of Alberta, Dept of Laboratory Medicine & Pathology. The toxicity of oil sands process water (OSPW) has been mainly attributed to a complex mixture of large (C_8-C_{22}) aliphatic and alicyclic carboxylic acids, called naphthenic acids (NAs; $C_nH_{2n-z}O_2$). However, a number of NA -like compounds containing heteroatoms (i.e., N, S, O), aromatic groups, or multiple carboxylic acid moieties are also reported to be present in OSPW. Partial identification of OSPW components often relies on ultra high resolution mass spectrometry (MS), but even by this method the 'identification' of compounds is limited to chemical formula, with little information about chemical structure. Two-dimensional (2D) gas chromatography-MS techniques have allowed identification of numerous NA, including in OSPW, and shown promise for characterizing other OSPW components, but usually has the disadvantage of low resolution mass spectrometry and often also requires a derivatization step. The goal of the present work was to further characterize NA and NA-like components of OSPW using a novel comprehensive two-dimensional (2D) HPLC with high resolution or tandem mass spectrometry detection. Using a combination of a ThermoFisher Hypercarb column in the first dimension and a C18 monolithic column in the second dimension, NAs were fully resolved from their oxidized degradation products and other isobaric acid-extractable compounds. Structure-retention relationships were studied by utilizing a series of "model" naphthenic acid compounds. By doing so, the retention behavior was calibrated, allowing for the prediction of compound structure based on retention time in the two-dimensional system. In the first dimension, NAs could be separated from their oxidized products, while a combination of first and second dimension separation was needed to separate NAs from aromatic and heteroatom containing compounds. Furthermore, the improved chromatographic resolution over one-dimensional systems allowed for the collection of tandem mass spectra of individual naphthenic acid components, aiding in compound identification. The 2D HPLC method was further applied to investigate the unique compound fingerprints in commercial naphthenic acids, authentic OSPW, and environmental samples from the Athabasca River and surrounding area.

WP032 Synchrotron Technology Used to Identify the Presence of Multiple Elements within Naphthenic Acids Extracts Derived from Process-affected Waters N. Toor, Level Science Inc., Environmental Science; C.H. Ryan, Y. Hu, Canadian Light Source Inc., ; J. Headley, Environment Canada, Water Science and Technology Directorate. Naphthenic acids (NAs) and related components derived from oil sands process-affected waters (OSPW) have not been completely characterized using conventional

analytical techniques. As a novel alternative, synchrotron technology can provide valuable information on the elemental composition of OSPW NAs. However, this method has the added benefit of being able to identify different elemental oxidation states, local molecular geometries, and chemical forms based on the absorption spectra generated during analysis. To date, both sulfur and boron components have been identified and speciated in these complex NAs mixtures. Additionally, the Soft X-Ray Microcharacterization Beamline (SXRMB) equipped with a Princeton Gamma-Tech (PGT) multi-element X-ray detector was used to complete a broad spectrum analysis of concentrated NAs extracts. Elements such as Cu, Ni, Mn, Cr, Fe, V, K, Cl, and Ca were identified in select extracts derived from regional process-affected and natural water sources. Differences in these components and their oxidation states could inevitably be used as potential markers for delineating anthropogenic impacts. This research highlights the potential for synchrotron technology, used alone or in combination with other analytical methods, to enhance the current understanding of the complex acid-extractable organic fraction of OSPW, which in the past has simply been referred to as naphthenic acids in the classical sense.

WP033 A Comparison of Reproductive Performance of Yellow Perch Held in Experimental Ponds Containing Oil Sands Affected Waters Over a 13-year Period M.R. Vandenheuvel, Canadian Rivers Institute, Univ of Prince Edward Island; N.S. Hogan, Canadian Rivers Institute, Univ of Prince Edward Island, Dept of Biology; S. Roloson, Canadian Rivers Institute, Univ of Prince Edward Island; G. Van Der Kraak, Univ of Guelph, Dept of Integrative Biology. The oil sands of Northern Alberta produces large volumes of tailings and process affected waters that must be safely incorporated into the reclaimed landscape. Unextracted materials in exposed oil sands or lean oil sands incorporated into reclaimed area may also chemically influence water bodies. In this study we describe the results of stocking experiments with yellow perch held in two experimental ponds over a 13-year period. Demonstration Pond contained oil sands fine tailings capped with natural surface water whereas South Bison Pond contained unprocessed oil sands material. Yellow perch were captured from a nearby reservoir, Mildred Lake, and placed in the two experimental systems. Two natural lakes, one at the edge of the Athabasca oil sands deposit, and one removed from the formation were also used for comparison purposes. The initial stocking experiments conducted from 1995 to 1997 showed that both male and female yellow perch had increased gonad size in the experimental ponds as compared to Mildred Lake and that gonad size and fecundity fell within, or was greater than that observed in the natural reference lakes. The only difference in sex steroid hormones were significant reductions in both testosterone and 11-ketotestosterone in males in the Demonstration Pond and South Bison. Yellow perch successfully reproduced in the ponds during the 1995 to 1997 period. In a repeat study conducted in 2009, male yellow perch in the Demonstration Pond had the lowest gonad size while the South Bison Pond had the highest gonad size. This was paralleled by the Demonstration Pond males having significantly lower testosterone and 11-ketotestosterone than all other populations while South Bison Pond perch steroid concentration were higher than all other populations. Female yellow perch gonad size was not significantly different than the other populations but plasma estradiol and testosterone was significantly lower than the other sites. The reproductive results are consistent with an observed increase in oil sands-related contaminants in the Demonstration Pond as the tailings consolidate over time, releasing material in the water column. Conversely, organics in the South Bison Pond decreased after the area was reclaimed in 1996. Results also suggest a more severe effect of unknown oil sands constituents in male perch than in female perch.

WP034 Evaluating the Effects of Naphthenic Acid Fractions on *Pimephales promelas* A.E. Bauer, Univ of Waterloo, Dept of Biology; R.A. Frank, Environment Canada, National Water Research Institute; L. Bragg, Univ of Waterloo, Dept of Biology; M. Kohli, M. Hewitt, Environment Canada, National Water Research Institute; D.G. Dixon, Univ of Waterloo; M.R. Servos, Univ of Waterloo, Dept of Biology and Canadian Water Network, Univ of Waterloo, Dept of Biology. Naphthenic Acids (NAs) are a complex group of alkyl-substituted acyclic, monocyclic and polycyclic carboxylic acids, with surfactant properties that are released from oil sands during bitumen extraction. In fact, they have been deemed the most toxic component of oil sands process material and process water (OSPW). Studies have indicated that an increase in NA concentration within reclamation pond water increases the potential for detrimental reproductive effects, as well as increased larval mortality and pathologies in fish. High molecular weight NAs are degraded more slowly than low molecular weight NAs resulting in a higher proportion of high molecular weight NAs in aged OSPW. Furthermore, studies have identified a decrease in toxicity associated with aged OSPW and degraded NAs. Few studies have evaluated the toxicity associated with a fractionated extract of oil sands NAs. This study assesses the difference in toxicity associated with different molecular weight fractions of an oil sands NA extract on the fathead minnow (*Pimephales promelas*). The NA extract was fractionated by distillation, allowing for the collection of fractions by molecular weight. Each fraction was then tested at multiple concentrations with an acute fathead minnow 7-d larval bioassay to determine 7-d LC50s and IC25s. These endpoints were then compared such that a lack in overlap of 95% confidence limits indicated a significant difference. Initial results suggest a potential for low molecular weight NAs to be more toxic to fathead minnows than high molecular weight NAs.

WP035 The Effects of Oil Sands Naphthenic Acids on the Growth and Physiology of *C. reinhardtii* K.L. Goff, Univ of Saskatchewan, Toxicology; J.V. Headley, Environment Canada, AEPRD; J.R. Lawrence, Water Science and Technology Directorate, Environment Canada, Water Science and Technology Directorate; T. Ellis, Canadian Light Source; K.E. Wilson, Univ of Saskatchewan, Biology. Studies of the biodegradation of petroleum hydrocarbons – and in particular, naphthenic acids (NAs) – have focused on the role of bacteria, fungi, and emergent macrophytes. Algae have the possibility to become an important part of a biodegradation program. In addition to direct biodegradation, photosynthetic reactions intrinsically release oxygen into water, aerating it and promoting an environment for aerobic reactions. In order to utilize both algal biodegradation and community level effects, however, a greater understanding must be reached of the interaction of algal communities and oil-sands process-water. One of the algal species identified in oil-sands process-waters is Chlamydomonas frigida, which grows up to 10-20 ppm NA; while there is little information in the literature regarding this species, the genus is well-understood due to *C. reinhardtii*'s frequent use as a model organism. To begin understanding how green algae can tolerate NA contaminated water we performed a dose-response test with a wild type strain of *C. reinhardtii*. We found that it could grow in the presence of 100 ppm NA but observed that following 24 h of exposure to 100 ppm NA, the cells formed large clumps. The cells later grew as individual cells, albeit at a lower rate than untreated cells. We hypothesized that this clumping was due to interactions of NA with the glycoprotein cell wall of *C. reinhardtii*. To test our hypothesis we performed the same dose-response treatment with two cell-wall deficient, mutant strains of *C. reinhardtii*. While treatment with 100 ppm of NA slightly decreased the growth rates of both cell-wall deficient strains, we did not observe the same clumping phenomenon. To explore how NA interacts with the algal cell wall we examined NA treated cells of each strain using infrared spectromicroscopy and confocal laser scanning microscopy. We will present our data suggesting that NAs can suppress algal growth by directly interacting with the cell wall and causing the cells to sediment out of solution.

WP036 Evaluating Sub-lethal Effects of Oil Sands Process-affected Waters on the White Sucker (*Catostomus commersonii*) C.J. Arens, Univ of Prince Edward Island, Dept of Biomedical Sciences; N.S. Hogan, Canadian Rivers Institute, Univ of Prince Edward Island, Dept of Biology; G.J. Van Der Kraak, Univ of Guelph, Dept of Integrative Biology; M.R. van den Heuvel, Univ of Prince Edward Island, Dept of Biology. Conventional surface oil sands mining and extraction produces large volumes of tailings and oil sands process water (OSPW) that, under a zero-discharge policy, must be safely incorporated into a reclaimed landscape. One reclamation strategy under consideration is the development of end-pit lakes wherein microbiological processes detoxify tailings over time, improving water quality and allowing the base of a lake ecosystem to develop. However, there is evidence that fish exposed to OSPW exhibit disease pathologies and other signs of sublethal toxicity. The objective of our research was to determine the extent of potential impacts OSPW in end-pit lakes may have on the health of a native fish species, white sucker (*Catostomus commersonii*). In May 2010, two experimental ponds, Demonstration Pond and Bison Pond, containing mature fine tailings and lean oil sands material respectively, were each stocked with 200 white sucker from a local reservoir. In September 2010, 20 male and 20 female fish were sampled from each of these ponds, as well as the source population and two additional reference populations. Several endpoints were examined including disease occurrence, somatic indices, age

and growth relationships, immunological parameters, histopathology, as well as toxicant accumulation within tissues (e.g., naphthenic acid). Results indicated that fish introduced to Demonstration Pond exhibited a significant reduction in male gonad size, though this was not paralleled by decreases in sex steroid hormones. The Demonstration Pond population showed a reduction in growth relative to other populations sampled. Several other endpoints did not indicate detrimental impacts over a four month period. Bile fluorescence measurements showed a gradient of oil sands-associated exposure with the two experimental ponds being elevated over the source population of sucker, and over other local sucker populations. The results of this work allow us to develop an understanding of the potential impact oil sands tailings have on wild fish populations, as well as guide decisions regarding introduction and monitoring of fish in full scale end-pit lakes.

WP037 Accumulation and Biliary Excretion of Naphthenic Acids in Yellow Perch Exposed to Oil Sands Influenced Waters G.Z. MacDonald, Canadian Rivers Institute, Univ of Prince Edward Island; N.S. Hogan, Canadian Rivers Institute, Univ of Prince Edward Island, Dept of Biology; P. Fedorak, R. Young, Univ of Alberta; M.R. Vandenheuvel, Canadian Rivers Institute, Univ of Prince Edward Island. The major organic contaminant in waters influenced by oil sands mining are naphthenic acids. Naphthenic acids are a chemically complex group of compounds and the unavailability of analytical techniques confounded by their biotransformation in the environment has limited our understanding of the environmental fate of these compounds. Muscle tissue accumulation and biliary excretion of naphthenic acids was examined in yellow perch exposed to oil sands-influenced surface waters for 4 months. Pond stocking experiments with yellow perch were conducted in 2009 in two experimental ponds. One pond, the Demonstration Pond contained oil sands fine tailings capped with natural surface water and the other location, the South Bison Pond. Those ponds are currently known to contain 15 and 4 mg/L total naphthenic acids. Yellow perch were captured from a nearby reservoir, Mildred Lake, and placed in the two experimental systems. Two natural lakes, one at the edge of the Athabasca oil sands deposit, and one removed from the formation were also used for comparison purposes. Yellow perch dorsal muscle tissue was extracted and naphthenic acids were analyzed using GC-MS. A new method was adapted for the analysis of naphthenic acids in yellow perch bile involving the basic ethanolysis of conjugates, pH adjustment, solvent extraction, derivitization, and analysis by GC-MS. Duplicate bile extracts were analyzed by HPLC fluorescence at phenanthrene wavelengths. Perch tissue showed no accumulation of naphthenic acids in any of the five perch populations examined. In contrast, there was a clear gradient of naphthenic acids in the bile of perch, consistent with the water concentrations. Fluorescent metabolites were highly correlated with the bile naphthenic acid constituents, indicating that either the naphthenic acids have a fluorescent components, or that they are highly correlated with other aromatic constituents associated with oil sands. This study has demonstrated for the first time that weathered oil-sands derived naphthenic acids do not significantly accumulate in tissue, and are rapidly excreted in bile, making the analysis of napthenic acids in bile a useful indicator of exposure to oil sands-impacted waters. The nature of the aromatic component within the mixture will be the subject of further studies.

WP038 Weight of Evidence Approach to Assess Metal Cycling in Oil Sands Tailings and Natural Environments – 1. Metals in Water P. Huntsman-Mapila, Natureal Resources Canada; N. Puttasswamy, R. Cameron, M. Pawlak, Y. Thibault, C. Rickwood, Natural Resources Canada. A project to examine the fate and effect of thirteen priority metals in oil sands tailings and the Athabasca River was launched by Natural Resources Canada in 2010 with the first round of samples collected in Spring 2011. The overall investigation into fate measures metal concentrations and assesses the abiotic and biotic factors influencing their fate in various environmental compartments (water, sediment and suspended solids). This presentation outlines the results of the first round of snow and river samples collected from both the Athabasca and Muskeg River area in Spring 2011. To link with the effects component of the project, metal bioavailability was also examined through laboratory speciation analysis of various metals and the deployment of diffusive gradient thin film (DGT) devices in the river for a period of 10 days.

WP039 Weight of Evidence Approach to Assess Metal Cycling in Oil Sands Tailings and Natural Environments – 2. Metals in Sediment P. Huntsman-Mapila, Natureal Resources Canada; S. Langley, N. Puttaswamy, Y. Thibault, C. Rickwood, Natural Resources Canada. A project to examine the fate and effect of thirteen priority metals in oil sands tailings and the Athabasca River was launched by Natural Resources Canada in 2010 with the first round of samples collected in Spring 2011. The overall investigation into fate measures metal concentrations and the abiotic and biotic factors influencing their fate in various environmental compartments (water, sediment and suspended solids). This presentation outlines the results of the first round of sediment samples collected from both the Athabasca and Muskeg River. Sediment cores collected at 6 sites on the river were sectioned and examined for sediment and pore water metal concentrations. Microcosm studies were performed to elucidate potential links between microbial respiratory processes and metal release from sediments. Sequential extractions of the metals in the sediments and sediment mineralogical characterization were also undertaken to identify the phases in which the metals of interest reside. Results of the sediment analyses are linked to the sediment toxicology component of the project.

WP040 Weight of Evidence Approach to Assess Metal Cycling in Oil Sands, Tailings, and Natural Environments – 1. Exposure to Water C. Rickwood, Natural Resources Canada, CANMET MMSL, Univ of Saskatchewan, Dept of Toxicology; M. Desforges, M. King, Natural Resources Canada, CANMET MMSL; N. Puttaswamy, Natural Resources Canada; P. Huntsman-Mapila, Natural Resources Canada, CANMET-MMSL. An investigation was conducted to assess the distribution and fate of metals in oil sands tailings streams and adjacent natural rivers. Based on recently published work regarding metals in the local environment, this project aimed to assess both the fate and effect of thirteen priority metals. The investigation into fate measured the type of metals and the abiotic and biotic factors influencing their fate in various environmental compartments (water, sediment and suspended solids). The investigation into effect used various toxicity testing methods to assess the impacts of both natural rivers and tailings ponds water, fluid fines/suspended sediments and sediments. This presentation outlines the results of the impact assessment of the water exposure component conducted during the first round of testing with samples collected in spring 2011 from both the Athabasca and Muskeg River. Tests were conducted with algae (*Pseudokirchneriella subcapitata*), invertebrates (*Ceriodaphnia dubia*) and fish species (*Pimephales promelas*). Metal bioavailability was assessed in conjunction to the metal data collected during the fate portion of the project (presented elsewhere). Using a weight of evidence approach it is possible to investigate the fate of metals and their potential effect on aquatic organisms from water samples in the Athabasca river region.

WP041 Weight of Evidence Approach to Assess Metal Cycling in Oil Sands Tailings and Natural Environments – 2. Exposure to Sediments C. Rickwood, Natural Resources Canada, CANMET MMSL, Univ of Saskatchewan, Dept of Toxicology; N. Puttaswamy, M. Desforges, O. Samotus, P. Huntsman-Mapila, Natural Resources Canada. An investigation was conducted to assess the distribution and fate of metals in oil sands tailings streams and adjacent natural rivers. Based on recently published work regarding metals in the local environment, this project aimed to assess both the fate and effect of thirteen priority metals. The investigation into fate measured the type of metals and the abiotic and biotic factors influencing their fate in various environmental compartments (water, sediment and suspended solids). The investigation into effect used various toxicity testing methods to assess the impacts of both natural rivers and tailings ponds water, fluid fines/suspended sediments and sediments. This presentation outlines the results of the impact assessment of the sediment exposure component conducted during the first round of testing with samples collected from both the Athabasca and Muskeg River in Spring 2011. Tests were conducted using benthic invertebrate (*Chironomus dilutus*) and fish species (*Pimephales promelas*). Metal bioavailability was assessed using peepers and DGTs in sediments and compared to the metal data collected during the fate portion of the project (presented elsewhere). Using a weight of evidence approach it is possible to investigate the fate of metals and their potential effect on aquatic organisms from Athabasca river region sediment samples.

WP042 Assessment of the Aquatic Toxicity of Waters from Oil Sands Tailings Rapidly Dewatered Using Atmospheric Fines Drying Process S. Armstrong, Shell Health – Americas; J. Reid, Shell Canada Ltd. The following research investigated the aquatic toxicity of release waters from Shell's pilot atmospheric fines drying (AFD) process from its oil sands operation and compared it to the reclaim waters of untreated mature fine tailings

(MFT). The AFD tailings treatment process is essential technology developed to rapidly release water from oil sands tailings that would otherwise be trapped in traditional tailings deposits so that these waters may be recycled back into the extraction process. The objective of this research is to verify that the pilot AFD release waters have not increased toxicity or environmental risk compared to the current MFT and associated waters. AFD and MFT waters were tested for acute toxicity using 96 h rainbow trout (*Oncorhynchus mykiss*) bioassay and the Microtox® (Vibrio fischeri) bacterial luminescence acute toxicity bioassays. Chronic toxicity was investigated using Fathead minnow (*Pimephales promelas*) 7-day chronic bioassay and the freshwater invertebrate (*Ceriodaphnia dubia*) 7-day chronic reproduction bioassay. There was no acute toxicity differences between MFT reclaim water and AFD release waters in fish bioassays for lethality and growth. Toxicological effects due to oil sands tailings waters were only observed in the reproduction of the freshwater invertebrate *Ceriodaphnia dubia* after chronic exposure. There was no increased toxicity observed in the AFD compared to that of the MFT reclaim waters. The inhibition to reproduction in *Ceriodaphnia* was moderate and comparable for AFD and MFT treatments. Based on the results collected to date, the AFD release water has no increased inherent hazard for acute toxicity and chronic toxicity over current MFT reclaim water. The long term stability of the AFD tailings after drying and rewetting and overwintering is still unknown and is the subject of ongoing research. These current results indicate that AFD tailings treatment is a suitable tailings treatment strategy for MFT and will assist oil sands operators in meeting the Alberta Environment's Directive 74 to produce solid trafficable tailings.

WP043 Application of Ozone/Hydrogen Peroxide Advanced Oxidation Process for Treatment of Naphthenic Acids in Oil Sand Process Water A. Afzal, P. Drzewicz, Univ of Alberta, Civil and Environmental Engineering; J.W. Martin, Univ of Alberta, Dept of Laboratory Medicine and Pathology; M. Gamal El-Din, Univ of Alberta, Civil and Environmental Engineering. The oil sands deposits of Northern Alberta, Canada contain approximately 1.7 trillion barrels of oil in form of bitumen, from which crude oil is extracted using surface mining method. For every 1 barrel of oil produced, between 2 and 5 barrels of freshwater are required. This high amount of oil sand process water (OSPW) is acutely toxic and contained in large tailing ponds due to zero discharge policy. Naphthenic acids (NAs) are believed to be the most significant toxic components in oil sand deposits and tailing ponds. Biodegradation which occurs naturally in tailing ponds is too slow to be an effective remediation technology for NA removal from OSPW. Advanced oxidation processes are among techniques that can be used for degradation of refractory NAs. In this study combination of ozone (O_3) and hydrogen peroxide (H_2O_2) was used for decomposition of NAs in OSPW. In our research experiments, in a semi-batch reactor with 4 L capacity, O_3 was bubbled to the OSPW and the NA concentration was measured using Fourier Transform Infrared Spectroscopy (FT-IR) before and after treatment. H_2O_2 with different molar ratios to O_3 was added to the OSPW right before the ozonation. Results of a control experiment showed that after 4 min ozonation without H_2O_2 addition, 29% of NAs was removed. The O_3 concentration was 30 mg/L and the NA concentration was 70 and 50 mg/L before and after treatment, respectively. However with adding the H_2O_2 at molar ratios of 1:1, 1:2, and 2:1 to O_3, the degradation was increased by 39, 39, and 37 %, respectively. The reason is that O_3 in combination with H_2O_2 generates an OH radical which is a strong oxidizing agent that can oxidize the NAs to more biodegradable compounds such as hydroxyl-NAs. It is expected that the optimized method with the higher ozone and H_2O_2 concentrations is promising for NAs removal in OSPW.

WP044 Toxicity Reduction of Oil Sands Process Affected Water by Native Phytoplankton Species A.P. Woodworth, Univ of Waterloo, PhD Candidate; A. Bauer, Univ of Waterloo, Dept of Biology; R.A. Frank, Environment Canada, AEPRD, Univ of Guelph, Dept of Env. Biology & Toxicology; K.M. Muller, B. McConkey, Univ of Waterloo, Dept of Biology. Naphthenic acids (NAs), a class of compounds resulting from bitumen extraction processes, have been identified as one of the principal toxic components of oil sands process-affected water (OSPW). NAs are known to be acutely toxic to many organisms including fish and aquatic invertebrates, but are considerably less toxic to many algal species. Due to the toxic nature of NAs, they have recently been the focus of several studies investigating potential remediation strategies. One such investigation, involving the accumulation or adsorption of NAs by phytoplankton strains isolated from the Athabasca oil sands region, has recently identified three phytoplankton strains capable of reducing total naphthenic acid concentrations in an oil sands naphthenic acid mixture. This study examines the reduction of NA mixture toxicity to the aquatic invertebrate *Daphnia magna* by the three phytoplankton strains. The effects of phytoplankton culture density and nitrogen limitation on the capacity of algae to reduce NA mixture toxicity were also examined. Axenic phytoplankton cultures were exposed to a 100mg L^{-1} mixture of NAs for a total of 14 days. The resulting algal biomass was then removed using centrifugation followed by vacuum filtration and the filtrate retained for toxicity testing. Forty- eight hour acute lethality tests were then performed on *D. magna* neonates, and the relative toxicity of the NA mixtures before and after algal treatment were compared. Preliminary results indicate algae species were effective at reducing NA toxicity, and the toxicity reduction is correlated to phytoplankton culture density.

WP045 Understanding Interactive Effects of Climate Change and Toxicity: Cadmium Reverses Beneficial Effects of Temperature in a Freshwater Snail D.A. Kimberly, Texas Tech Univ/TIEHH, Environmental Toxicology, Texas Tech Univ, Environmental Toxicology; C.J. Salice, Texas Tech Univ/TIEHH, Environmental Toxicology, Assistant Professor, Texas Tech Univ. The goal of ecological risk is to protect ecosystems against the adverse effects of toxicants. In practice, ecological risk assessments are frequently based on data in which study organisms are exposed to a single stressor only. However, natural populations of organisms invariably experience multiple, simultaneous stressors. As an example, many aquatic systems experience a wide range of temperatures which may expand given projected changes in climate. Hence, ecological risk assessments of chemicals should consider the impacts of higher and more variable temperatures on aquatic species. The objective of this study was to characterize the interactive effects of cadmium and temperature stress on development and hatching of eggs from the freshwater snail, *Physa pomilia*. Ninety six egg masses were collected from 20 breeding pairs and evenly divided between two temperatures of 25C and 35C and among four cadmium treatments of 0, 5µg/L, 15µg/L, and 25µg/L for a total of eight treatments. The temperatures represent a normally occurring (25C) and a higher temperature that may be expected under climate warming scenarios (35C). Egg masses were observed twice daily for days-to-hatching and hatching success. Overall, egg masses reared at 35C and exposed to Cd had significantly lower hatching success and greater time-to-hatching, compared to the control. In fact, control egg masses at 35C had a slightly higher hatching success in the absence of cadmium compared to controls at 25C. Additionally, time to hatch was lower at 35C compared to 25C in the absence of cadmium. It was only when egg masses were exposed to temperature and cadmium in combination that adverse effects of higher temperature were observed. Climate change is a factor that may be highly variable in the field and is of major importance to the physiological state of organisms. Our data suggest that, in some cases, adverse effects of climate change may only exist in the presence of certain other stressors. Specifically in our study, an increase in cadmium exposure concomitant with high temperatures lead to adverse effects in freshwater snails. Thus, ecological risks associated with climate change must be assessed in the context of other stressors such as pollutants as the combined exposure may dwarf or intensify overall adverse effects. Future efforts should also focus on how biological stressors such as competition and predation may interact with chemical stressors in a changing climate.

WP046 Preliminary Model Prediction of Climate Change Impact on the Multimedia Distribution of Polycyclic Aromatic Hydrocarbons (PAHs) in South Korea J. Song, D. Lee, S. Kim, Y. Lee, Seoul National Univ, Dept of environmental planning, Graduate school of environmental studies. A dynamic multimedia model was developed and evaluated to predict the change in multimedia distribution of semi-volatile organic compounds by taking into account the effects of climate change (CC) including those of temperature and other meteorological and environmental conditions such as wind speed and direction, precipitation rate, radiation intensity, hydroxyl radical concentration, particulate matters and suspended solids levels, vegetation, and land cover. The model is capable of predicting the time change of the concentrations in air, water, soil, and vegetation in the entire territory of South Korea (34N~39N, 125E~130E). A total of 176 air grids and 98941 watersheds were within the model domain. Four vertical layers were used to describe the vertical concentration variation in air. The model was evaluated by comparing the predicted relative concentrations with the monitoring data (4) from 1999 to 2003 for 15 PAHs. From the simulations extended for a 30 year period from 2000 to 2030, the relative

concentrations of water/air, soil/air, vegetation/air, water/soil, and sediment/water were compared between BAU and A1B scenarios. Five different cities chosen for the comparisons were Seoul, Kwangwon, Chungbuk, Kwangjoo, and Pusan. Emission rates were set identical in the two scenarios to explore the impacts of CC alone. The impacts of CC on the relative concentrations varied with the physicochemical properties of the PAHs. The direction of the impacts also changed with the locations. For example, under the A1B scenario, the relative benzo[*a*]pyrene concentration of water/air and water/soil increased in all locations while soil/air, vegetation/soil, and sediment/water decreased in some of the locations. It was also noted that the fluctuation of the concentrations or relative concentrations substantially increased under the A1B scenario due to more frequent occurrence of extreme weather conditions. More details of the simulation results and the contributing factors to the CC impacts will be presented. The model prediction strongly suggests that CC will change the distribution of PAHs among the environmental media, which may lead to increased risk to human or ecosystem even when the emission rate is kept constant or reduced. Further studies are warranted to predict the direction and the magnitude of such changes and to reduce the uncertainties associated with the predictions.

WP047 Maternal Transfer of MeHgCl in Northern Water Snakes, *Neroida sipedon* and its Effects on Neonate Performance R.C. Wright, J.W. Cusaac, C. Henry, F.C. Bailey, Middle Tennessee State Univ, Biology. In ecotoxicology, reptiles have historically been underrepresented, with most studies focusing on the concentration of a contaminant found in an organism at a site. Fewer studies have been conducted to examine the fate or physiological/biochemical effects of contaminants on these animals. This study was designed to look at the effects of maternally-transferred MeHgCl on locomotor performance in Northern Water Snake (*Nerodia sipedon*) neonates. In the study, adult female *N. sipedon* were randomly assigned to one of three treatments: 0, 10, or 10,000 ug/Kg. Fourteen females gave birth and after a two week acclimation period the neonates were tested for average and maximum terrestrial locomotor speed in a laboratory race track. Mercury analyses of neonate livers indicated that neonates from the high dose treatment had the highest concentration of Hg. No statistical difference was found in speed of locomotion between treatments (ANOVA, $F_{2,11} = 0.021$, $p = 0.980$).

WP048 The Relative Importance of Diet and Dermal Contaminant Exposure in Reptiles: Results from Empirical Studies on the Western Fence Lizard S. Weir, Texas Tech Univ, The institute of environmental and human health; L. Talent, Oklahoma State Univ; C. Salice, Texas Tech Univ, The institute of environmental and human health. Reptile ecological risk assessment is currently limited by a lack of acute and chronic toxicity data as well as a dearth of knowledge regarding contaminant exposure. Recent advances in the use of the western fence lizard (*Sceloporus occidentalis*) as a model organism creates opportunities for filling in important data gaps that may improve reptile risk assessment. Of particular interest is in understanding which exposure routes contribute most to total exposure. Because many reptiles spend a large proportion of time in contact with substrate, there is potential for dermal exposure to be important for reptiles; dermal exposure is known to be important for birds. We conducted a study to provide insight into the relative importance of diet and dermal contaminant exposure in reptiles. Fence lizards were exposed to phthalate esters by either oral gavage or dermal application and we analyzed liver and body fat for phthalates at 3 time points following exposure. Phthalates were chosen as model chemicals because lipophilicity changes with the length of the side chain allowing relationships between dermal exposure and lipophilicity to be estimated. We used di-methyl phthalate (DMP, logKow = 1.6), di-butyl phthalate (DBP, logKow = 4.5), and di-n-octyl phthalate (DNOP, logKow = 8.0). Our results suggest that dermal exposure increases with increasing lipophilicity and is generally sequestered into fat tissue rather than liver. Of the phthalates tested, DMP did not show significant tissue concentrations via the dermal route, and also relatively low concentrations via oral exposure as well. DBP appeared to be significantly absorbed by both dermal and oral exposure, with oral exposure generally resulting in greater tissue concentration than dermal exposure. Finally, DNOP was very highly absorbed via both oral and dermal exposure routes, with little difference in tissue residues between the two. Our results highlight the potential importance of dermal exposure as a significant exposure route, especially for reptiles. Future research will further quantify the relative importance of oral and dermal exposure routes under more realistic scenarios including contaminated soil and food items. We suggest that ecological risk assessments involving reptiles should consider the dermal exposure route, especially because dietary exposures may be relatively low due to low metabolic demands.

WP049 Organotypic Cultures in Protected Wildlife: Applications in the Toxicology of Chemical and Natural Stressors in Sea Turtles J. Cole, S. Wiggins, G.V. Zychowski, The Institute of Environmental and Human Health, Texas Tech Univ, Dept of Environmental Toxicology; B. Higgins, NOAA/NMFS; J. Strahlendorf, Texas Tech Univ Health Sciences Center Dept of Cell Physiology and Biophysics; J. Olson, Univ at Buffalo SUNY; C. Godard-Codding, The Institute of Environmental and Human Health/Texas Tech Univ, Assistant Professor, Texas Tech Univ/The Institute of Environmental and Human Health, Assistant Professor. Sea turtle health assessment is crucial to conserving declining sea turtle species and evaluating contaminant impacts on ocean life. All seven species of sea turtles are protected under the Endangered Species Act. Because they are protected, researchers are challenged to develop minimally-invasive methods to detect and evaluate contaminant impacts.To address this issue, we developed a methodology pairing organotypic cultures of precision-cut slices prepared from sea turtle skin biopsies with gene, protein and enzymatic analyses. Here, we exposed organotypic cultures of loggerhead sea turtle (*Caretta caretta*) skin tissue obtained from biopsies to a dose range (0, 0.01, 0.1, 1 and 10 uM) of benzo[*a*]pyrene (BAP), a prototypical polycyclic aromatic hydrocarbon and known marine contaminant. We evaluated the viability of the organotypic culture slices after 24 and 72 h by measuring intracellular potassium concentrations of control slices using a Flame Atomic Absorption Spectrometer. As expected, viability was observed in control cultures at all time points. Protein expression analyses were optimized on membrane bound protein lysates after tissue slices were homogenized using a mortar and pestle, liquid nitrogen and ultrasonication. Western blot analysis showed CYP1A-like activity measured in BAP-induced organotypic cultures using a polyclonal goat IgG anti-rabbit P4501A1/2 antibody. Gene expression and enzymatic studies using qRT-PCR and a kinetic catalytic assay, respectively, are underway. Our preliminary results and ongoing analyses indicate that precision-cut organotypic cultures studies are promising tools for 1) studying the impacts of contaminants on marine reptiles at the molecular level 2) investigating impacts of toxic chemical exposure and natural stressors on marine reptiles and 3) identifying and validating molecular changes as biomarkers of pollution impacts on marine reptiles and other wildlife.

WP050 Research on the Migration of Young Green Turtles (*Chelonia mydas*) in the Arcelormittal Tubarão Industrial Effluent J.O. Santos, ARCELORMITTAL TUBARÃO, Environment; F. Passamani, ARCELORMITTAL TUBARÃO, Environment, ArcelorMittal Tubar?o, Environment; C. BAPTISTOTTE, E. TOREZANI, TAMAR-ICMBIO. The green turtle, *Chelonia mydas,* is globally distributed in tropical and subtropical seas. In Brazil, their reproduction areas area located in the oceanic islands of Fernando de Noronha, Atol das Rocas and Trindade Island. Young and adult specimens are found in feeding areas along almost the entire coast of Brazil. This species, as well as the other four species existing in the Brazilian coast, is part of the list of endangered fauna species in Brazil, also considered endangered by the World Conservation Union (Hilton-Taylor 2000). The research institution – Projeto TAMAR-IBAMA – has acted especially on the main reproduction areas in Brazil since 1980, and in 1990 it started working in the feeding areas. Biometric and marking works are carried out in the reproduction and the feeding areas by the institution, aiming to better understand the biological and migration standards of this species, which serve as basis for preservation activities (Marcovaldi et a. 1998). In 2000 a technical cooperation agreement was signed between the research institution and ArcelorMittal in order to carry out studies on the biology of the species in the area of influence of the company. Field works have been performed since August 11th, 2000 with the main objective of carrying out biometric studies by capturing and marking them to record growth, migration patterns, haematological profile and health conditions of the green turtles that use the marine water of ArcelorMittal Tubarão effluent area. ArcelorMittal Tubarão is located 14km north of Vitoria (State of Espírito Santo, Brazil). Treated domestic and industrial effluents from the company are thrown in one single marine area (final effluent). Water and sediments receive physical-chemical and toxicological monitoring every six months and a biological monitoring is also carried out examining the bioaccumulation of heavy metals in bivalve molluscs. The area studied is located at the end of the effluent channel and has an average temperature 6o above sea water temperature, which, together

with the availability of organic matter, favours an environment rich in algae. This study presents the monitoring results from 2009-2010 including field methods and data collection results from the effluent area.

WP051 Influence of Atrazine Utilization in Paddy Field on Morphology of the Populated Rice Frog *Fejervarya limnocharis* in Thailand P. Thammachoti, W. Khonsue, Chulalongkorn Univ, Dept of Biology; J. Kitana, Chulalongkorn Univ, Dept of Biology, Faculty of Science; P. Varanusupakul, Chulalongkorn Univ, Dept Chemistry; N. Kitana, Chulalongkorn Univ, Dept of Biology. Intensive herbicide utilization in agricultural area can lead to an environmental contamination and adverse effects on non-target organisms living in the area including amphibians. In northern part of Thailand, there are many agricultural areas where herbicide, especially atrazine, has been used for a long time. To test for atrazine contamination, environmental samples (soil and water) were collected from a potentially contaminated agricultural area with intensive atrazine usage and a reference site with no history of atrazine usage in Nan province, northern part of Thailand during 2010-2011. The results of gas chromatography-mass spectrometry analysis showed that atrazine can be found in low level (0.15 mg/L) in water of the potentially contaminated paddy field, but not in the reference paddy field. To test for influence of atrazine contamination on non-target organisms, the rice frog *Fejervarya limnocharis* was used as a sentinel species for environmental health hazards. Frogs were field-collected during July 2010 to June 2011 from the contaminated site and the reference site. Frogs were subjected to contaminant analysis for atrazine by high performance liquid chromatography, and morphometry and gravimetry of liver, kidney, gonad and body. Site-related difference on tissue residue of atrazine and parameters of morphometric and gravimetric analyses will be presented and discussed. Since atrazine is known as endocrine disrupting chemicals, potential impacts of its contamination on reproductive and fecundity fitness of this populated frog species will be evaluated. The results of this study could be used as an early warning of environmental health hazards of atrazine utilization in other vertebrates living near the agricultural areas including human.

WP052 Effects of Pond Sediment Exposure on Steroidogensis in Juvenile Cane Toads (*Bufo marinus*) D. Fort, Fort Environmental Laboratories, Fort Environmental Laboratories, Inc.; C. Fort, B. Todhunter, Fort Environmental Laboratories, Inc.; J. Bacon, Bermuda Zoological Society. The impacts of contaminated sediment from two ponds in Bermuda on early sexual differentiation and gonadal steroidogenesis in juvenile cane toads were examined. Pond sediment from Bermuda was previously found to cause reduced reproductive fecundity and alter steroidogenesis in fathead minnow (*Pimephales promelas*) and killifish (*Fundulus heteroclitus*). A partial lifecycle study exposing Gosner stage 20 cane toad tadpoles to pond sediment and laboratory culture water through metamorphosis and into a juvenile state was performed. An increase in phenotypic males was noted in the pond sediment treatments; however, no effects on survival, metamorphic completion, body weight, snout-vent length, or GSI were noted. To further examine the effect of pond sediment exposure on gonadal differentiation aromatase and CYP 17 lyase (CYP 17) were measured; in addition to plasma estradiol (E2), testosterone (T), dihydrotestosterone (DHT), and vitellogenin (VTG) levels in post-metamorphic toads. Gonad and plasma samples were collected from juvenile control specimens and organisms exposed to pond sediment from early embryo through metamorphosis. Increased mean plasma DHT and T, and decreased mean E2 and VTG levels were found in juvenile toads from the pond sediment treatment compared to controls. Toads exposed to the pond sediment exhibited a decrease in mean gonadal aromatase activity, but CYP 17 lyase activity was unaffected relative to control toads. These results are consistent with similar studies conducted in fish and suggest that the decreased aromatase activity may have resulted in the increase in plasma T and DHT levels found in pond sediment-treated toads. Consistent CYP 17 activity suggested that upstream androgen biosynthesis was not affected by pond sediment exposure. Further, the increase in the proportion of phenotypic male frogs may be the result of increased gonadal androgen levels induced by exposure to pond sediment contaminated with petroleum hydrocarbons, polycyclic aromatic hydrocarbons, and metals.

WP053 Influence of Roadway Proximity on Mercury Accumulation and Population Dynamics in a Wetland-dwelling Amphibian J. Bushey, Univ of Connecticut, Asst Professor; S. Brady, Yale Univ, Ecology & Evolutionary Biology; A. Aragon-Jose, Univ of Connecticut; D. Skelly, Yale Univ. Roads are distributed pervasively throughout much of North America. Runoff from impervious surfaces contributes trace metal contaminants to roadside wetlands. However, the impact of salinization of waterways on biogeochemical cycles, particularly organic carbon cycling, and Hg speciation is lacking. DOC and Hg-Cl complexes impact potential bioavailability, particularly at sub-lethal levels. Many investigations focus on lethal doses of single chemical exposure. However, our burgeoning understanding of the influence of rapid evolution on ecological patterns suggests that sub-lethal geochemical processes and demographic processes may interact, resulting in outcomes that vary among local populations. We examined the potential influence of road proximity on the chemical characteristics of five forest and five roadside temporary wetlands located in northeastern Connecticut. In roadside wetlands, specific conductance—a close proxy for road salt—was approximately 25 times that of forest pools, demonstrating the influence of impervious road surfaces. Hg species along with base cation, anion and DOC content were analyzed from water samples collected in April, May and early July 2009. To investigate biological outcomes, we used a reciprocal transplant experimental design in which spotted salamanders embryos were grown out in field enclosures in each of the ten wetlands to parse the influence of the environment and the population on bioaccumulation. Total Hg values in late-stage larvae in roadside ponds increased 25% relative to forested ponds. Average larval content was 0.10 ppm with surprisingly lower levels for roadside ponds relative to forested ponds, possibly reflecting the decrease in dissolved organic carbon. Additionally, we examined the potential impact of maternal transfer on the reproductive success of amphibians. We collected adult woodfrogs in Spring 2010 returning to select roadside and forested vernal pools in the Yale Experimental Forest, CT. Pairs of amphibians were bred in captivity with mating adults and a subsection of the fertilized eggs analyzed for Hg content. Reproductive success was documented by hatchling success. Adult females contained higher Hg concentrations (176 ng/g) relative to males (130 ng/g), with slightly higher content in forest specimens. While egg content increased with female parent Hg content for both roadway and forest specimens, maternal transfer of Hg was only significantly related ($p=0.05$) for the forested samples.

WP054 Occurrence of Current Use Pesticides in Amphibian Habitats in Northern California K.L. Smalling, US Geological Survey; G. Fellers, P. Kleeman, US Geological Survey, Western Region Ecological Center; M. McWayne, US Geological Survey; W. Battaglin, US Geological Survey, Denver Federal Center; K. Kuivila, US Geological Survey. Amphibian populations worldwide have been in decline for at least the past two decades. Habitat loss, predation, disease--particularly the proliferation of the chytridiomycosis causing fungus, Batrachochytrium dendrobatidis (Bd)--and pollution, including pesticides, are factors that have been implicated. Surveys of natural populations have shown correlations between population declines and proximity to agricultural lands. Pesticides are receiving increasing attention as a potential cause of amphibian declines, acting singly or in combination with other stressors. This study focuses on the potential exposure and accumulation of pesticides in pond-breeding frogs collected from 11 sites in Northern California. Water, sediment and frog tissue were analyzed for over 90 current-use pesticides and pesticide degradates including 34 fungicides by using gas chromatography mass spectrometry. Eighteen pesticides were detected in water and sediment samples. The herbicide, glyphosate, and its primary degradate, AMPA, were detected most frequently (11 and 15 %, respectively) and at the highest concentrations in water while fungicides, such as tebuconazole and pyraclostrobin, were most frequently found in sediment (40 % detection frequency). Preliminary results suggest that amphibians are exposed to a variety of pesticides in both water and sediment and fungicides represent a substantial portion of the potential pesticide exposure. Tissue analysis is ongoing; however, previous studies report detections of organophosphate insecticides including chlorpyrifos in amphibians collected from similar sites in Northern California. Limited information is available on the accumulation of pesticides and pesticide degradates, particularly fungicides, in amphibians as well as the degree to which these agents may be playing a role in the loss of amphibians worldwide.

WP055 Assessment of the Endocrine Toxicity of the Fungicide Prochloraz Using the Larval Amphibian Growth and Development Assay A. Olmstead, US Environmental Protection Agency, Mid-Continent Ecology Division; L. Blake, P. Kosian, J. Haselman, J. Korte, R. Johnson, C. Blanksma, K. Lillegard, S. Zavodnik, B. Heggestad, S. Degitz, US Environmental Protection Agency. Prochloraz is a broad spectrum fungicide that acts by inhibiting ergosterol biosynthesis in target species. Toxicity results

in non-target vertebrate species suggest this toxicant acts as an endocrine disruptor that inhibits aromatase, the enzyme responsible for the conversion of androgens into estrogens. We used the Larval Amphibian Growth and Development Assay, a Tier II test in the USEPA's Endocrine Disruptor Screening Program to examine the effects of prochloraz on the model amphibian species, Xenopus laevis. Larval X. laevis were exposed from just after fertilization until nine weeks after completion of metamorphosis in a flow-through diluter system. Exposed animals were assessed at completion of metamorphosis and at the end of the exposure for endocrine-related endpoints as well as general measures of toxicity. No effects on mortality, growth, or metamorphosis times were observed. Using genetic sexing, no sex reversals among exposed individuals were observed. Both females and males had reduced liver somatic indices at exposure concentrations of 60 and 180 µg/L respectively. Exposure to prochloraz concentrations of 60 µg/L and above resulted in very low, but significant induction of circulating vitellogenin. Observed effects indicate that prochloraz has some endocrine activity, however, these effects are different from those observed with the pharmaceutical aromatase inhibitor, fadrozole, suggesting that prochloraz is eliciting these effects with a different mode of action. In addition, these results illustrate the utility of the Larval Growth and Development Assay to evaluate endocrine toxicity of toxicants.

WP057 Preliminary Histological Examination as a Means to Evaluate the Effects of Aqueous Pine Extract of Virginia Pine on African Clawed Frogs L. Minton, J. Rayburn, M. Hamissou, G. Cline, Jacksonville State Univ, Biology Dept. Estrogenic compounds are introduced into the habitats of amphibians through a multitude of mediums, the majority of which are influenced or created due to human actions. Couple the reliability of amphibians as indicators with the ease to which they are exposed and the model genus of *Xenopus* becomes important test organisms for a wide array of environmental problems. Some naturally occurring estrogens found in the environment as compounds in some pine trees have been determined to cause estrogenic changes in fish and other organisms. For our test, we exposed groups of *X. laevis* in tanks to concentrations of aqueous pine tree extract (from Virginia Pine, *Pinus virginiana*). The long-term exposure experiment lasted 3.5 months, with individuals being exposed from 96hrs after fertilization until they were at approximately NF stage 64-66 (at metamorphosis), including the stage of gonadal differentiation. Once they reached this stage of development they were removed from the tanks, anaesthetized and fixed in formalin to await histological procedures. Dosages of the pine tree extract were administered on a biweekly basis using test concentrations of differing percentages (1% – high, 0.5% – low), and throughout the experiment, the frogs were kept in covered 20L tanks with a controlled temperature range of 25-29° Celsius. Effects from this pine tree extract were examined using time to metamorphosis, malformations, mortality, and histological observations. Treated individuals were compared to subjects in the positive control groups (exposed to estrogen) and negative control (no treatment). The study is focused on determining potential gonadal abnormalities caused by pine tree leachate exposure. These evaluations will focus on the testes and the ovaries, and will be examined using histological slides, staining, and light microscopy.

WP058 Battle in the Bucket: Competitive Interactions Among Invasive Mosquitoes and Implications for the Potential Spread of Infectious Disease M.K. Trawick, C.J. Salice, Texas Tech Univ, Dept of Environmental Toxicology. Invasive species cause significant ecological and economic damage and, in some cases, can represent a more direct risk to humans as vectors of infectious disease. Probabilistic risk assessments represent a cost effective and useful tool for maximizing resource allocation by policy makers and public health officials to minimize damage caused by invasive species. Mathematical models of ecological processes can help refine empirical studies by elucidating critical field parameters and can point to population level consequences of stage-specific management action. Additionally, well constructed models can assist in predicting how ecological interactions such as competition might change in novel locations or conditions, such as those predicted by climate change forecasts. Mosquito-borne zoonoses contribute to significant morbidity and mortality in developing nations, and have been predicted to increase their prevalence within the United States in the near future. The invasive mosquito *Aedes albopictus* competes with the major Dengue fever vector *Ae. aegypti* in the larval stage of development. Hence, ecological interactions among these species have important consequences for public health. To gain further insight into mosquito population dynamics and competitive interaction, we designed a stage-specific discrete time mathematical simulation model that takes into account larval competition between these two species. Based on the projection matrix framework with five distinct live life stages and a two-day timestep, density dependence functions operate in two larval stages. Our modeling results support those of others in which mosquito population dynamics are driven strongly by the larval period. Additionally, our results indicate that species persistence is sensitive to the average larval survivorship and the magnitude to which species impact each other. Some research suggests that differential egg mortality under changing climatic conditions could explain the persistence of the inferior competitor *Ae. aegypti*, and we are currently incorporating this into the model. Furthermore, pesticide exposure has been shown to impact competitive interactions between invasive mosquito populations. To that end, we will supplement our model with empirical studies of the effects of target and non-target pesticides. The model presented in this abstract will ultimately be combined with forecasted climate change models to identify areas of high concern of disease transmission.

WP059 Understanding the Spread of Invasives: Using Functional Traits to Guide Assessment and Management Efforts of Nonindigenous Species C.J. Salice, Texas Tech Univ/TIEHH, Environmental Toxicology, Assistant Professor, Texas Tech Univ; S. Weir, Texas Tech Univ, The institute of environmental and human health; L. Beaty, Texas Tech Univ, Dept of Biology. Invasive species are a significant threat to ecological systems and the economy worldwide. Hence, there is a need to develop methods to identify, evaluate and reduce risks of invasion. Although the ecological risk assessment process has traditionally focused on chemical pollutants, there are elements that can be adapted to invasive species risk assessment. In particular, trait-based assessments may be well suited to evaluating risks associated with the spread of nonindigenous species. In effect, species' traits determine their invasion potential and success. Broadly, invasive species possess traits that (1) allow for enhanced growth and exploitation of resources and/or (2) allow for persistence under stressful conditions. By understanding which functional traits are characteristic of particular noninidigenous species, we may be better able to control invasions. Here, we present two case studies in which we evaluated the traits of different invasive species as part of ongoing risk assessments for both. The invasive red-rimmed melania, *Melanoides tuberculatus* is a slow-growing freshwater gastropod that is among the most invasive mollusks. We showed that this species is significantly more tolerant than native gastropods to a wide range of chemical and physical stressors imparting an advantage, especially in anthropogenically impacted sites. These data suggest that defensive traits may favor the invasion potential of *M. tuberculatus* but also provide insight into potential areas to which this species could spread. Alternatively, high reproductive and growth rates in cane toads, *Rhinella marina*, are clear contributors to the spread of this species in Australia. We used a series of stage-based and individual-based population models to explore the life history mechanisms by which this species obtains high population size and further used the models to help identify optimal control strategies. Control techniques that reduced survival of young toads had favorable management outcomes. In this case, identifying control strategies that target key traits (juvenile growth) likely have the strongest beneficial effect. We discuss the potential for both of these species to exert negative ecological effects and explore potential next steps in the risk assessment process. These examples highlight the potential utility of trait-based approaches in invasive species risk assessment and are congruent with other approaches such as the relative risk model.

WP060 Application of a Biodiesel Co-product to Control Apple Snail: Acute Toxicity and Active Compound Identification D. Deng, Oceanic Institute, Aquatic Feeds and Nutrition Dept; Z. Ju, W. Dominy, Oceanic Institute; A. Moriwake, E. OHara, Pacific Biodiesel, Inc.; P. Mosher, Pacific Biodiesel Technologies; P. Levin, The Hawaii Land Restoration Institute. Apple snail (Pomacea canaliculata) is one of the 100 worst global invaders affecting wetland crops in 18 countries. In Hawaii, the invasion of apple snails causes 18-25% annual reduction in taro crop yields and a two-fold increase in farm labor. There is still no cost effective and environmentally safe approach protecting wetland crops from this destructive pest. A previous preliminary field test showed that a biodiesel co-product, unrefined glycerin used as a soil conditioner, had caused significant mortality in apple snails. Therefore, we propose a novel approach to control apple snails by using the unrefined glycerin co-product. The objectives of this study were 1) to determine the lethal concentration (LC) of the unrefined glycerin on the

apple snail; 2) to categorize the major components of the unrefined glycerin; 3) to identify the active compound causing mortality in apple snails. The acute exposure tests were conducted in 3L beakers placed in a water bath at 25_C. There were three replications per treatment and 10 apple snails per replicate. Results of this study showed that the LC50 of the unrefined glycerin co-product for apple snail was 1.59, 0.77, 0.62 and 0.60g/L for 24, 48, 72 and 96 hours of exposure. The major compounds in the co-product used for the exposure test was methanol (27.0%), glycerin (25.3%), potassium soaps (26.0%), water (11.3%), and other salts and fatty acid methyl esters (10.7%). Potassium oleate was suggested to be a major candidate active compound in the unrefined glycerin. The pure glycerin, methanol and potassium singularly, or in combination, did not affect mortality under the test conditions used, suggesting they are not the active compounds causing mortality of apple snails. Other compounds, such as potassium soaps of different fatty acids, may also be active compounds but are not expected to be the major factor causing mortality of the apple snails. This remains to be investigated in the future. Result of this study suggested potential use of the unrefined glycerin co-product to eradicate the apple snails. Further studies, however, will be needed to test the impact of the biodiesel co-products on non-target species (other invertebrate, fish, ducks, etc.) inhabiting the same environment. Furthermore, chronic effect of the co-product will be studied in order to address issues regarding environmental sustainability and safety.

WP061 Adaptive Management of Invasive American Bullfrogs (Rana Catesbeiana) in the South Okanagan Valley, Canada N. Lukey; S. Ashpole, Univ of Waterloo; S. Murphy, Univ of Waterloo, Environment and Resource Studies; S. Murphy, Univ of Waterloo, Dept of Environment and Resource Studies. American Bullfrogs, Rana catesbeiana, are known to significantly and negatively impact ecosystems. Alien bullfrogs out-compete, predate upon, and transmit diseases to native amphibians. Accidentally introduced in the 1950's to the South Okanagan Valley, British Columbia, Canada, bullfrogs in recent years have been detected in 5 wetlands. We developed a three-tiered, adaptive management system in response to the bullfrog threat. The first management tier is physical removal of, and active monitoring for, bullfrogs of all stages. Removal has resulted in significant reduction in bullfrog detections from a high of 73 adults and/or juveniles in 2005 to 4 adults and/or juveniles in 2010. The second management tier assesses the risk level for future colonization or recolonization post-removal. We are using maximum entropy habitat suitability modeling in conjunction with effort analysis to determine the proportion of wetlands vulnerable to recolonization post-removal efforts, and how much human and financial resources are required for continual population suppression. The third management tier incorporates stakeholder awareness and education to facilitate monitoring of bullfrog populations. In 2010, we distributed surveys to 4 stakeholder groups to measure each group's level of bullfrog knowledge and their presence, identification, and reporting. We targeted 1) grade-school teachers, 2) landowners adjacent to at-risk or infected wetlands, 3) businesses that may act as vectors, and 4) the general public who use infected or at-risk bullfrog locations for recreation. The majority of all surveyed groups were aware of bullfrog presence, however, 50 % of landowners, 84 % of vector businesses, 50 % of teachers, and 91 % of the general public were not confident with identifying and/or reporting bullfrogs. The survey results indicate that the general public and vector businesses are greater at-risk stakeholders than teachers and landowners, and education programs need to focus on bullfrog identification and reporting avenues. Success of the stakeholder awareness and removal phases, combined with the habitat suitability model and effort analysis will ensure the long-term suppression and possible eradication of bullfrog colonies in the South Okanagan. This three tiered management system provides a strong example of a successful invasive species risk assessment and management approach to other vertebrate invasions throughout the world.

WP062 A Risk Assessment of the Cuban Treefrog (Osteopilus septentrionalis) Invasion in Florida K. Rouse Campbell, ENVIRON International Corporation, Manager, ENVIRON International Corp, Manager; T.S. Campbell, Univ of Tampa, Dept of Biology; A.J. Smith, ENVIRON International Corp. Since their initial introduction into the Florida Keys in the 1930s, Cuban treefrogs (Osteopilus septentrionalis) have spread rapidly throughout peninsular Florida. While Cuban treefrogs have been shown to represent a threat to native wildlife and ecosystems, few prospective assessments have been conducted on their effects on natural systems. Using the Trinational Framework for Aquatic Alien Invasive Species, data from a long-term investigation in West-Central Florida were integrated with the literature to conduct a Cuban treefrog risk assessment. Factors evaluated to determine the probability of establishment included entry potential, colonizing potential, and spread potential, while factors assessed to evaluate the consequences of establishment included environmental impacts and risks to native treefrogs. Spatial factors that were considered in the risk assessment included the rate of spread of the Cuban treefrog invasion, how Cuban treefrogs invade new aquatic systems, projected potential Cuban treefrog distribution under future global warming scenarios, and their preferred habitats. Temporal factors included the timing of their invasion and whether tadpoles, adults, or both life stages affected native wildlife. Important life history factors considered included the rapid growth of Cuban treefrogs, the large number of eggs laid by females, the large size of females, and the fall spread of adult treefrogs to areas distant from the site of egg/tadpole development. The results of the risk assessment indicated that both the probability of establishment and the consequences of establishment of the Cuban treefrog were high.

WP063 A Methodology to Evaluate the Economic Impacts of the Cuban Treefrog (Osteopilus septentrionalis) Invasion in Florida M. McKenzie, ENVIRON International Corp.; K. Rouse Campbell, ENVIRON International Corporation, Manager, ENVIRON International Corp, Manager; G. Greene, ENVIRON International Corporation, Ecology & Sediment Mngmt. The Cuban treefrog (Osteopilus septentrionalis) was initially introduced into the Florida Keys and has spread northward up the Florida peninsula. Though a recent assessment has evaluated the ecological effects of this invasive treefrog on natural systems in Florida, no assessment has examined its economic impacts. Using the Trinational Framework for Aquatic Alien Invasive Species, we developed a methodology to evaluate the economic impacts of the Cuban treefrog. Three anecdotal economic effects of this species were identified. For each, a methodology was developed for attempting to collect data useful for assessing the Cuban treefrog's economic impacts. The effects examined included: 1) the impact of the species on the exotic pet trade; 2) effects on public health due to hypersensitivity reactions in humans who handle Cuban treefrogs; and 3) the impacts on power companies and utility customers associated with power outages and repairs resulting from Cuban treefrog intrusion into electric equipment. Evaluating effects of the Cuban treefrog on the exotic pet trade included contacting pet store managers and online exotic pet dealers, who were administered a set of questions regarding the sales and distribution of the animal. Evaluating the effects of the Cuban treefrogs on public health included contacting emergency rooms, county health Depts, and poison control centers in Central and South Florida to determine the incidence of reported severe allergic reactions. Lastly, a methodology was developed for acquiring data from power companies in Central and South Florida; Environmental Specialists or Operations personnel at electric power companies were contacted and questioned about power outages caused by treefrogs' intrusion into electric equipment. Preliminary results suggest ways to move forward with quantifying the most critical of economic impacts.

WP064 Ecological and Socioeconomic Risks of Japanese Eelgrass and Its Control with Imazamox Treatment J.P. Fisher, ENVIRON International Corporation, Principal--Sediment and Ecology Management Practice, ENVIRON International Corporation, Principal; K. Patten, Washington State Univ. While ecological functions and benefits can be prescribed to virtually all species, including non-native invasive species, the habitat and biological community changes that result from the establishment and spread of invasive species can adversely impact native species, and the socioeconomic fabric of local communities where invasions become problematic. In Washington State, Japanese eelgrass, *Zostera japonica*, introduced in the 1950's, has expanded aggressively over the past decade in coastal embayments of Washington and is expanding in portions of Puget Sound. Japanese eelgrass is not considered a noxious weed by Washington State, however, it has been associated with altered ecological functions where it has established and created conflicts in shellfish growing regions where it was not formerly present and/or prevalent. Risk assessments summarized in this presentation were conducted to consider both its ecological and socioeconomic impacts as an invasive species using Aquatic Nuisance Species Task Force guidelines, and the ecological risks from the use of the herbicide imazamox to control the species on shellfish growing areas. Adverse socioeconomic and ecological impacts to shellfish production were identified from measurements of clam recruitment and production, and benthic infauna richness on untreated

relative to treated beds. Potential effects from herbicide treatment on non-target organisms were evaluated using a food web model to explore potential exposure and effect. Based on experimental applications, imazamox appears non-persistent with a high margin of safety for asserting potential adverse effects on non-target organisms. Native eelgrass, *Zostera marina*, however, can be adversely affected from herbicide treatment, and alternative control mechanisms may need to be considered where the two species overlap. In areas where no eelgrass is found, however, Japanese eelgrass may provide habitat diversification and associated benefits. Thus, management of the non-native species represents a challenging natural resource management paradox in that protections historically afforded the species run counter to eradication and control recommendations specified under the National Invasive Species Management Plan, yet its establishment in otherwise unvegetated aquatic habitat could be interpreted to provide a surrogate for native eelgrass that has been reduced in some areas where historically present.

WP065 Using Solid Phase Microextraction to Predict Body Residue and Toxicity of Hydrophobic Pesticides Y. Ding, P.M. Landrum, Southern Illinois Univ; J. You, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy Sciences, State Key Laboratory of Organic Geochemistry; M. Lydy, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology. For solid phase microextraction (SPME) to be successfully used in risk assessment, a relationship linking contaminant accumulation, toxicity in biota, and accumulation in the SPME fiber must be established. In our study, the bioaccumulation and toxicity of seven hydrophobic compounds were measured in the midge *Chironomus dilutus* larvae and amphipod *Hyalella azteca* in water-only static exposures. The seven compounds included an organochlorine pesticide dichlorodiphenyltrichloroethane (*p,p'*-DDT), and its major degradation products, dichlorodiphenyldichloroethane (*p,p'*-DDD) and dichlorodiphenyldichloroethylene (*p,p'*-DDE); an organophosphate pesticide, chlorpyrifos; and three pyrethroid insecticides, permethrin, bifenthrin, and tefluthrin. The accumulation and kinetics of the target compounds were also determined for disposable polydimethylsiloxane (PDMS) fibers. Median lethal concentration estimates based on water concentrations (LC50), measured organism concentrations (LR50), and PDMS fiber concentrations ($LC50_{fiber}$) were determined for each compound and species. The relationship of total contaminant concentrations in biota (C_b) against concentrations in PDMS fiber (C_f) showed significant log-log linear relationships across compounds and species, regardless of whether the fiber concentration was measured after a fixed exposure time ($C_{f\,4d}$, R^2=0.80, p< 0.0001) or at equilibrium condition ($C_{f\,eq}$, R^2=0.92, p< 0.0001). A significant log-log relationship was also found between $C_{f\,4d}$ and $C_{f\,eq}$, and $\log C_{f\,eq} = 0.99 \log C_{f\,4d} - 2.21$ (R^2=0.86, p< 0.0001). These results demonstrated that the measured chemical concentrations in SPME fibers were correlated to the total body residue in biota and could predict exposure and therefore the toxicity of pesticides in a water medium.

WP066 Predicting the Toxicity of Permethrin to *Daphnia magna* in Water Using SPME Fibers A.D. Harwood, Southern Illinois Univ, Zoology, Southern Illinois Univ; A. Bunch, Southern Illinois Univ; J. You, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy Sciences, State Key Laboratory of Organic Geochemistry; M. Lydy, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology. The multiple factors influencing bioavailability can make predictions of toxicity in natural systems difficult. The current study examined the potential use of solid phase microextraction (SPME) fibers as a matrix-independent approach to predicting the toxicity of permethrin to *Daphnia magna* across various water sources including a laboratory reconstituted water, two natural waters, and a modified natural water. Water source strongly affected the toxicity of permethrin as well as the concentration response relationships. While permethrin concentrations in the water predicted toxicity to *D. magna* for individual water sources, there was no relationship between permethrin concentrations among water sources and mortality. This indicates that differences among water sources can greatly influence toxicity, suggesting that benchmarks established using reconstituted water may be overly conservative. Additionally, while tissue residues could predict mortality for individual waters, the correlation among waters was not as clear. Finally, both 48 h and equilibrium-based SPME fiber concentrations could adequately predict toxicity independent of water properties. This demonstrates that bioavailability-based estimates provide a more accurate prediction of toxicity than water concentration and that SPME fibers could be utilized in environmental monitoring as a rapid, accurate means of predicting toxicity in natural waters.

WP067 Accumulation of PCBs in Passive Samplers and Biota: Field Data Analysis K. Maenpaa, M. Leppanen, Univ of Eastern Finland, Dept of Biology; P. Mayer, Aarhus Univ, Dept of Environmental Chemistry and Microbiology; K. Figueiredo, Univ of Eastern Finland, Deprtment of Biology; J. Akkanen, A. Kostamo, Univ of Eastern Finland, Dept of Biology; S. Herve, Finnish Environment Institute, Research and Innovation Laboratory. The scope of this study is to apply equilibrium sampling techniques to determine PCB concentrations in the aquatic environment, and to investigate the use of these methods for bioaccumulation research. The study also aims to determine the leak of PCBs downstream from the sediment of the highly contaminated lake. In 2010, polyethylene and silicone samplers were exposed for several months in the water column of the contaminated lake and along its discharge course. The samplers were measured for PCBs at several time points during the study period of six months. Sediment at each sampling site was collected and analyzed for PCBs with traditional exhaustive extraction, and also with the equilibrium passive sampling method to determine freely dissolved pore water concentrations. In addition, uncontaminated mussels were caged for two months in the water column in the contaminated lake, and native mussels also were collected from the lake sediment. Furthermore, phytoplankton was collected from the Lake water column. All of the biota samples were analysed for several PCB congeners and total lipids. The concentrations in the passive samplers were converted to lipid based concentrations and compared to the actually measured values in the organisms. The both passive sampling devices were found to be applicable to measure PCBs from the water column yielding close to similar results of the freely dissolved concentrations. Theoretical concentrations in lipids derived from passive samplers will be compared to the concentrations measured in biota.

WP068 Bioavailable Contaminant Mixtures and Toxic Effects: Using Passive Sampling and the Embryonic Zebrafish Model to Bridge Exposure and Effects S.E. Allan, Oregon State Univ, Environmental and Molecular Toxicology, Oregon State Univ, Graduate Researcher; B. Smith, Oregon State Univ, Environmental and Molecular Toxicology; K. Waters, Pacific Northwest National Laboratory; K.A. Anderson, Oregon State Univ, Environmental & Molecular Toxicology. The BRIDGES bioanalytical tool, which links passive sampling with the embryonic zebrafish developmental toxicity model, was developed in response to the need for methods that examine the toxicity of environmentally relevant complex mixtures. Passive sampling devices (PSDs) sequester and concentrate the freely dissolved, and therefore bioavailable fraction of hydrophobic organic contaminants, mimicking key bioconcentration mechanisms. PSD samples can be chemically analyzed as well as applied to bioassays. The embryonic zebrafish model is a widely utilized vertebrate organism bioassay. Lipid free tubing, low density polyethylene PSDs were deployed at nine different sites within, upstream and downstream of the Portland Harbor Superfund site on the Willamette River in Portland, OR for multiple 30 day periods in 2009-2010. Paired samplers were deployed at each site to obtain samples for chemical analyses and bioassays. Samples were analyzed for unsubstituted, methylated and oxygenated polycyclic aromatic hydrocarbons and screened for over 1200 chemicals of concern using Deconvolution Reporting Software (Agilent Technologies). The bioassay samples were applied to the embryonic zebrafish model. Dechorionated embryos were maintained in a static exposure solution for 5 days. Approximately 48 embryos were individually exposed to each of four concentrations of PSD extract solution from each site and sampling period. Observations of mortality and morphological endpoints were made at 1 and 5 days. Significant differences in chemical concentrations and profiles were observed between sites both within, and outside of the Superfund area. Furthermore, there were significant temporal differences, associated with seasonal changes in temperature and river flow. Significant differences in the rates of lethal and sub-lethal toxic effects were observed in zebrafish embryos exposed to PSD extracts from different sites and sampling times. Additionally, a significant dose response was observed. The BRIDGES tool proved to be sensitive to differences in toxicity between sites and times. Modeling was carried out to elucidate associations between chemicals present in the PSD samples and toxic responses observed in the exposed embryos. Suites of bioactive chemicals within the complex mixtures were identified and there was evidence of additive and synergistic toxic

effects. Furthermore, associations between specific chemicals in the mixture and developmental malformations were detected.

WP069 Polyoxymethylene (POM) Passive Sampling Method for Measuring Pg/L Freely -Dissolved Aqueous Concentrations of Parent and Alkyl PAHs (PAH-34) S.B. Hawthorne, Univ of North Dakota, Energy & Environmental Research Ctr; M.T. Jonker, S.A. van der Heijden, Utrecht Univ, Institute for Risk Assessment Sciences; C.B. Grabanski, Univ of North Dakota, Energy and Environmental Research Center; N.A. Azzonlina, Carnegie Mellon Univ, Civil and Environmental Engineering; D.J. Miller, Unversity of North Dakota, Energy and Environmental Research Center. Passive sampling with non-depletive sorbents is receiving increasing interest because of its potential to measure freely-dissolved concentrations of hydrophobic organic compounds (HOCs) at very low concentrations, as well as its potential for both lab use and field deployment. However, consistent approaches have yet to be developed for the majority of HOCs of environmental and regulatory interest. In the present study, a passive sampling method was developed which allows the freely-dissolved concentrations of 18 parent and 16 groups of alkyl polycyclic aromatic hydrocarbons (PAHs) on the EPA's "PAH-34" target compound list to be measured. Commercially-available 76 µm thick polyoxymethylene (POM) was placed in sediment/water slurries and exposed for up to 126 days, with 28 days found to be sufficient to obtain equilibrium among the sediment, water, and POM phases for the target 2- to 6-ring PAHs. In addition to measuring KPOM values for parent PAHs, since the so-called "16" alkyl PAHs on the PAH-34 list actually include several hundreds of isomers for which no standards exist, sediments impacted by coal tar, or spiked with a coal tar/petroleum non-aqueous phase liquid (NAPL) were also used to measure KPOM values for each alkyl PAH cluster. Log KPOM values ranged from ca. 3.0 to 6.2 for 2- to 6-ring parent PAHs, and correlated well with SPARC octanol/water coefficients (KOW) (r2 = 0.986). However, log KPOM values for alkyl PAHs deviated increasingly from SPARC log KOW values with increasing degree of alkylation. A simple empirical model that incorporates the number of carbon atoms in a PAH gave a better fit to the experimental log KPOM values, and was used to estimate log KPOM for alkyl PAHs that could not be directly measured. Detection limits (as freely-dissolved concentrations) range from ca. 1 part per trillion (ng/L) for the 2-ring PAH naphthalene, down to < 1 pg/L (part per quadrillion) for the 5- and 6-ring PAHs. Sorption isotherms were linear (r2 > 0.99) over at least 4 orders of magnitude. KPOM values determined independently in two laboratories (one using contaminated sediments and one using pure compounds) for several parent PAHs and PCB congeners agreed well, thus supporting the use of the commercially-available 76 µm POM and a "standard" set of KPOM values for regulatory investigations.

WP070 Passive Dosing Under the Microscope – Producing Gradients of Hydrophobic Organic Chemicals D. Gilbert, S.N. Schmidt, A. Winding, P. Mayer, Aarhus Univ, National Environmental Research Institute. The environmental chemodynamics of hydrophobic organic chemicals (HOCs) are often rate limited by their diffusive mass transfer through stagnant boundary layers (SBL). This then results in concentration gradients on the microscale, which are crucial for both diffusive mass transfer phenomena and the chemotaxis of motile cells and organisms that are able to sense chemical signals. We present here a new experimental setup where passive dosing is employed on microscope slides, allowing for the direct visualisation of cell behaviour under tightly controlled exposure conditions. We produced microgradients of HOCs by partitioning between a loaded and clean polymer. Silicone O-rings were placed in a Dunn chemotaxis chamber whereby an outer clean ring served as a sink and a loaded inner ring as source imposing a gradient over the distance of a 1mm bridge between the rings. The gradients were well defined and remained highly stable over extended periods of time, which was confirmed by quantitative measurements. The new experimental system offers the unique possibility to study both chemotaxis of prokaryotic and eukaryotic cells exposed to gradients of chemical activity and mass transfer phenomena of HOCs.

WP071 Incorporation of Passive Sampler and Active Biomonitoring for Assessing the Impacts of Complex Metal Pollution in Maluan Bay of China Z. Wang, Institute of Urban Environment, Chinese Academy of Sciences, Key Laboratory of Urban Environment and Health. The development and implementation of effective remedial measures depends on our ability to predict the fate and biological effects of pollutants in aquatic systems. To obtain a more complete picture of impacts of metal pollutants released into Maluan bay and its surrounding environments and achieve a more holistic understanding of their mechanisms on coastal marine organisms, the biomarker responses of critical tissues of indigenous clams *Ruditapes philippinarum* (digestive glands) and shrimps *Litopenaeus vannamei* Boone (hepatopancreas) were determined after 7 days in situ exposure or under laboratory conditions, which included the xenobiotic metabolizing phase II enzyme responses glutathione S-transferase (GST) and antioxidant enzymes involving in detoxifying reactive oxygen species such as superoxide dismutase, catalase and glutathione peroxidase. Moreover in order to determine the bioavailability and bioaccumulation of metal contaminants, along with active bio-monitoring of clams and shrimps, passive samplers of diffusive gradient in-thin film (DGT) were simultaneously deployed to accumulate dissolved metals in a controlled fashion, while synchronously quantifying the mean contaminant concentrations in surface water of the device, besides through the conventional methods such as measuring water quality parameters and metal contaminant levels in water columns. In this presentation, concentrations taken-up by the passive samplers will be compared to conventional methods and tissue concentrations accumulated by clams and shrimps, which showed that DGT may be able to more accurately assess the performance than other analytical techniques because of its ability to mimic the uptake of metal contaminants by biota, and innovative passive sampler technologies can be used to monitor contaminated sites and estimate metal contaminant bioavailability. Furthermore, results in this investigation also suggested that the incorporation of critical tissue residue analysis with a battery of the activity of biomarker responses in organisms after in situ cage exposure can be used as an appealing tool of active biomonitoring for assessment of metal pollution in marine coastal ecosystems. In sum, experiences from Maluan bay may be valuable for environmental management and risk assessment at contaminated sites of similar environment scenarios. (The author gratefully acknowledges the support of KC Wong Education Foundation, Hong Kong.)

WP072 Linear Solvation Energy Relationship Models as Classifiers for the Identification of Unknowns in Environmental Samples U. Nadin, Helmholtz Centre for Environmental Research UFZ; W. Brack, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis, UFZ Centre for Environm. Research, Dept of Chemical Ecotoxicology. The identification of unknown substances in complex environmental mixtures plays an important role in effect-directed analysis (EDA). Our approach for the identification of unknowns is based on the generation of possible structures followed by the progressive exclusion of structures that do not match experimental chromatographic and spectroscopic behaviour sufficiently. Models such as the linear solvation energy relationships (LSERs) have been applied successfully in the past to differentiate structures and retention behaviour with greater accuracy than retention indices in liquid chromatography (LC). The aim of this study is to develop a method to derive retention estimates from the proposed structures using LSERs in order to reduce the number of candidate structures in EDA. This approach focuses on the determination of the hydrophobicity index CHI using gradient elution in liquid chromatography on a capillary LC system. By prediction of CHI for candidate compounds by the LSER model and comparison to measured values of unknowns, the number of possible structures can be reduced.

WP073 Towards a Community Driven Open Access Accurate Mass Spectral Database for the Identification of Environmental Contaminants T. Schulze, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis; S. Emma, Helmholtz Centre for Environmental Research UFZ, Effekt-Directed Analysis, EAWAG – Swiss Federal Institute of Aquatic Science and Technology; N. Steffen, Leibnitz Institute of Plant Biochemistry, Dept for Stress and Development Biology; C. Hug, C. Gallampois, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis; M. Krauss, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis, Helmholtz Centre for Environmental Research, Effect-Directed Analysis; J. Slobodnik, Environmental Institute; W. Brack, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis, UFZ Centre for Environm. Research, Dept of Chemical Ecotoxicology. A recent focus of organic environmental chemistry is nontarget screening and identification of transformation products and unknown compounds in water, soils, sediments and biological samples. Improvements in the analytical technology by accurate and multidimensional mass spectrometry (e.g., ToF-MS, QToF-MS, FT-MS, Orbitrap) in combination with liquid

chromatography and soft ionization techniques allows the analysis of a broad range of polar compounds and the restriction of the elemental composition in many cases to one or few formulae. In contrast to the large GC-EI-MS spectral databases, databases containing accurate mass spectra contain up to now relatively few spectra and are not yet widely used, as these lack many compounds relevant for environmental samples. One obstacle is the limited comparability of mass spectra generated with different MS techniques, ionization and fragmentation settings as compared to quite reproducible EI-MS spectra. However, mass spectra from different instruments share similarities if well defined experimental conditions are used for all instruments [1]. The motivation of our research is to improve the identification of unknowns in environmental samples using a common and open access mass spectral database including MS data from all instrument types and with sophisticated data evaluation tools. The web-based database MassBank (http://www.massbank.jp) was developed within a metabolomics consortium [2] and fulfills the prerequisites to establish a community-driven open access mass spectral database. It allows the storage of a wide variety of spectra from both GC-MS and unit and high mass resolution LC-MS^n. Different tools are available to process the raw data and upload the data to MassBank including a spreadsheet based record editor for the addition of metadata. The NORMAN EMPOMASS MassBank database is hosted by UFZ and can be accessed via the NORMAN website (http://www.norman-network.net) or via the UFZ website (http://www.ufz.de/index.php?en=6598). This project is funded by NORMAN. References: [1] Oberacher, H.; Pavlic, M.; Libiseller, K.; Schubert, B.; Sulyok, M.; Schuhmacher, R.; Csaszar, E. & Köfeler, H. C. WP074 Improvement of a Site Specific Screening by the Application of a Linear Solvation Energy Relationship Model C. Hug, N. Ulrich, Helmholtz centre for environmental research – UFZ, Effect-Directed Analysis; M. Krauss, T. Schulze, Helmholtz centre for environmental research – UFZ; W. Brack, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis, UFZ Centre for Environm. Research, Dept of Chemical Ecotoxicology. For the assessment of waste water treatment plant (WWTP) effluents and their possible impact on benthic organisms in receiving waters, target analysis of a limited number of the most frequently identified compounds in treated waste water and surface water is not sufficient. The investigated WWTP handles mainly sewage from chemical industry facilities and minor shares of municipal waste water and groundwater contaminated by former industrial activities. We compiled a site-specific suspect list of more than 1800 organic chemicals produced in this area. Solid phase extracts of treated sewage were analyzed by a liquid chromatography-high resolution mass spectrometry using a LTQ Orbitrap XL system. Exact monoisotopic masses of suspects were automatically searched by the MZmine software in LC-MS chromatograms in different ionization modes. Chromatographic retention time of the suspects whose exact masses were present as a peak in chromatogram were predicted from structure by a Linear Solvation Energy Relationship (LSER) model. The LSER model was adapted to applied chromatographic conditions. Based on a prognosis interval of 2.6 min in a 21 min gradient, two-thirds of the 300 suspects with present mass were excluded. MS/MS spectra were acquired for the remaining suspects showing peaks fitting to the predicted retention time. MS/MS fragments were compared with data from literature and MS/MS databases. About twenty compounds produced at the site were tentatively identified. A final identification was performed by commercially obtained reference standards. The application of the LSER model improved the exclusion of suspects compared to previous used correlations of parameters as log K_{ow} value and retention time. By the performed data processing several side specific pollutants were identified in an accelerate way.

WP075 Identification of Thyroid Hormone-like Compounds in Polar Bear Plasma by Effect-Directed Analysis E. Simon, BioDetection Systems; J. Bytingsvik, Norwegian Univ of Science and Technology, Dept of Biology; T. Hamers, P. Leonards, J.d. Boer, Institute for Environmental Studies, VU Univ; B.M. Jenssen, Norwegian Univ of Science and Technology, Dept of Biology; J. Aars, Norwegian Polar Institute; E. Lie, The Norwegian School of Veterinary Science, Dept of Food Safety and Infection Biology; M. Lamoree, Institute for Environmental Studies, VU Univ, Chemistry & Biology, Institute for Environmental Studies, Chemistry & Biology. Endocrine disrupting compounds (EDCs) released into the environment may bioaccumulate and biomagnify in the foodchain. Significant concentrations of thyroid hormone-like (TH-like) compounds were found in biological tissue (e.g., in fat and blood) of top predators such as humans and polar bears (Ursus maritimus). This study aims to identify TH-like compounds in plasma of polar bear cubs-of-the-year by Effect-Directed Analysis (EDA). Solid-phase extraction (SPE) followed by liquid-liquid extraction (LLE) was evaluated for known TH-like compounds (hydroxylated polychlorinated biphenyls (OH-PCBs), hydroxylated polybrominated diphenyl ethers (OH-PBDEs), other halogenated phenols (OHPs) and perfluorinated compounds (PFCs)) as well as the less potent non-hydroxylated parent compounds of the PCBs and PBDEs spiked to cow plasma. Good chemically determined recoveries were obtained for the hydroxylated compounds extracted from spiked plasma (>90%) and lower recoveries for PFCs (~60%) and for PCBs and PBDEs (~30%). In the radioligand T4*-TTR binding assay the extracts showed TTR binding potencies which were in good agreement with the calculated theoretical spiking levels. Using the validated method, the polar bear plasma samples were extracted and screened in the T4*-TTR binding assay. Measured TH-like activities were generally higher than the estimated activity based on the measured concentrations of target TH-like compounds. Three samples were selected for further analysis, where the analyzed target compounds could only explain part of the measured TH-like activity, to identify the compounds causing the remaining activity. The selected extracts were analyzed by GC-MS operated in full scan mode and showed relatively simple chromatograms. Therefore, the identification of unknowns causing the unexplained TH-like activity was conducted by accurate mass measurements on GC- and LC-TOF (Time-of-Flight)-MS without further fractionation. In addition, GC-ECNI-MS was carried out to identify chlorinated and brominated known TH-like compounds. The presence of OH-PCBs in the polar bear plasma extracts could be confirmed, as well as the presence of the compounds that had been tentatively identified using the GC-MS screening method. Currently, testing of the biological activity of the analytically confirmed compounds is underway and more in-depth identification of unknown toxicants is scheduled, using high resolution mass spectrometry in combination with both liquid and gas chromatography.

WP076 The Potential of Selective Combinations of Strains of Salmonella to Enhance Mutagenicity Characterization of Air Samples and Guide Chemical Analysis D.K. Alves, USP, FCF; D.A. Morales, UNICAMP, Leal, FT; A.A. Albuquerque, UNICAMP, FT; F. Kummrow, UNIFESP; G.A. Umbuzeiro, UNICAMP, FT, UNICAMP, Professor. Atmospheric particulate matter is recognized as mutagenic and although several compounds have been identified in this matrix, they do not seem to explain the effect observed when the same sample is tested in bioassays. The Salmonella/microsome mutagenicity assay has been largely used for the evaluation of atmospheric samples. It is very sensitive can detect various types of mutagens because it is performed with different strains with and without exogenous metabolic activation (S9). The objective of this work was to verify the applicability of selective pairs of strains of the Salmonella/microsome assay to characterize the mutagenicity of airborne particulate matter collected in a city in the country side of São Paulo State, Limeira, known to be highly polluted because of intense traffic, industrial and agricultural emissions including from sugarcane plantations. We tested six extracts obtained with methylene chloride by ultrasonication using the microsuspension method in the presence and absence of rat liver S9 in dose response experiments, with maximum doses of 50 µg of extractable organic matter (EOM) per plate. The following pairs of strains were used: YG1041/TA98, to verify the presence of nitro-compounds, as 1-nitropyrene and/or aromatic amines, YG5161/TA1538, highly sensitive to non-substituted polycyclic aromatic hydrocarbons (PAHs) as benzo[*a*]pyrene (BaP) and YG7108/TA1535, for the indication of alkylating agents, as ethyl methanesulfonate. The results indicated that the compounds that could explain better the observed effect are the nitro/aromatic amines and not non-substituted PAHs such as BaP. The pair YG7108/TA1535 provided negative responses for all the samples. The comparison of the observed responses for the samples analyzed the mutagenicity profiles of pure compounds found in the literature did not provide any candidates that could alone represent the mixture. More mutagenicity studies with pure compounds using the proposed pair of strains along with chemical analysis of fractioned extracts are needed to verify if this approach can be useful in EDA (effect directed analysis) studies and consequently in

the discovery of new air priority pollutants. Acknowledgements: The authors thank CNPq and Capes.

WP077 Effects-Driven Fractionation of Heavy Fuel Oil to Isolate Compounds Toxic to Trout Embryos J. Bornstein, Queen's Univ, Chemistry, Queen's Univ, Chemistry Dept; J. Adams; B. Hollebone, Environment Canada, Emergencies Science & Technology; P.V. Hodson, Queen's Univ, School of Environmental Studies; R.S. Brown. Recent oil spills have raised many issues about potential harm to aquatic and marine life. For risk assessment, an important question to ask is, "Which compounds in the oil have the potential to cause the most damage, due to both bioavailability and toxicity?" Heavy fuel oils used by large cargo ships and cruise liners are quite thick and viscous, and contain a variety of high molecular weight hydrocarbons, many of which cause acute and chronic toxicity to fish. Due to the high frequency of small volume transports, the risk of a spill of heavy fuel oils is quite high. Thus, it is critical assess the toxic properties of such oils, and to compare them with lighter oils that might be better characterized. A multi-disciplinary approach was used to identify the oil components that are most toxic to the early life stages of rainbow trout. Bunker C (a Heavy Fuel Oil) was fractionated to identify which of its chemical constituents are most closely associated with toxicity to embryonic fish. First, a vacuum distillation apparatus was used to divide the oil into four fractions by boiling point. Based on toxicity testing, fraction F3, the most toxic fraction, and the one containing most polycyclic aromatic hydrocarbons (PAHs), was further separated into fractions rich in asphaltenes, waxes, and PAH, according to their relative solubility in cold solvents (e.g., acetone). The wax precipitation was optimized for solvent, solvent-to-oil ratio, and precipitation temperature. Finally, the PAH-rich fraction (F3-1) was separated by HPLC into sub-fractions by the approximate number of aromatic rings per molecule. For each fraction, GC-MS, GC-FID and fluorescence were used in addition to HPLC to measure PAH and alkyl-PAH concentrations, and toxicity tests with rainbow trout identified which fractions and groups of compounds were associated with acute and chronic toxicity, recognizing physical and chemical properties such as size, shape and Log K_{OW}.

WP078 Advances in Ecological Modeling for Assessing Ecological Risks and Ecosystem Services M. Convertino, Univ of Florida, Agricultural and Biological Engineering; G. Kiker, Univ of Florida; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center. The anthropogenic pressure and climate change often result in species shifts that are broadly categorized as: decline, extirpation, extinction, and population boom. Early warning of population shifts is necessary for efficient environmental management, including adaptive ecosystem management in which monitoring plays a big role. We propose a new analytical model for predicting shifts of species coupling space-time patterns.A model based on a 2-D lattice for a bird guild tested the theory here introduced. The probabilistic risk model uses the abundance of the species considered that is one of the outputs of common metapopulation models. Early-warning classical signals of shifts are the variance and the autocorrelation of the abundance of a particular species. The fractal dimension was introduced as a more meaningful early-warning signal combining the autocorrelation and the variance of the abundance in space and time. In order to capture the shift the fractal dimension has been monitored in time for minimum 3 species generations. Shifts produce change in the spatial configuration of species, e.g., transitions from random to clustered patterns and viceversa.The species risk at-a-point has been defined as the expected probability of shift occurrence (hazard) of a given intensity which takes place in a certain area within the landscape at a given time. We calculate the total risk for all the predicted shift occurrence (exposure), that is thereby representative of the sum of all the risk at-a-point. We assume a power-law model of damage for the ecosystem (vulnerability) that is a function of the lost/gained species abundance and the species-dependent threshold of decline and extinction.The model is promising for testing the response of different species under varying degrees and types of exogenous stress (e.g., climatic, toxicological) and anthropic interventions possibly aiding decision-making for ecosystem adaptive management policies.

WP079 An Individual-Based Model for Extrapolating Standard Toxicity Test Data into Population-Level Adverse Outcomes in the Fathead Minnow A. Olmstead, US Environmental Protection Agency, Mid-Continent Ecology Division; M. Etterson, R. Bennett, D. Hoff, J. Hoffman, R. Johnson, P. Schmieder, US Environmental Protection Agency. While environmental toxicity testing typically focuses on organism-level endpoints such as mortality, growth, and reproduction, risk assessment guidelines specify protection goals at the level of the population and above. One method of linking these different levels of biological organization is the development of models that extrapolate toxicant impacts at the individual level to adverse outcomes at the population level. However, annual population growth projections in highly fecund species such as fathead minnow are subject to extreme uncertainty. We have developed an individual based model for the fathead minnow that integrates adverse effects of stressors on individual growth, reproduction, and survival over a single breeding season using toxicity data inputs from standard toxicity tests such as the early life stage and full life cycle assay. The model uses a daily time step and projects the size-distribution of the population at freeze-up, which is a reliable indicator of the over-winter potential of a fathead minnow population. Specific model outputs are population biomass, census, and size structure. Exposure inputs allow for varying the timing of the exposure in order to compare the effects of various temporal patterns of contamination. Advantages of this type of modeling framework are the ability to introduce greater realism, including density-dependent factors. Data outputs are amenable to long-term, multi-year population modeling if sufficient data on overwinter survival exists.

WP080 Improving Population Models for Assessing Pesticide Risks to Pacific Salmon R. Pastorok, B. Parks, D. Preziosi, Integral Consulting, Inc. Under Endangered Species Act (ESA) consultations supporting Federal Insecticide Fungicide and Rodenticide Act assessments, the National Marine Fisheries Service (NMFS) issued several biological opinions (BiOps; 2008-2010) that evaluate risks of certain organophosphate (OP) and carbamate pesticides to Pacific salmon. Population modeling was one approach NMFS used to evaluate the potential effects of pesticides on salmon. We present a critique of these population models and their application in the BiOp for OPs to illustrate problems that may arise when applying such models in an environmental regulatory context. NMFS developed density-independent population matrix models to estimate changes in population growth rate for four salmon life-history types. In each case, the population matrix model was linked to toxicity models to separately evaluate: 1) changes in subyearling salmon growth and survival resulting from decreases in feeding rate (via pesticide inhibition of brain acetylcholinesterase activity) and reduced prey abundance and 2) acute lethality of pesticides to subyearling salmon. Although linking population projection models to sublethal and lethal toxicity models can enhance a risk assessment, our evaluation of these models revealed critical shortcomings for their intended application. Essentially, they were screening-level analyses which are insufficient for a determination of jeopardy under the ESA. For example, assumptions of density independent population growth and no spatial structure for the salmon populations ignore basic biological/ecological processes known to be important in Pacific salmon populations. Exposure assumptions used in the BiOps were invalid, including: 1) all salmon are exposed within a water body where pesticides are applied in the watershed, 2) all salmon subyearlings use off-channel habitats with still water, and 3) pesticide exposure concentration is constant over the exposure and orders of magnitude above what has been found in salmon streams in the Pacific Northwest. Data inputs for the toxicity models were also overly conservative. We recommend a strategy for developing improved models to provide more realistic spatially-explicit assessments of exposure, toxicity, and risk to support population-level risk analysis for Pacific salmon.

WP081 NOAA HEA Tools: A Spatially Explicit Framework for Habitat Equivalency Analysis B. Shorr, Noaa/Orr; D. Hudgens, A. Geel, Industrial Economics; Z. Nixon, Research Planning Inc.; A. Dvarskas, T. Penn, Noaa/Orr; R. Neely, NOAA. Habitat Equivalency Analysis (HEA) has become an industry-standard analytical approach in natural resource damage assessment to quantify ecological injuries and scale compensatory restoration actions. Over time, the method has been increasingly applied to more complex sites, including sites with multiple habitat types, sites characterized by multiple contaminants at varying concentrations, and sites subject to different types of primary remediation at various points in time. Performing HEA calculations that take into account all these factors, particularly when combined with the desire for a higher degree of spatial resolution and the ability to evaluate a variety of scenarios, requires a great deal of model complexity and computational power. Performing and effectively communicating these analyses also require more flexibility than can be accommodated by the spreadsheet tools most commonly used to perform HEA calculations. NOAA's HEA Tools include toolboxes built in ESRI® ArcGIS software, and

a database calculation application built in Microsoft® Access. These flexible and scalable tools facilitate geospatially explicit calculations of estimated injuries. The tools are designed to provide functionality for simple (single contaminant) to complex (multiple contaminant) sites and scenarios. The tools allow users to enter multiple HEA inputs as distinct "scenarios" to enable sensitivity analyses. The tools also enable users to input characteristics of compensatory restoration projects and estimate the scale necessary to compensate for site injuries. A key feature behind this approach is the custom application that allows the user to access HEA functionality from a coordinated navigation system. The framework in both the GIS environment and guided navigation forms in MS Access helps guide the scientific team through the collection and processing of data, spatial analyses, and HEA calculations. The tools also automate generation of metadata and processing steps and outputs of spreadsheet and GIS data layers to facilitate communication and negotiation of damage assessment.

WP082 A Simple Ecosystem Model to Predict Endocrine Disruptions in the Aquatic Environment L. Clouzot, Universite Laval; M. Paterson, D. Findlay, P. Blanchfield, K. Mills, Fisheries and Oceans Canada; K. Kidd, Univ of New Brunswick; P. Vanrolleghem, Universite Laval. Ecological risk assessment (ERA) requires simple tools to predict critical changes in ecosystems. Nowadays, ERA is evolving from individual measurements to population modeling. However, a chemical's impact needs to be evaluated at higher levels of organization to guarantee reliable ERA. Ecosystem models are considered too complex and too specific to be applied in ERA. This study therefore aims to provide a simple ecosystem model to risk managers to support the Ecosystem Services concept. Considering the increasing concern towards endocrine disruption in aquatic ecosystems, an additional objective is to add appropriate reproductive endpoints. The model was developed to consider direct effects of chemicals but also ecological interactions (feeding and competition relationships). In the software package WEST, an object-oriented model was built with different trophic levels: phytoplankton, zooplankton, planktivore and piscivore fish. Equations from the AQUATOX model (USEPA, 2002) were simplified and adapted to describe endocrine disruptions. The model consists of (i) a food web model (ii) toxic effect sub-models and (iii) a model for nutrient and detritus cycling. The model was developed with data obtained from a unique experimental lake study. A multi-year whole-ecosystem study was performed at the Experimental Lake Area (ELA, Ontario, Canada) with exposure of well-defined fish and lower-trophic-level populations to environmentally-relevant concentrations of the synthetic hormone 17α-ethinylestradiol (EE2). The experimental lake study was divided in three steps (i) baseline data (ii) EE2 addition and (iii) recovery data. The fathead minnow population collapsed after the second year of EE2 addition and endocrine disruption was observed in other species (Pearl dace, Lake trout, White sucker). Direct effects of EE2 were concluded from this experimental lake study and hypotheses on indirect effects such as decrease of some species were raised. The model was developed with the baseline data, calibrated with the data collected during EE2 addition and validated with the recovery phase. To assess the reliability of this simple ecosystem model, other experimental lake studies in the ELA will be modeled.

WP083 Aquatic Risk Assessment of Chemicals Supported by Individual and Population Level Models – A Contribution of the CREAM Project U. Hommen, Fraunhofer IME. In September 2009, CREAM, a Marie Curie Initial Training Network funded by the European Commission, was initiated. Currently, 20 PhD students and 3 postdocs are employed at the 13 host institutions to develop ecological models for the risk assessment of chemicals, primarily pesticides. What is unique and important is that this network prioritizes also the involvement of 10 associated partners from industry, regulatory authorities, and contract research organizations, in order to efficiently tailor the results of the projects to the actual risk assessment needs in practice. Several of the projects deal with aquatic populations, i.e., invertebrates and fish, and aim to contribute to questions such as: How can we predict toxicity on the organism level, e.g., for different exposure patterns? How can we estimate the consequences of lethal and sublethal organism level effects on the population level? How can we extrapolate effects and recovery from local to regional scale? The adopted approaches range from laboratory experiments and trait analyses, to toxicokinetic/toxicodynamic models, matrix population and individual-based models, as well as geographically referenced fate-and-effect modelling on a landscape-scale. The poster will shortly describe each of the projects on aquatic organisms, including the main results achieved so far.

WP084 From Laboratory Derived Individual Level Endpoints to Population Level Risk Assessment C.R. Hazlerigg, Imperial College, Division of Biology; K. Lorenzen, Univ of Florida, School of forest resources and conservation; C. Tyler, Univ of Exeter; J. Wheeler, Syngenta Ltd, Environmental Safety; P. Thorbek, Syngenta Ltd. Most ecotoxicological endpoints used in risk assessments are measures taken at the level of individuals and derived from laboratory tests. For fish, typical endpoints are mortality, growth, development and sometimes reproduction. However, protection goals for wildlife are generally at the level of the population. Population level processes such as density dependence and behavioural interactions are also important, meaning that translating simple effect measures from laboratory based studies directly to population level effects is extremely difficult. To investigate how toxic effects and population level processes may interact, we have formulated an individual-based zebrafish population model. The zebrafish was chosen as the model species due to its use in laboratory ecotoxicity tests for risk assessment. The model was designed and parameterised based on results from a survey of wild fish, semi-field experiments and data derived from an extensive literature review. The model, written in Netlogo (CCL, Northwestern Univ), mimics a 6m2 pond with a habitat appropriate to zebrafish found in the wild. Zebrafish development was divided into four life-stages (eggs, larvae, juveniles and adults) with life history characteristics adjusted with each time-step. The model was used to measure the sensitivity of the population to changes in those individual-level endpoints used in OECD laboratory tests (e.g., hatch success, growth). These individual-level processes were decreased by 10, 20 and 50% and the resulting changes to population abundance measuring the sensitivity of the population response. Each simulation ran for 1500 days and each scenario was repeated 70 times. Different individual-level endpoints had very different response sensitivities in the model. Whilst some endpoints, including growth, showed an immediate effect at the population level, others had limited effects, especially at lower levels of disruption (e.g., sex ratio). The compensatory processes in the population (density dependence) appeared to absorb these effects so that limited or no population-level responses were identified. We rank the tested individual-level endpoints in order of their effect at the population-level. The goal of this study was firstly, to demonstrate how ecological modelling can aid in extrapolating from individual-level endpoints to population-level endpoints and secondly, how these models can help prioritise which endpoints are most important at the population level.

WP085 How Can Ecology Help Us Predict the Effects of Contaminants on Population Dynamics? A. Palmqvist, Roskilde Univ, Environmental, Social and Spatial Change, Roskilde Univ, Dept of Environmental, Social & Spatial Change; V. Forbes, Univ of Nebraska Lincoln, School of Biological Sciences. Marine deposit-feeding polychaetes belonging to the *Capitella* sibling species complex are classic re-colonizing species frequently used as an indicator of habitat disturbance (natural and anthropogenic). Within this species complex some species are very opportunistic whereas others are both less mobile and less tolerant to disturbance. Some of these sibling species have been extensively used for both laboratory experiments and field surveys, though in the field different sibling species are indistinguishable based on morphological characteristics alone. With a combination of various types of laboratory experiments and model simulations the present study aims to pinpoint the most important factors driving the dynamics of field populations of *Capitella* spp., in order to focus further research, monitoring, and management of disturbed areas. The importance of larval dispersal ability and settling behaviour was explored through both a matrix metapopulation study and targeted settling experiments. With increased focus on incorporating more ecological relevance into ecotoxicological studies, we designed experiments to mimic and explore the boom-bust dynamics of *Capitella teleta*. Our results emphasize the influence of dispersal ability and settling behavior on the population dynamics of re-colonizing polychaetes and highlight the importance of understanding the principal factors driving re-colonization of disturbed sediments. Not surprisingly, food availability seems to be the main driver for both larval dispersal and settling behavior as well as the main determinant of density dependence in *Capitella* spp., and is more important for settling in organically contaminated areas than is the presence of sediment-associated contaminants at ecologically relevant concentrations. The take-home message from this study is that in order to extrapolate to field populations for risk assessment and management purposes, it is necessary to choose representative model species for which we understand and can incorporate key aspects of their ecology and biology. Such knowledge can

help to focus testing and research on endpoints that are more relevant for predicting effects on populations.

WP086 How Does *Hyalella azteca* Respond to Pulse Exposure of Environmentally Realistic Concentrations of Permethrin? S. Pedersen, Roskilde Univ, Environmental, Social and Spatial Change, Roskilde Univ, Dept of Environmental, Social and Spatial Change; A. Palmqvist, Roskilde Univ, Environmental, Social and Spatial Change, Roskilde Univ, Dept of Environmental, Social & Spatial Change; P. Thorbek, Syngenta Ltd, Environmental Safety, Syngenta, Environmetal Safety; M. Hamer, Syngenta Ltd; V. Forbes, Univ of Nebraska Lincoln, School of Biological Sciences. Exposure of non-target aquatic organisms to pesticides often occurs in short pulses following periods of drain flow, surface run-off or spray drift. Since standard aquatic toxicity tests for acute effects assessment are primarily based on continuous and maintained exposure periods on individuals, there is a mismatch between laboratory and field exposure patterns. The aim of the present study was to examine the potential for short-term and delayed effects of different pulse exposures and concentrations of a pyrethroid pesticide, permethrin, on the freshwater amphipod *Hyalella azteca*. Two different tests with juveniles of *H. azteca* were conducted to test the effect of pulse exposure. In the first test, *H. azteca* were pulse exposed to a single pulse of different nominal concentrations of permethrin; 0, 0.1, 0.3 and 2.7 µg/L. The exposure pulse lasted for either 1 or 3 hours. In the second test, *H. azteca* were exposed to two repeated pulses of one hour each with different intervals between the two pulses. The nominal exposure concentrations were 0, 0.3 or 0.9 µg/L, and the intervals between the pulses were 0, 6, 24, 48 or 144 hours. After a pulse the organisms were transferred to clean water. Mobility was recorded immediately after a pulse and again after 10 days from the start of the experiment and continuously until the end of the experiment. Each week the beakers were also monitored for juveniles. Pulse exposure of permethrin significantly affected mobility of *H. azteca*. Some immobile individuals regained mobility after transfer to clean water and there was no indication of delayed effects on mobility. The results suggest that exposure concentration has a higher impact on mobility than pulse duration. Mobility, time to first reproduction, and reproductive output were not affected by the interval between the two pulses for the tested concentrations. There were no marked differences in mobility after the first pulse and the second pulse. The data will eventually be integrated into an individual-based model to provide information on how a population of *H. azteca* will respond after exposure to pesticide and the potential for the population to recover. This approach will be more ecologically relevant compared to the normally used constant exposure and can be used as a tool to provide information regarding ecological risk.

WP087 How Much of a Difference in Assessing Ecological Risk Between Effects of Organism-Level and Population-Level? B. Lin, National Institute of Advanced Industrial Science , Research Institute of Science for Safety and Sustaintability, National Institute of Advanced Industrial Science and Technology, Research Institute of Science for Safety and Sustainability. Most protection goals stated in environmental regulations or policies are aimed at the population level or higher and a movement toward population-level ecological risk assessment (ERA) is gaining acceptance for support of chemical management in recent years. However, due to the reason that population-level ERA is a data-intensive analysis (it requires much more ecotoxicity data than organism-level), assessing the ecological risk of toxic chemical is mainly based on a limited number of measures of organism-level effects in laboratory toxicity tests. Thereby, there is an enormous concern in understanding how much of the difference in assessing the ecological risk between effects of organism-level and population-level. To get a rough answer to this concern, this study performs a comparative study on the difference between the derived reference values (PNECs) for risk calculation from approaches of organism-level and population-level. To derive the reference value defined as $C_{lambda=1}$ for use in population-level ERA, extrapolation approach (Lin and Meng, 2009) using available acute (LC_{50} or EC_{50}) and chronic (NOEC) toxicity test data is employed. From the comparative results of selected chemicals, a range of difference will be shown and discussed. This study is expected to be help in bridging the gap between the protection goals and practical ecological risk assessment. Lin and Meng (2009) "Extrapolation of Available Acute and Chronic Toxicity Test Data to Population-Level Effects for Ecological Risk Management of Chemicals," *Environmental Toxicology and Chemistry*, 28(7): 1557–1566.

WP088 Matrix Modelling to Compare Population Sustainability of Realistic Worst-case Fish Species for Pesticide Risk Assessment in the EU L. Ibrahim, Fraunhofer IME; T.G. Preuss, RWTH Aachen Univ, Institute for Environmental Research; U. Hommen, Fraunhofer IME. The assessment of potential effects of chemicals, e.g., pesticides, on fish in Europe is usually based on ecotoxicological tests, taking non-European species as surrogates. These tests deliver organism-level endpoints (e.g., effects on survival, growth and reproduction). However, because the goal is to protect individuals and populations of species native in Europe, there are two types of extrapolation which might improve risk assessment for fish: from test species to ecologically relevant species and from (sub-)lethal effects on individuals to the population level. Hence, we intend to develop a population model of a realistic worst case fish species to support pesticide risk assessment in the EU. For this purpose, first a list of 11 most potentially vulnerable species was concluded via a step-wise screening of a comprehensive list of European freshwater fish based on their potential exposure to pesticides. These 11 species are native to Europe, widespread in the EU (at least in one of the three zones of mutual recognition for pesticide regulation) and are reported in and dependent on edge-of-field water bodies. Some of them are protected under the EU habitats directive. Then, these species were ranked for population sustainability based on their life history traits; matrix modeling was used to analyze the relative effects of reduced development, survival and/or reproduction rates on the population growth rate of the different species. Consequently, based on these results as well as the availability of additional information on the species, including field data for model testing, one species will be chosen for a more detailed analysis by means of an individual-based population model which will be developed.

WP089 Population Level Risk Assessments – Science or Fiction? M. Wang, Rifcon GmbH, Dept Efate & Modelling. Population models are considered as a rather novel method for risk assessment on the population level. Such models have a long history in ecology and they are increasingly being used also for the risk assessment of pesticides. However, it is frequently debated to which extent population models are useful for risk assessment and if their output can be considered being realistic or if they produce rather fictitious predictions. We address this question by analyzing different published population models developed specifically for pesticide risk assessment. We demonstrate advantages and disadvantages of using population models in risk assessment compared to established assessment methods, especially when addressing protection goals within the ecosystem services concept.

WP090 The Use of Bayesian Networks to Integrate Population Modeling, Community Interactions and Ecosystem Services W.G. Landis, Institute of Environmental Toxicology, Western Washington Univ, Western Washington Univ, Institute of Environmental Toxicology, Western Washington Univ, Institute of Environmental Tox. & Chem.; K.K. Ayre, Western Washington Univ, Institute of Environmental Toxicology. One of the difficulties in environmental toxicology and risk assessment has been in creating a framework where toxicants, other stressors, populations, community interactions, landscape features and ecosystem services can be combined in a predictive manner. Bayesian networks can be used as such a tool to tie the effects of stressors to large scale ecological functions such as habitat quality, water condition and landscape characteristics to predict risk to ecological services. This use of Bayesian networks has already been demonstrated in the case of whirling disease affecting valuable populations of cutthroat trout in the American Southwest. This study incorporated habitat for the pathogen, its intermediate host and the trout and the distribution of that habitat into a risk of infection. Also it is also possible to incorporate the output of probabilistic population models such as produced by RAMAS or other tools into a Bayesian network via the conditional probability tables (CPTs). The CPTs inform the interactions between parent and daughter nodes of the Bayesian network. One of the characteristics of Bayesian networks also is the ability to take specifications for ecosystem services and being able to back calculate to the appropriate initial conditions, or management activities, to produce the desired outcomes. The nature of the BN approach is that it is also very clear what critical data are missing in order to produce predictions with acceptable uncertainty. We will present case studies, such as the Pacific herring of Cherry Point WA, of using BNs in conjunction with population models and field data to model large-scale ecological functions and relate them directly to ecosystem services. In conclusion, it is very possible to combine population models, cause-effect interactions and ecological interactions into probabilistic models of risk to ecosystem services.

WP091 Use of the Comprehensive Aquatic Systems Model for Atrazine (CASMATZ) to Estimate Potential Changes in Primary Producer Community Structure R. Brain, Syngenta Crop Protection, LLC., Dept of Environmental Risk Characterization; P. Hendley, Syngenta Crop Protection, LLC., Senior Syngenta Fellow; S.B. Wall, Syngenta Crop Protection, LLC., Ecological Sciences; A. Hosmer, Syngenta Crop Protection, LLC.; S. Bartell, E2 Consulting Engineers, Inc. In 2003, the USEPA required an intensive stream water exposure monitoring program to determine the potential impact of atrazine on the aquatic primary producer community structure. The Comprehensive Aquatic Systems Model (CASM) was parameterized to use atrazine laboratory toxicity data and region-specific characteristics to translate daily atrazine exposure concentrations generated from the stream monitoring program into estimated potential effects on individual model populations of aquatic primary producers and consumers in a generalized 2nd–3rd order Midwestern US stream. CASM_Atrazine (CASMatz) is a bioenergetics-based approach that describes daily production dynamics for a user-specified aquatic food web. It considers the combined implications of varying exposure concentrations/durations, changing environmental conditions, differential population sensitivity to atrazine, and grazing/predator-prey relations in estimating any potential direct and indirect risks posed by site-specific measured atrazine chemographs The generic stream producer community consists of populations of phytoplankton, periphyton, and macrophytes while populations of zooplankton, benthic invertebrates, decomposers, and fish constitute the consumers. In reference simulations, individual population biomass (carbon) values vary as nonlinear functions of daily values of light, temperature, nutrients (N, P, Si), current velocity, water depth, and complex grazing and predator-prey interactions. CASMatz estimates of magnitudes and temporal patterns of population biomass in the absence of other stressors are similar to those reported for 2nd/3rd-order streams. CASMatz provides the flexibility to use alternative methods to estimate exposure-response based on an extensive database of atrazine laboratory toxicity studies and the resulting modelled changes in producer population biomass for varying atrazine exposure scenarios compare favorably with effect and recovery results measured in 33 atrazine microcosm/mesocosm experiments. This generic stream version of CASMatz demonstrates that potential population-level responses to time-varying herbicide chemographs can be characterized for risk assessment using bioenergetics-based models. Importantly, CASMatz provides ecological complexity commensurate with more realistic modeling of potential changes in aquatic primary producer community structure and consumer communities.

WP092 Using Ecological Models in Chemical Risk Assessments of Vertebrates: Contributions from CREAM P. Thorbek, Syngenta Ltd, Environmental Safety, Syngenta, Environmetal Safety. Mechanistic Effect Models for Ecological Risk Assessment of Chemicals (CREAM) is a Marie Curie Initial Training Network, funded by the European Commission within the 7th Framework Programme. CREAM includes 20 PhD and 3 postdoc projects. All projects are related to developing ecological models for the risk assessment of chemicals. CREAM has full and associated partners from industry, regulatory authorities and contract research organizations. The Vertebrates Work Package consists of 8 projects covering both aquatic and terrestrial habitats and chemicals ranging from metals over PCBs to pesticides. The following organisms are being modelled: wood mouse, bats, skylark, wood pigeon, polar bear and fish. The model types range from toxicokinetic models, over foodweb bioaccumulation models and matrix models to individual based models. Some models predict field exposure and the toxic effects this might cause; others predict the population level effects of both chronic and acute toxic effects. Here, the different projects and the main results produced so far will be shortly presented. The Vertebrate Work Package includes the following fellows: Agnieszka Bednarska (Applying toxicokinetic modelling to wildlife risk assessment for pesticides), Chun Liu (Modelling the importance of exposure patterns, life history traits & toxicokinetics for the risk to populations of small mammals), Beatrice Hernout (Modelling the effects of soil contaminants on the bat population in the UK), Tomasz Kulakowski (Ecological modelling to assess the risks that pesticides pose to skylark populations), Katarzyna Matuszewska (Ecological modelling to assess the risks that pesticides pose to woodpigeon populations), Viola Pavlova (Modelling effects of chemicals on polar bear population dynamics), Julita Stadnicka (Predicting toxicity to fish based on in vitro data via a two step model) and Lara Ibrahim (Towards a more realistic chemical risk assessment for fish: development and use of population models).

WP093 Using Population Models to Guide Management Activities: Optimal PCB Remediation Strategies Based on an Individual Based Model of Mink C.J. Salice, Texas Tech Univ/TIEHH, Environmental Toxicology, Assistant Professor, Texas Tech Univ; B. Sample, Ecological Risk, Inc.; R. Miller Neilan, Louisiana State Univ, Dept of Oceanography and Coastal Sciences; K.A. Rose, Louisiana State Univ, Oceanography and Coastal Sciences; S. Sable, Louisiana State Univ, Dept of Oceanography and Coastal Sciences. The use of population models in ecotoxicology and ecological risk assessment has increased in recent years. A key advantage is that population models can be used to place observed toxic effects into an assessment of the impacts on population-level endpoints, which are generally considered to provide greater ecological and societal relevance. The most common applications of population models have been to assess potential effects of contaminants. An additional use is in evaluating the potential outcomes of various remediation strategies for particular populations of concern. We used an individual-based model of mink to evaluate the population-level effects of exposure to polychlorinated biphenyls (PCBs) and the impact that different remediation strategies had on mink population endpoints (population size and extinction risk). An individual-based approach was chosen because it allowed us to explore the population-level consequences of individual variation in PCB exposure as may occur in habitats with heterogeneous distributions of contaminants. The model was parameterized with data from previously published studies and reports and included both stochasticity and density dependence. Although the model was not spatially explicit, *per se*, we created certain "hot spots" of contamination within the mink population to approximate a spatially explicit approach. We investigated the impact of different initial population size (100 or 1000 mink) and simulated remediation efforts that varied in effectiveness (2.22 – 100%), frequency, and timing after the contamination event (5 – 20 years). Simulations of a baseline, uncontaminated mink population had no extinction risk while extinction risk for the PCB contaminated population was 1.0 in the absence of any clean-up. Initial population size had a strong impact on mink population dynamics with a greater extinction risk associated with an initially smaller population. In addition, mink populations were extremely responsive to clean-up scenarios that were initiated soon after the contamination event. In fact, the rate of PCB clean-up did not have as strong a positive effect on mink as did the initiation of clean-up (start time). There was also a beneficial effect of cleaning up "hot spots" compared to uniform PCB removal. Population-level approaches can be used to not only understand adverse effects of contamination but to also explore the potential benefits of various remediation strategies.

WP094 Stakeholder Engagement in Dredged Material Management Decisions in Long Island Sound Z. Collier, M. Bates, E. Chu, US Army Corps of Engineers, Engineer Research & Development Center; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center; T. Fredette, US Army Corps of Engineers, Engineer Research & Development Center; M. Habel, S. Wolf, M. Keegan, US Army Corps of Engineers, New England District. Typically, decisions regarding the method and location for the disposal of dredged materials have considered site-specific and engineering constraints such as capacity, funding, and transportation, and environmental considerations, such as risk, while only integrating views held by local stakeholders in an ad-hoc manner. Lack of transparency in stakeholder process could result in conflicts and biased decisions. For example, the decision of where to place dredged materials in Long Island Sound has historically been highly politically charged between New York and Connecticut. In fact, the US Army Corps of Engineers is in the process of redoing the Dredged Material Management Plan, costing millions of dollars, due to dissatisfaction among the various stakeholders with the initial proposal. Clearly, a method for integrating stakeholders into the decision making process is required if a mutually acceptable decision is to be reached. This presentation will outline a methodology in which values were elicited from stakeholders representing competing interests and applied to the placement of dredged materials in Long Island Sound. Stakeholders included representatives from government agencies, economic associations and environmental groups from New York and Connecticut. Through a series of interactive working groups and interviews, a comprehensive list of criteria, sub-criteria, and metrics was built, and values were gathered regarding tradeoffs between risks and benefits related to environmental, ecological, economic, social welfare, and human health and safety impacts. A model was built in which disposal sites

for dredged materials were prioritized based on both site-specific constraints as well as stakeholder values.

WP095 *Prymnesium parvum*, An Emerging Threat to Inland Waters B.W. Brooks, Baylor Univ, Environmental Science and Biomedical Studies, Baylor Univ, Dept of Environmental Science; J.P. Grover, Univ of Texas at Arlington, Professor; D. Roelke, Texas A&M Univ. The Cuyahoga River. Sandoz and the Rhine River. *Exxon Valdez*. For most, reading these names triggers thoughts of human activities producing immediate impacts on aquatic life. In many countries, environmental regulatory frameworks have developed to support risk assessment and management approaches addressing prospective and retrospective risks of chemical contaminants to ecological receptors and human health. When unacceptable risks are identified, a variety of management efforts may be employed. Such approaches are not as widely defined or employed, however, for harmful algal blooms (HABs), whose increase in frequency and magnitude has occurred globally, resulting in deleterious effects ranging from fish kills to human health risks. Though the majority of HAB research has occurred in marine systems, cyanobacterial HABs are increasingly reported in inland waters. Unfortunately, environmental conditions leading to HABs are complex and often species specific, making it difficult if not impossible to develop a universal approach to management. Since 2000, HABs of *Prymnesium parvum* (golden algae), an invasive haptophyte historically examined in estuarine and coastal habitats, have increasingly produced devastating fish kills in inland waters of the United States. Managers no longer stock sport fish in some impoundments due to repeated, fish-killing *P. parvum* blooms. Seasonal *P. parvum* blooms in water supply reservoirs have resulted in cessation of municipal drinking water withdrawals. The Sandoz and the *Exxon Valdez* spills represent more widely publicized environmental disasters than the increased prevalence of *P. parvum* or other HABS in inland waters. However, recurrent golden algae blooms may be a much larger problem, particularly in light of climate change that might exacerbate the severity of blooms. In contrast to environmental management strategies for chemicals, a more complex web of chemical, physical and biological factors influences the site-specific risks of *P. parvum* to aquatic life. Consequently, challenges to existing ecological risk assessment and management paradigms for aquatic life use protection are more difficult. Here we examine mechanisms associated with the increased prevalence of *P. parvum* blooms and their impacts to aquatic life. Specifically, we identify challenges *P. parvum* presents to integrated watershed assessment and management strategies, and provide future perspectives and recommendations for research needs.

WP097 Toxicity of an Uncharacterized Neurotoxin Linked to Avian Vacuolar Myelinopathy (AVM) to Algae, Crustaceans and Fish J. Herrin, Univ of Georgia, Warnell School of Forestry and Natural Resources; R. Bringolf, Univ of Georgia, Interdisciplinary Toxicology; R. Haynie, S. Wilde, Univ of Georgia, Warnell School of Forestry and Natural Resources. Avian vacuolar myelinopathy (AVM) is an often lethal neurological disease primarily affecting American coots (*Fulica americana*) and bald eagles (*Haliaeetus leucocephalus*) in reservoirs and impoundments throughout the southeastern United States. Affected birds lack coordination and display characteristic lesions in the white matter of the central nervous system. The disease is a seasonal phenomenon, with observations of clinical signs and mortalities occurring from late autumn through the winter. All affected water bodies support robust populations of exotic submerged aquatic vegetation (SAV)-predominantly *Hydrilla verticillata*, *Egeria densa* and *Myriophyllum spicatum*-and a previously undescribed epiphytic cyanobacterium. The disease agent is theorized to be a neurotoxin produced by the cyanobacterium and consumed with SAV by herbivorous waterbirds. The toxin is transferred up the food chain when neurologically impaired waterbirds are consumed by bald eagles. Previous investigations indicate that the toxin is water soluble and that methanol is a suitable solvent for extraction of the toxin from SAV. To date, toxicity of extracts has been confirmed in avian gavage trials after examining brain tissue for characteristic lesions. Suspect lesions have also been observed in triploid grass carp fed SAV from an affected site. We hypothesize that the extract, derived from SAV collected during a winter 2010 epizootic, will elicit a response in other aquatic biota. We used standard toxicity tests, EPA Methods 1001.0, 1002.0 and a modified 1003.0 to determine the toxicity of the extract to fathead minnow (*Pimephales promelas*), *Ceriodaphnia dubia* and *Nostoc sp*., respectively. These tests are 7-day static renewal exposures with endpoints measuring survival, reproduction and changes in algal biomass. The results will be used to forecast vulnerable populations, other than waterbirds and bald eagles, at affected sites. We discuss the utility of the test species for developing a bioassay for the detection of the AVM toxin without using an avian model.

WP098 Chronic Toxicity of Microcystis aeruginosa in Fish: Unexpected Effects and Potential Implications J. Park, Univ of Tennessee, Center for Environmental Biotechnology; E.D. Rogers, Univ of Tennessee, Center for Environmental Biotechnology, Dept of Forestry, Wildlife and Fisheries, The Univ of Tennessee, Dept of Forestry, Wildlife and Fisheries; M.J. Twiner, The Univ of Michigan Dearborn, Dept of Natural Sciences; T. Henry, Univ of Plymouth, School of Biomedical and Biological Sciences, Univ of Plymouth, School of Biology, Univ of Plymouth, School of Biological Sciences; S.W. Wilhelm, Univ of Tennessee, Center for Environmental Biotechnology, Dept of Microbiology. Blooms of the harmful cyanobacteria *Microcystis* sp. occur in many freshwaters and persistence of the environmental conditions that favor blooms can cause chronic exposure of organisms to microcystin (MC) toxins. We investigated effects of environmentally relevant chronic concentrations of MC-LR and lyophilized *Microcystis aeruginosa* in aqueous and dietary exposures in fish and evaluated changes in gene expression, reproduction, and tissue histopathology. After 96-h exposure of larval zebrafish to either MC-LR (0, 100, 1000 ppb) or lyophilized *M. aeruginosa* (4.5 ppb MC-LR) analysis of changes in global gene expression (Affymetrix GeneChip® Zebrafish genome arrays) revealed changes in expression in genes known to be associated with MC exposure and in some genes of particular interest that we not associated with exposure to MC-LR (i.e., unique to *M. aeruginosa* treatment). Among these genes were the vitellogenin genes (*vtg*), which were highly up-regulated and indicative of the presence of an estrogenic substance being produced by the cyanobacteria and the potential for endocrine disruption in fish. Subsequently, we investigated chronic exposure to *M. aeruginosa* in adult zebrafish and evaluated reproduction. No effects were observed on number of embryos, hatching rate, or survival of larvae after 3-week exposure, and male fish did not have induction of *vtg*. Further experimentation with chronic aqueous and dietary exposure to *M. aeruginosa* or MC-LR in channel catfish *Ictalurus punctatus* indicated induction of *vtg* in some fish exposed through diet to *M. aeruginosa*. These results indicate that *M. aeruginosa* can produce a substance(s) with estrogenic properties, but the conditions which this substance(s) is produced are complex and unpredictable. Further experimentation to culture the cyanobacteria to elucidate conditions favoring production of estrogenic substance(s) and fractionation of the algae into components to identify the substance(s) are underway.

WP099 Response of Freshwater Harmful Algae to Aquatic Nutrients in Qinshan Lake of Taihu Watershed, China J. Zhang, W. Ni, Zhejiang Univ; Y. Luo, The Third Institute of Oceanography, State Oceanic Administration; J. Stevenson, Center for Water Sciences, Michigan State Univ. The harmful algal blooms in the Lake Taihu that occurred in 2007 were reported worldwide. This study was designed to understand how nutrients, such as TN,NH4+-N,NO3—N,and TP, influence the growth and species of freshwater algae. Our research site was in Qinshan Lake, which is located in the headwaters of the Taihu watershed. Water and algal samples were collected monthly from ten sites of Qinshan Lake during 2008-2009. The results showed that average TN concentration was 4.47 mg/L, with 92.2% of sampling sites exceeding the TN standard. Average TP was 0.051 mg/L, with 37.9% of sampling sites exceeding the TP standard. The average Trophic Level Index (TLI) of Qinshan Lake was 53, which indicated the beginning stages of the eutrophic conditions. Average chl-a concentration was 12.83 mg/m3 .Abundance of green algae and diatoms far outweighed other freshwater algae, and they dominated during most of year with the highest relative abundances of which was 96% and 99%,respectively. During the summer, blue-green algae became the most dominant with a maximum relative abundance of 69%.The blue-green algae were composed mainly of potentially toxic taxa, such as Microcystis sp., Nostoc sp. and Oscillatoria sp. During the winter season, dinoflagellates were the dominant taxa, with the highest relative abundance of 89%. Our study suggested that nutrients were the main factor regulating population growth of blue-green algae, and control of ammonia and covarying nutrient loads are the key solution for the prevention of algal blooms in Qinshan Lake of Taihu watershed.

WP100 A Watershed Focus on Harmful Algal Blooms: Undergraduate, Graduate Student and Stakeholder Engagement M.T. Homsher, The Univ of Findlay, Environmental Safety & Occupational Health Dept, Univ of Findlay, Environmental Safety & Occupational Health Dept; B.

Dolan, Univ of Findlay; C. Norris, The Univ of Findlay, Chemistry Dept; A. Shepherd, The Uiniverity of Findlay, Pharmacology; P. Martin, Blanchard River Watershedpartnership, Watershed Coordinator. Collaborators from The Univ of Findlay College of Science Biology, Chemistry, Environmental Health and Safety, and the Blanchard River Watershed Partnership are conducting macro-invertebrate surveys, phosphorus, nitrate/nitrite, *E. coli* screens, Suspended Solids, and Total Dissolved Solids studies to identify potential contribution sources to harmful algal blooms within the Lye Creek Area of the Blanchard River Watershed. We have nurtured this collaboration since 2004 when planning for the State of Ohio EPA Total Maximum Daily Load investigations. Regional watershed partners share expertise and creative solutions to resolve our watershed deficiencies. The Univ of Findlay conducts two annual Blanchard River cleanups supported by our under graduate, and graduate students, faculty volunteers and local stakeholders. We have engaged with three volunteer service grants in the last six years to engage Findlay Central Middle School six grade students, Findlay, High School students, and, to conduct public watershed forum's within our a six country watershed group. The 2010 Spring and Summer Harmful Algal Blooms of Lake St. Mary's and other Ohio locales, caused an estimated recreation venue loss of 100 million dollars. Our watershed action plan and education committee strives to coordinate a watershed proactive approach to these issues to improve our watershed. Every living organism in a watershed requires water.

WP101 Elucidating Trichloroethylene Toxicity Mechanisms V. De La Rosa, UC Berkeley, Nutritional Sciences and Molecular Toxicology; C. Vulpe, Univ of California – Berkeley, Nutritional Science and Toxicology. Trichloroethylene (TCE) is an industrial solvent that has been used since the early 20th century as a replacement for chloroform and ether in many industrial processes. Improper disposal of TCE has led to major drinking water contamination and increased public health concern. The toxicity of TCE has long been studied, but findings are controversial and inconsistent. Animal studies have shown that TCE is metabolized to the reactive metabolites DCVG and DCVC, which are responsible for adverse effects such as liver and kidney tumors, mitochondrial toxicity and apoptosis. Still, the molecular events underlying these endpoints remain unknown or debated. Using a functional genomics approach in the model organism *S. cerevisiae*, we aim to obtain a better understanding of the pathways involved in TCE toxicity by analyzing the metabolites DCVG and DCVC. Many of the metabolic pathways, stress response pathways and gene functions are conserved from yeast to higher eukaryotes, permitting the results from this analysis to inform studies in higher organisms. The IC_{20} for dichlorovinyl glutathione (DCVG) and dichlorovinyl cysteine (DCVC) in yeast were determined to be 6.7uM and 18.3uM, respectively. These doses were used for acute exposures, followed by parallel deletion analysis. Preliminary data for DCVG shows an enrichment of genes involved in DNA repair, signaling cascades and autophagy. Confirmations of DNA repair genes *rad6, rad18* and *rad9* showed increased sensitivity to DCVG implicating DNA damage as a possible mechanism of toxicity. These genes function as critical components of translesion synthesis in yeast and humans, implying that DCVG may cause DNA lesions that cannot be repaired or hinder replication, leading to cell death. Other results to be presented include a comparison of DCVG and DCVC gene profiles to determine if the two metabolites act via similar mechanisms and DNA repair studies conducted in DT40 cells. Altogether these results provide a better understanding of trichloroethylene toxicity mechanisms in yeast and insight on possible TCE toxicity mechanisms in humans.

WP102 Using Yeast Functional Toxicogenomics to Decipher the Toxicity of Organochlorinated Pesticides B. Gaytan, Univ of California – Berkeley, Nutritional Science and Toxicology, UC Berkeley, Nutritional Science and Toxicology; A. Loguinov, Univ of California – Berkeley, Nutritional Science and Toxicology; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology; C. Vulpe, Univ of California – Berkeley, Nutritional Science and Toxicology. Exposure to organochlorinated pesticides (OCPs) has been linked to neurotoxicity, endocrine disruption, and cancer, but the cellular mechanisms of toxicity behind these effects remain largely unknown. It was hypothesized that a chemical genomics approach using a *Saccharomyces cerevisiae* gene deletion library could help elucidate the cellular mechanisms by which various OCPs induce toxicity. Pools of deletion strains were exposed in triplicate for five and fifteen generations to the IC_{20}, 50% IC_{20}, and 25% IC_{20} OCP concentrations. The oligo sequences unique to each deletion strain were PCR-amplified and hybridized to TAG4 arrays to identify sensitive, unaffected, and resistant strains. The overrepresented biological terms within the data assisted in the selection of individual deletion strains for growth curve experiments. It is demonstrated here that genes involved in transcriptional elongation, nitrogen utilization, and amino acid sensing are necessary for resistance to the toxaphene OCP, a profile very similar to that for the GMP synthesis inhibitors 6-azauracil and mycophenolic acid. Preliminary analyses for the dieldrin OCP indicate that autophagy and components of the pyruvate dehydrogenase complex are critical for cell survival under dieldrin exposure. Future investigations will refine the mechanism(s) in yeast and perhaps examine how the knockout or knockdown of orthologs in higher organisms, such as *C. elegans* or human cell lines, affects OCP toxicity.

WP103 Biology-Environmental Health Science Nexus: Inquiry, Content and Communication R. Hesselbach, Univ of Wisconsin-Milwaukee; C. Berg, Univ of Wisconsin-Milwaukee, Curriculum and Instruction; M. Carvan, Univ of Wisconsin-Milwaukee, Great Lakes Water Institute; L. Petering, H. Tomasiewicz, Univ of Wisconsin-Milwaukee; D. Weber, Univ of Wisconsin-Milwaukee, Childrens Environmental Health Sciences Center, Univ of Wisconsin-Milwaukee, Great Lakes Water Institute, Univ of Wisconsin-Milwaukee; D. Petering, Univ of Wisconsin-Milwaukee, Chemistry/Biochemistry. We have developed an inquiry-based program for high school environmental science and biology students. The objective of the program is to provide students with multiple, integrated opportunities to conduct authentic experiments that link biological concepts with environmental health issues. The aim is for students to learn through the process of scientific discovery, thereby gaining not only specific knowledge and interest in biomedical science, but also to begin to acquire the critical skills necessary to effectively assess and understand the empirical world. Specifically, students studied the effects of various environmental agents on zebrafish embryo development, earthworm behavior, and fathead minnow reproduction, which served as models for human health effects. Integrated in the modules were opportunities for students to write peer review research papers, communicate their results within and between science classes, and participate in an annual student research conference modeled after the format used in professional society meetings presenting their findings via oral presentations and posters. At this conference, professional scientists, community members, and Univ graduate students were in attendance and also shared their knowledge in the poster session. By this process, students had a unique opportunity to personally interact with researchers and community leaders in a professional manner. Teachers were provided with in-depth professional development experiences through a comprehensive summer training workshop, and yearlong scientific and educational support by UWM faculty and scientists at the UWM Great Lakes WATER Institute. The summer workshop has 3 goals: 1) to provide a mini-course in environmental health concepts, 2) to engage the teachers in a hands-on experience with the modules they will be using with their students and 3) to develop the pedagogical skills necessary for successful completion of the standards-based experimental modules. Inherent to the program is the systematic evaluation process to assess the various facets of the project. (Support: NIEHS and NCRR 1R25RR026299-01)

WP104 Laboratory-based Research Immersion Experiences: Creating Environmental Scientists in a Single Semester C. Broussard, The Univ of La Verne, Univ of La Verne, Biology, Univ of La Verne, Professor of Biology. Research experiences for undergraduates are among the most effective tools to recruit, retain, and promote the success of undergraduates in science, technology, engineering, and mathematics (STEM), particularly for underprepared and under represented groups in STEM. In addition to retaining students in college, research immersion experiences can galvanize undergraduate interest in pursuing STEM careers, including research. A recent challenge has been to provide research opportunities in light of diminished budgets and shifts in fiscal priorities away from laboratory experiences for undergraduates. Given these challenges, how can the environmental science community expose undergraduates to research in environmental science and encourage them to pursue graduate studies in the field? In the current project, laboratory-based research immersion experiences were designed to introduce undergraduates to environmental science research and to actively involve undergraduates in emerging contaminant research using developmental biology as a lens to focus their efforts. We will concentrate on the overall design and how other institutions can adopt the model developed

at La Verne. This research was supported by the Dept of Biology and NSF DUE 0632831. The opinions expressed in this work are solely the author's.

WP105 A Game-based Pedagogy for Sustainability Ethics T. Seager, Arizona State Univ, School of Sustainable Engineering & Built Environm; E. Selinger, Rochester Institute of Technology; S. Spierre, Arizona State Univ, School of Sustainability; J. Sadowski, Rochester Institute of Technology. Existing approaches to ethics education in environmental professions typically rely on a liberal arts approach of reading, discussing and writing about case studies abstracted from historical experience or hypothetical scenarios. However, this approach is of only limited interest to the typical engineering and science student that is accustomed to more experimental and experiential learning styles. This presentation describes a new approach to teaching ethics that immerses the students in four non-cooperative game theory problems abstracted from several salient problems in sustainability that have their origins in environmental economics: 1) environmental externalities, 2) Tragedy of the Commons, 3) weak versus strong sustainability, and 4) intergenerational equity. Each game problem consists of an educational module that can be delivered in series or independently, and is designed to engage each stage of the Kolb learning cycle. Modules have been tested at multiple Universities in a blended classroom and on-line format. The results suggest that students believe they gain deliberative, leadership, teamwork and moral reasoning skills by participating in the games. The presentation also discusses the implication of the game experiences for real-world environmental problems such as climate change negotiation.

WP106 Online Teaching and Learning Environmental Toxicology K. Dixon, Texas Tech Univ, TIEHH; H. Zhao, Texas Tech Univ, Teaching, Learning, and Technology Center; H. Morrison, T. Tyagi, Texas Tech Univ. Teaching Environmental Toxicology courses over the internet offers students opportunities not available in the classroom course. Online learning can be synchronous, using tools such as chat, audio and video conferencing, and shared desktop. Online courses also can be offered asynchronously. That is, students can arrange their schedules to work on the course any time it is convenient for them. Asynchronous learning tools include e-mail, threaded discussion, and file attachments for assignments and exams. One of the greatest advantages of online teaching is that the online course is more accessible, especially for non-traditional students. Students do not have to attend regularly scheduled classes on campus. Because the number of environmental toxicology programs still is relatively small, access to environmental toxicology courses is limited. Teaching online means that non-resident students, including out-of-state and international students, will be able to take these courses. A second advantage of the online course is its flexibility, particularly in asynchronous learning. This flexibility also makes the course more accessible, allowing more students to take the course. A course can be designed to grade assignments and exams automatically. This requires a significant amount of time in course design and, because exam questions generally are limited to short answers, may not be appropriate for graduate level courses. We found that distributing assignments and exams as attachments works best. Likewise, the student's answers to exam questions and assignments can be "turned in" as attachments, either in an e-mail or using online teaching software. With the exception of wet lab courses, an entire curriculum in environmental toxicology could be offered online.

WP107 Impacts of Mining-derived Metals on Riffle-dwelling Crayfish in the Tri-State Mining District of Southwestern Missouri and Southeastern Kansas, USA A.L. Allert, USGS – Biological Resources Division, Columbia Environmental Research Center, USG.S. – Columbia Environmental Research Center, Biologial Resources Division; R.J. DiStefano, Missouri Dept of Conservation; C.J. Schmitt, US Geological Survery, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center; J. Fairchild, USGS – Biological Resources Division, Columbia Environmental Research Center; W. Brumbaugh, US Geological Survey, Columbia Environmental Research Center. The Tri-State Mining District, USA was one of the largest producers of lead-zinc ore in the world. Previous field and laboratory studies of this area found evidence of aquatic biota exposure to metals and documented toxicity of sediment to benthic invertebrates. Studies in two other Missouri lead-zinc mining areas documented impacts of mining-derived metals on crayfish populations and on caged crayfish in in situ exposures. We sampled riffle-dwelling crayfish communities at 16 sites in three tributaries of the Spring River in Missouri and Kansas. Crayfish species richness, crayfish density, physical habitat, and water quality were examined at each site to assess the ecological effects of mining-derived metals. Metals (Ni, Cu, Zn, Cd, Pb) were analyzed in surface water, sediment, detritus, and crayfish. Four species of crayfish were collected during the study, with Orconectes neglectus being the predominant species at all sites. Orconectes medius was found only at headwater sites in two of the tributaries. Mean crayfish densities were significantly lower at sites directly downstream of areas with deposits of mine wastes (i.e., chat and tailings piles). Also, mining-derived metals in water, sediment, detritus, and crayfish were significantly higher at these sites. Additional analyses will be conducted to investigate whether crayfish densities are primarily associated with concentrations of mining-derived metals, physical habitat or water quality. Potential adverse effects to wildlife and ecosystem function may result from the consumption of metals-contaminated crayfish and from the absence of the predominant shredder in Ozark streams.

WP108 Evidence of Exposure to the Montara Oil Spill in Timor Sea Wildlife M. Gagnon, Curtin Univ, Dept of Environment and Agriculture, Curtin Univ (Bentley Campus), Dept of Environment and Agriculture, Curtin Univ, Environment and Agriculture; C. Rawson, Curtin Univ, Dept of Environment and Agriculture. From August to October 2009 the Montara well in the Timor Sea released crude oil and gas condensate to the surrounding environment causing concern over the impacts on wildlife and commercial fisheries. During and immediately after the well hydrocarbon release, a number of deceased animals suspected of being impacted by the release were collected from the region along with a small number of live animals which later died in captivity from unknown causes. Necropsies were collected from 16 birds (14 common noddy, 1 lesser frigatebird, 1 wedge-tailed shearwater), one spotted sea snake, one horned sea snake and one green turtle. A total of 49 tissue samples and 39 swab samples were analysed for the presence of total petroleum hydrocarbons and polycyclic aromatic hydrocarbons. One common noddy collected deceased from the vicinity of the Montara incident had crude oil on its feathers, in its gizzard contents, in its lungs and in its breast tissue indicating significant pre- and/or post-mortem exposure to crude oil. One common noddy collected at Ashmore Reef had crude oil in its lungs but in no other samples (e.g., feathers, trachea etc). It is likely that this indicates non-recent exposure. While the spotted sea snake had hydrocarbons in its lung only, the horned sea snake had crude oil in its stomach only and none in any other tissues (skin, trachea, lung). The presence of oil in the stomach of the horned sea snake suggests exposure through the ingestion of prey and not through surfacing in an oil contaminated environment. There was no evidence that the sea turtle had been exposed to crude oil either pre- or post mortem. Results indicate that across the wide geographical area where animals were collected, oil exposure might have contributed to lethality in only a few cases.

WP109 Nearshore Avian Densities in the Northern Gulf of Mexico: Changes from May 2010 to May 2011 J.R. Wakefield, L. Noel, K. Gable, S. Fidler, P. Reilly, Cardno Entrix. A common refrain at SETAC's Gulf Oil Spill Focused Topic Meeting was the absence of studies designed to evaluate survival and reproduction among higher trophic organisms such as birds or marine mammals that may have been impacted by the spill. Studies conducted by Cardno ENTRIX scientists in 2010 and 2011 directly address this concern. From May 9 to May 15, 2010, BP representatives conducted comprehensive helicopter-based bird counts and photo-documentation along all coastal beaches, barrier islands, major bays, and marshes located between Venice, Louisiana and Pensacola, Florida. Collected days or weeks before oil came ashore, these observations include observations of nearly all major colonial water bird breeding colonies in the northern Gulf of Mexico and provide a comprehensive snapshot of pre-impact avian density in the nearshore environment. The overflights were repeated one year later (May 10 to May 15, 2011) and the data from the two sets of overflights provide the first comprehensive snapshot of pre- and post-accident avian populations; variation between these snapshots reflects both natural environmental variation as well as the integrated effect of oil and oil spill related changes in the avian prey base and habitats. Data from overflights will be depicted in a series of maps illustrating avian density and species composition in approximately 275 grid cells distributed throughout the northern Gulf of Mexico. These data and any variation between 2010 and 2011 will be placed in the context of time series data describing the magnitude of, and variation in, Louisiana's breeding bird densities during the past 15 years.

WP110 Provisioning of Chicks by Leach's Storm-Petrels: Preliminary Insights into Energy Content, Lipid Content, and Contaminants of Stomach Oils S. Camilleri, Univ of North Carolina Wilmington; H. Koopman, Univ of North Carolina Wilmington, Dept of Biology and Marine Biology; A. Westgate, Univ of North Carolina Wilmington, Dept of Biology and Marine Biology, Grand Manan Whale and Seabird Research Station; D. Gannon, Bowdoin Collete, Bowdoin Scientific Station c/o Dept of Biology; R. Mauck, Kenyon College, Dept of Biology; J.R. Kucklick, National Institute of Standards and Technology (NIST), Analytical Chemistry Division, National Institute of Standards & Technology, Hollings Marine Laboratory. Many adult Procellariiformes provision chicks with oils concentrated from consumed prey in contrast to most seabirds that supply chicks with whole prey. This feeding strategy is considered adaptive because chicks are provided with relatively higher energy lipids to better sustain them between parental foraging trips. Consequently, chicks may be ingesting higher concentrations of persistent organic pollutants (POPs) than if they ingested whole prey. Our goal was to evaluate the "oil" strategy by determining the energy content, lipid composition and organic contaminant concentrations in stomach oils of Leach's storm-petrels (LHSPs; *Oceanodroma leucorhoa*) from the Bay of Fundy, Canada and compare these with similar measurements from whole prey items. Samples collected in 2010 (n=83) indicate that the stomach oils are very energy dense (mean 35.18 kJ/g, SD=6.86, n=27). Wet weight values for potential prey items of other seabirds (herring 7,487 J/g; copepods 6,316 J/g) suggest that adult LHSPs can produce a significantly concentrated form of energy in stomach oils over the raw ingested prey items. Stomach oil (n=34) were comprised mostly of triacylglycerols (mean 73% SD=32.3) and wax esters (mean 25%, SD=30.84), however there was a wide range (0 to 90.2) of wax ester content, providing the first information that there is variation in diet among individuals. Stomach oil samples were analyzed for polychlorinated biphenyl congeners (PCB), DDT and related compounds, polybrominated diphenyl ether congeners (PBDE), chlorobenzenes, and mirex using gas chromatography mass spectrometry. Preliminary contaminant analyses of stomach oils (n=27) revealed ΣPCB levels ranging from 143-2433 ng/g lipid weight (median 590), ΣDDT levels ranging from 23-697 ng/g (median 161). Mirex ranged from 0.7-8.4 (median 2), HCB ranged from 1.7-41.9 ng/g (median 16), and oxychlordane ranged from 2-21 ng/g (median 7). These values are higher than published values (wet weight) for zooplankton collected from the same area (ΣPCB 114-241 ppb, ΣDDT 14-23 ppb), suggesting that stomach oils concentrate contaminants; consequently chicks may be receiving oils with enhanced organochlorine concentrations compared to whole zooplankton and other prey items.

WP111 Footprint of Mercury in Terrestrial Songbirds Along the South Fork Shenandoah River A. Jackson, D. Evers, Biodiversity Research Institute; A. Condon, US Fish and Wildlife Service, US Fish and Wildlife Service, US Fish and Wildlife Service; J. Schmerfeld, US Fish and Wildlife Service; D.A. Cristol, College of William & Mary, Professor of Biology, College of William & Mary, Dept of Biology. Mercury (Hg) is a persistent environmental contaminant found in many freshwater and marine ecosystems. In riverine systems, historical Hg contamination impacts the surrounding terrestrial ecosystem, but there is little known about how far downstream this contamination occurs. As part of a Natural Resource Damage Assessment, in 2009, we sampled terrestrial forest songbirds at five sites up to 137 kilometers downstream of the historical source of Hg along the South and South Fork Shenandoah Rivers (Virginia, USA).We found that blood total Hg concentrations remained elevated over the entire sampling area and there was little evidence of decline with distance. We also found that blood mercury concentrations varied based on foraging guild (invertivore or omnivore) and migration strategy (resident or migrant). While it is well known that Hg is a pervasive and long-lasting aquatic contaminant, it has only been recently recognized that it also biomagnifies effectively in floodplain forest food webs. This study extends the area of concern for terrestrial habitats near contaminated rivers for more than 100 kilometers downstream.

WP112 Acute Oral Lead Pellet Exposure in Adult Domestic Pigeons: A 28 Days Study J. Holladay, M. Nisanian, S. Holladay, R. Kerr, Univ of Georgia, Anatomy and Radiology; L. Tannenbaum, US Army Public Health Command, Environmental Health Risk Assessment Program, US Army institute of Public Health; S. Williams, Univ of Georgia, Poultry Diagnostic and Research Center; R. Gogal, Univ of Georgia, College of Vet Med, Anatomy and Radiology. Avian wildlife and domestic species commonly ingest lead (Pb) spent shot or bullet fragments as grit or mistakenly as food. In previous studies in our laboratory and others, the reported toxicities varied based on the avian species, diet, type and quantity of Pb ingested. In the current study, domestic pigeons were gavaged with 1, 2, or 3 Pb pellets and followed with weekly radiographs and blood physiologic endpoints for 28 days. Pellet retention decreased by roughly 50% per week as pellets were either absorbed or excreted except for week 4 where the numbers remained constant. Size of retained pellets visually decreased based over time. Birds dosed with a single pellet showed mean blood Pb levels over 80 times higher than those of the controls, supporting a measured level of Pb absorption. Unlike our previous quail studies, no overt clinical signs of toxicity were seen across dose. However, similar to the Pb pellet-exposed quail, plasma d-aminolevulinic acid dehydratase (d-ALAD) activity remained depressed, suggesting an altered hematological function in the Pb pellet-exposed pigeons. Still compared to the quail, domestic pigeons appeared to have a higher tolerance to the oral Pb pellets.

WP113 Assessment of Population, Reproductive, and Health Impairments in Colonial Waterbirds Breeding in Michigan's Areas of Concern K. Grasman, Calvin College, Dept of Biological ; S. Fuhrman, A. Moore, W. VanDenHeuvel, Calvin College, Dept of Biology; L. Williams, US Fish and Wildlife Service, East Lansing Field Office. The purpose of this assessment was to investigate and monitor the effects of contaminants on the breeding population numbers, reproduction, and immunological health of fish-eating birds in the Saginaw Bay and Raisin River Areas of Concern (AOCs) as part of the Great Lakes Restoration Initiative-Fish and Wildlife Service AOC program. In the Saginaw Bay AOC, field studies were conducted during 2010 at two herring gulls colonies (the Confined Disposal Facility (CDF) in the southern bay and Little Charity Island in the outer bay), two Caspian tern colonies (the CDF and Charity Reef) and one black-crowned night heron colony (CDF). At the Raisin River AOC, studies were initiated on the herring gull colony at the Detroit Edison Monroe Power Plant on the western shore of Lake Erie. Gull nests were marked during egg-laying, and embryonic viability was assessed during mid/late egg incubation using an embryonic viability detector sensitive to heartbeat and movement. Embryonic nonviability in herring gulls in the Saginaw Bay and Raisin River AOCs (4-5%) was somewhat higher than at reference sites (< 2%). Total nonviability was most influenced by early failed development on the CDF and infertility on L. Charity, whereas at Monroe nonviability was spread throughout development. Herring gull colonies in the Saginaw Bay AOC showed marginally good chick survival. Caspian tern colonies showed marginal to poor chick survival, which is of concern for this state-threatened species. The herring gull colony at the Raisin River AOC experienced a complete reproductive failure with almost no chicks surviving through mid June. The phytohemagglutinin (PHA) skin test for T-cell mediated immunity was suppressed significantly in young gulls, terns, and herons living on several islands in the Saginaw Bay AOC. In herring gulls mean responses in both Saginaw Bay colonies were suppressed 65-66% compared to the marine reference site and 50-52% relative to the Great Lakes reference site. Compared to reference data, mean responses were suppressed 31-50% in Caspian terns, and 33% in black-crowned night herons. Ongoing immunological, developmental, and reproductive impairments in fish-eating birds at these AOCs are consistent with previous studies on the effects of persistent pollutants such as PCBs in Great Lakes birds, although other stressors may also be contributing, especially to the reproductive effects.

WP114 Dietary Exposure of Mink (Mustela vison) to Fish from the Upper Hudson River, New York, USA: Organ Mass and Pathology S.J. Bursian, Michigan State Univ, Dept of Animal Science; J.W. Kern, R.E. Remington, Kern Statistical Services, Inc.; J.E. Link, Michigan State Univ, Dept of Animal Science; S.D. Fitzgerald, Michigan State Univ, Dept of Pathobiology and Diognostic Investigation. The Hudson River is contaminated with polychlorinated biphenyls (PCBs) from Ft. Edward, NY to New York City. The predominant sources of PCBs to the upper Hudson River were 2 General Electric plants in Fort Edward and Hudson Falls, NY that manufactured electrical capacitors containing PCBs beginning in the 1940s. Reports spanning the past 20 years indicated that mink (*Mustela vison*) collected within 1 home range of the upper Hudson River contained concentrations of PCBs in their fat and livers comparable to concentrations causing reproductive impairment in controlled studies with ranch mink, and that tissue concentrations of PCBs have not decreased appreciably. Because the mink is a fish-eating mammal that satisfies criteria, including chemical

sensitivity, for a sentinel wildlife species, it is a commonly selected ecological receptor in studies at sites involving aquatic habitats with elevated concentrations of PCBs. A study was conducted to evaluate the health effects of feeding ranch mink diets containing PCB-contaminated fish from the Hudson River. The effects on adult and offspring organ mass and pathology are reported here. Diets contained 2.5% to 20% Hudson River fish, providing 0.72 to 6.2 µg ∑PCBs/g feed (5.1 to 38 pg toxic equivalents [TEQs]/g feed). Absolute thyroid gland and adrenal gland masses were increased in adults and 31-wk-old juveniles, respectively, and absolute liver and heart mass were decreased in 6-wk-old kits exposed to dietary PCBs. Dietary concentrations of 0.72 µg ∑PCBs/g feed (5.1 pg TEQs/g feed) and greater induced mandibular and maxillary squamous epithelial proliferation. The dietary concentration of ∑PCBs predicted to result in 20% incidence of the jaw lesion was 2.3 µg ∑PCBs/g feed (15 pg TEQs/g feed) and the hepatic concentration was 2.8 µg ∑PCBs/g liver, wet wt (89 pg TEQs/g liver, wet wt). The conclusions and opinions presented here are those of the authors and do not represent the official position of any of the funding agencies, the Hudson River Trustees or the United States.

WP115 Persistent Organic Pollutant (POP) Effects on Shovelnose Sturgeon (*Scaphirhynchus platorynchus*) Reproduction and Early Life Stages J. Buckler, Univ of Missouri-Columbia, US Geological Survey Cooperative Research Unit, Univ of Missouri-Columbia, Fisheries and Wildlife; J. Candrl, US Geological Survey, Columbia Environmental Research Center; M. McKee, Missouri Dept of Conservation; D.M. Papoulias, D.E. Tillitt, US Geological Survey, Columbia Environmental Research Center; D. Galat, Univ of Missouri-Columbia. The genus *Scaphirhynchus* is endemic to the United States and includes the federally endangered pallid sturgeon (*Scaphirhynchus albus*). The more abundant shovelnose sturgeon (*Scaphirhynchus platorynchus*) is commonly used as a biological surrogate for pallid sturgeon. However, populations of both *Scaphirhynchus* species have been in decline over the past century. Shovelnose sturgeon have consumption advisories in five of the 13 states that list them as a sport species. These advisories are largely due to concentrations of persistent organic pollutants (POPs) found in muscle and roe tissues. Concentrations of these POPs are above levels shown to have adverse reproductive effects in other species. This study was designed to determine if concentrations of POPs in egg samples from wild fish, specifically organochlorine pesticides (OCPs), polybrominated diphenyl ethers (PBDEs), and polychlorinated biphenyls (PCBs), affected early life stage development and survival in shovelnose sturgeon. Twenty-six female shovelnose sturgeon from two Middle Mississippi River sites were artificially spawned and contaminant concentrations in eggs were analyzed using gas chromatography. Percent fertilization, percent hatch, and percent survival to exogenous feeding were endpoints used to determine if POPs were affecting early life stages. Lipid normalized egg concentrations ranged from 540 – 2,560, 50 – 1,650, and 790 – 8,500 ng/g lipid for total OCPs, total PBDEs, and total PCBs respectively. Percent fertilization was not correlated with POP concentration. However, percent hatch (r = -0.42, p = 0.03) and cumulative percent survival at 2 (r = -0.42, p = 0.03), 3 (r = -0.41, p = 0.04), 4 (r = -0.48, p = 0.01), and 5 (r = -0.43, p = 0.03) days post fertilization (dpf) were inversely correlated with POP concentration. Furthermore, a total PCB LC_{50} of 2,700 ng/g lipid was calculated for shovelnose sturgeon at 3 dpf. Results from this study indicate that recruitment of shovelnose sturgeon and potentially pallid sturgeon may be adversely effected at the upper extreme of POP concentrations observed in the field.

WP116 Assessment of Potential Neosho Madtom Habitat in Tributaries of the Spring River of Kansas and Missouri C.J. Schmitt, US Geological Survery, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center. The Neosho madtom (Noturus placidus: Pisces, Ictaluridae) is a Federally listed (Threatened) fish endemic to the Neosho-Spring River system of Kansas, Oklahoma, and Missouri. It presently occurs in the main stem of the Spring, Neosho, and Cottonwood rivers upstream of the Tri-State Mining District; at several Spring River main stem locations further downstream; and in a few Kansas tributaries of the Neosho River. Neosho madtoms also occurred historically in the Illinois River of Oklahoma, a Neosho River tributary. However, there is only one historical record of the species occurring in any of the Spring River tributaries flowing westward from Missouri and Kansas (Center, Turkey, and Shoal creeks), which have been contaminated to varying degrees by metals from historical lead-zinc mining. Because the Neosho madtom was not formally recognized as a species until 1969, 100 y after mining began, it is not known whether some populations were extirpated. The objective of this study was to evaluate extant data to determine whether the westward-flowing tributaries could support Neosho madtoms absent mining-related contaminants. The approach was to apply a regression model developed from 1991 data for Neosho madtom density and habitat in the Neosho River system to more recently obtained tributary data, and to develop additional regression and principal components models based on all available habitat and fish data exclusive of contaminants. All the models indicated that the lower reaches of the westward-flowing tributaries could support Neosho madtoms. The results are consistent with extant information on the present and historical distribution of the species indicating that its range can expand and contract rapidly in response to flow and other habitat changes, and that it can tolerate a wide range of habitat conditions. Collectively, the results support the premise that Neosho madtoms inhabited the lower reaches of the tributaries at least occasionally prior to the advent of mining, and that re-establishment of populations in these streams is feasible absent contamination.

WP117 Effects of Mining-Derived Metals on Crayfish in Several Mining Districts of the Central USA: A Review A.L. Allert, USGS – Biological Resources Division, Columbia Environmental Research Center, USG.S. – Columbia Environmental Research Center, Biological Resources Division; J. Fairchild, USGS – Biological Resources Division, Columbia Environmental Research Center; R.J. DiStefano, Missouri Dept of Conservation; W. Brumbaugh, US Geological Survey, Columbia Environmental Research Center; C.J. Schmitt, US Geological Survery, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center; J.M. Besser, US Geological Survey, Columbia Environmental Research Center. The abundant lead and zinc resources of Missouri, Kansas, and Oklahoma, USA have been mined since the 1700s, resulting in large quantities of metal-enriched mine tailings being deposited into some streams of the mining districts. Contamination of fish and other aquatic biota, alteration of fish and invertebrate communities, and public health advisories against human consumption of lead-contaminated fish have resulted. We summarize the findings of studies that documented the impacts of mining-derived metals on crayfish populations in the Viburnum Trend Mining District (VTMD), Old Lead Belt (OLB), and Tri-State Mining District (TSMD). Metal concentrations, especially lead, zinc, and cadmium were significantly higher in water, sediment, organic matter, and biota at mining sites compared to reference sites. Crayfish densities were significantly lower at sites directly downstream of mining areas compared to reference sites in the three mining districts. In situ toxicity to juvenile crayfish was significantly higher at mining sites compared to reference sites in the VTMD and OLB and provides direct evidence that mining-derived metals are toxic to crayfish. In the VTMD, organic matter processing by crayfish was significantly lower at mining sites than at reference sites. Crayfish are an important prey item for other aquatic and terrestrial invertebrates, amphibians, reptile, fish, birds, and mammals and are critical to organic matter processing and the cycling of nutrients and energy through stream food webs. Therefore, the effects of mining-derived metals on crayfish may impact the functional integrity of Ozark streams and surrounding ecosystems.

WP118 Assessing Protection of EPA 304(a) Chronic Criteria Recommendations to Federally-listed Fishes T.K. Linton, Great Lakes Environmental Center; W.K. Taulbee, Great Lakes Environmental Center, Research Scientist; C.M. Voros, Great Lakes Environmental Center; D. Lehmann, US Environmental Protection Agency, Health and Ecological Criteria Division, OST, OW; J. Beaman, USEPA, Toxicologist; F. Mayer, GLEC Subcontractor. Under section 304(a) of the Clean Water Act (CWA) the USEPA develops ambient water quality criteria that serve as scientific recommendations for states and tribes in adopting and revising water quality standards. Currently, EPA is required under section 7 of the Endangered Species Act (ESA), to consult with the US Fish and Wildlife Service (FWS) and the National Marine Fisheries Services (NMFS) (collectively, the Services) when approving new and revised state and tribal water quality standards (WQS) under section 303(c) of the CWA. EPA's aquatic life criteria are designed to provide for the protection and propagation of aquatic communities in general, inclusive of federally threatened and endangered aquatic species. The goal of this research is to develop and validate a new approach for these consultations that 1) ensures EPA's recommended criteria are protective where locally sensitive populations of Federally-listed aquatic species and their critical habitat occur, and 2) is simple, flexible, and scientifically defensible so that such an approach can be readily adopted by

states and tribes. The approach builds on an already strong foundation from other such studies published in the peer-reviewed literature where select surrogate species tested with a wide array of data-rich chemicals against Federally-listed fish species have proved both representative and useful. The overall approach incorporates multiple lines of evidence from comparative and probabilistic-based toxicology to derive and validate a simple "criterion adjustment factor" based on the use of the taxonomically-representative and chemically-sensitive surrogate taxa: *Oncorhynchus mykiss* (rainbow trout). The approach is being developed for several chemicals with different adverse outcome pathways (copper, ammonia, carbaryl, and 4-nonlyphenol), using readily available predictive tools (e.g., interspecies correlation, acute:chronic estimator, species sensitivity distribution) and other scientifically-accepted conventions (e.g., acute-chronic ratios). Appropriate criterion adjustment factors derived with appropriate margins of safety based on a prescribed level of acceptable uncertainty will be presented.

WP119 Toxicity of Portland Harbor Sediments to Pacific Lamprey Ammocoetes (Lampetra tridentata) J.M. Morris, J. Peers, J. Lipton, Stratus Consulting; C. Schreck, R. Chitwood, J. Unrein, Oregon State Univ. Contaminants such as chlorinated hydrocarbons, petroleum-related compounds, metals, and other hazardous substances have been released from various sources into Portland Harbor and have accumulated in sediments. Sediments from specific areas in the Harbor are toxic to benthic invertebrates, and benthic organisms and fish in the Harbor have accumulated contaminants. Benthic habitat in the Harbor may be an important resting and foraging area for larval Pacific lamprey (Lampetra tridentata) as they transition to the lower Columbia River and undergo metamorphosis to their adult life stage. Larval lamprey (ammocoetes) in the Harbor likely are exposed to a variety of contaminants and ammocoetes collected from the Harbor have been found to have accumulated organochlorine compounds to a greater degree than ammocoetes collected from upstream areas. In support of the Portland Harbor Natural Resource Damage Assessment, this pilot project was aimed at developing experimental methodologies to assess effects of contaminated sediments on physiological and behavioral, endpoints. Ammocoetes collected from the Siletz River, OR, were used to evaluate sensitivity to contaminated Portland Harbor sediments. Phase I of this project included a series of experiments focused on methods development and results were presented at the annual SETAC meeting in Portland in 2010. Phase II of this project included sediment bioassays and behavioral testing using sediments collected from 9 sites in Portland Harbor. The results of Phase II testing will be presented.

WP120 Assessing Potential Injury for the Hanford Site NRDAR Using a Native Mussel J. Bartoszek, US Fish and Wildlife Service, Division of Environmental Assessment and Restoration; R. MacRae, US Fish and Wildlife Service. The Hanford Reach of the Columbia River has received contaminants from the Dept of Energy Hanford site since the 1940s. Hexavalent chromium has been released to the river through both surface water and upwelling ground water pathways, and preliminary laboratory studies indicate that concentrations of hexavalent chromium similar to those measured or predicted in the river could negatively impact Chinook salmon and/or Steelhead trout. However, because of their mobile life history and impacts from habitat alteration and hydrologic changes, attributing injury to these fish due to release of contaminants from the Hanford site is complex. Thus, the Hanford Natural Resource Trustee Council is considering several alternative species to determine if injury to aquatic biota has occurred. The Hanford Reach of the Columbia River has historically supported populations of native mussels such as species of the genera Anodonta and Margaritifera. Although reduced in numbers, Anodonta (floaters) still occur in the Reach, whereas the once abundant Margaritifera falcata (western pearlshell) may be extirpated. While habitat modifications may have contributed to these declines, historical contaminant releases may have also played a role, particularly if the western pearlshell is more sensitive to contaminants than floaters. Because they are sessile and can be exposed to contaminants both from the water column and sediments, these native mussels will likely be the subject of injury studies.

WP121 Can You Afford To Not Have Vegetation Data for Metals? E. Curtis, AMEC Environment & Infrastructure, Project Manager – Ecological Risk Assessment; M. Bystedt, M. Bystedt, N. Ruberti, L. Stubblefield, AMEC Environment & Infrastructure. Bioaccumulation of metals into vegetation is not a typical pathway of quantification in ecological risk assessment. Bioaccumulation factors (BAFs) and slopes provided in Empirical Models for the Uptake of Inorganic Chemicals from Soil by Plants (Bechtel, 1998) are often used for estimating metal concentrations in vegetation tissue in food-web modeling in the absence of site-specific plant tissue data. The vegetation BAFs in Bechtel (1998) are typical of literature based soil-to-biota bioaccumulation factors, but these values have a layer of conservatism, the upper prediction limit, built in for use at sites with no available plant data. The use of the upper predictive limit often leads to overestimation of metal concentrations in vegetative tissue. A site-specific plant bioaccumulation study on arsenic, cadmium, copper, lead, and zinc at a site in western Georgia was conducted using the approach presented in Bechtel's study. The site-specific dataset obtained from the plant bioaccumulation study was small with limited variability. A meaningful relationship (provided by R2 values) between soil and tissue concentrations could not be determined. By combining the site-specific data with the vegetation BAFs developed from the larger dataset in Bechtel (1998), a more realistic quantification of risk for ecological receptors was determined than was provided by the use of the literature-based BAFs.

WP122 Developing Effect-based Ecological Soil Screening Levels (EcoSSLs) for Use in Wildlife Terrestrial Baseline Ecological Risk Assessments S. Pauwels, TechLaw, Inc.; R. Sugatt, USEPA Region 1; R. Dionne, E. Czerepak, TechLaw, Inc.; B. Hoskins, USEPA Region 1, New England Regional Laboratory. The Environmental Protection Agency (EPA) published Ecological Soil Screening Levels (EcoSSLs) protective of plants, soil invertebrates, birds, and/or mammals. These values represent contaminant levels in soil not expected to cause ecological harm. A limiting factor is that EcoSSLs are No Observed Adverse Effect Level (NOAEL) screening benchmarks. Such values can help identify contaminants of concern, but are less useful to quantify risk or support risk management decisions. This study developed Lowest Observed Adverse Effect Level (LOAEL) EcoSSLs for terrestrial birds and mammals. The first step was to obtain the EcoSSL documents for each target contaminant and identify the NOAEL and LOAEL Toxicity Reference Values (TRVs) for reproduction and growth which were unbounded (i.e., derived from a study providing either a no effect or an effect value, but not both), bounded (i.e., derived from a study providing both no effect and effect values), or a compilation of both types of values. The latter were referred to as "combined TRVs". These TRVs were then used to calculate a geometric mean TRV for the three sets of toxicity values (i.e., unbounded TRVs, bounded TRVs, and/or combined TRVs) and the two toxicity levels (i.e., NOAELs and/or LOAELs). The second step used the food chain model and exposure parameters from the EcoSSL reports to "back-calculate" chemical-specific LOAEL-based wildlife EcoSSLs. The six receptors used by EPA in the original calculations were retained for this project. These species were two herbivores (mourning dove and meadow vole), two soil invertivores (American woodcock and the short-tailed shrew) and two higher trophic-level carnivores (red-tailed hawk and the long-tailed weasel). The lowest of the chemical-specific values for birds and mammals was selected as the final "bird" and "mammal" LOAEL EcoSSL. The calculations showed that, with a few exceptions, the two soil invertivores had the lowest LOAEL EcoSSLs. The accuracy of the food chain model and exposure parameters was also double-checked by recalculating NOAEL EcoSSLs and comparing these values against the original NOAEL EcoSSLs. This internal check showed that our food chain model, exposure parameters, and calculations were correct within rounding error. The LOAEL EcoSSLs developed for this project have been used successfully in several baseline ecological risk assessments to better evaluate the range of risks to terrestrial wildlife receptors exposed to soil contaminants.

WP123 Earthworm Behavior in Soils with Added Amendments, Various Agronomic Practices, and a Bioenergy Crop J. Choate, J.W. Klasky, Arkansas State Univ, Environmental Sciences; J.L. Bouldin, Arkansas State Univ, Dept of Biological Sciences, Arkansas State Univ, Environmental Sciences Graduate Program, Environmental Sciences Graduate Program, Arkansas State Univ, Dept of Environmental Science. Earthworm avoidance tests have advantages for use in soils for the determination of soil health, structure, and toxicants present. Since earthworms show behavioral responses at a lower scale than acute toxicity tests, avoidance tests are sensitive indicators of low-level contaminants. This avoidance is an ecological endpoint that is relative to the potential of the substrate's toxicity to organisms. When toxicants are present, impacts on earthworms can be tested in a short time frame. The influence of pollution and toxicants on earthworm

populations not only changes behavior but can also have an impact on the soil ecosystem. The experiments were conducted separately using three different soil medias. First, control soil was obtained and locally available soil amendments were added before the earthworms were introduced. Second, soil from a sorghum field (bioenergy crop) with varying nitrogen sources was utilized as a field representation of earthworm behavior. Third, soil was obtained from a cotton field with three different agronomic management regimes (no-tillage, conventional tillage, and cover crop). Results from the bioenergy crop soils indicate earthworms congregating behavior which suggests a soil preference due to the availability of food. Sensitivity of this research was approximate to the sensitivity of established tests. For soil amendments, a considerably higher sensitivity was determined as compared to soils from bioenergy crops. In tests with a control soil spiked with reference toxicants, worms avoided this soil and a high mortality rate was observed.

WP124 *Lobella sokamensis* (Collembola: Neanuridae) as a New Test Species to Assess Soil Toxicity Y. An, Konkuk Univ, Dept of Environmental Science; S. Kim, Konkuk Univ; W. Lee, Konkuk Univ, Konkuk Univ, Dept of Environmental Science. Collembola are one of the most abundant groups in soil ecosystems. *Lobella sokamensis* (Deharveng et Weiner, 1984) is in the Neanuridae family, which is one of the most diverse families belonging to Collembola). It is an orange-colored springtail. *L. sokamensis* is endemic species of Korea, commonly found with earthworms. The present study suggested *Lobella sokamensis* as a new test species to assess soil toxicity. The acute toxicities of zinc, copper, cadmium, antimony, and mercury on the survival of adults were performed in artificial soil. *L. sokamensis* juveniles (10-12 day old) were also exposed to Cd, Cu, and Sb, and 5d-LC50 was calculated. The survival of adults and juveniles were inhibited on metal spiked soil, and we found that *L. sokamensis* juveniles were sensitive enough to assess toxicity of contaminated soil system, compared with *F. candida* assay. We observed that 5d-acute soil test using *L. sokamensis* juveniles can be rapid and cost-effective protocols to assess soil toxicity.

WP125 Sensitivity Analysis on Terrestrial Risk Assessment Modeling to Aid the Development of Testing Strategy M. Fan, The Procter & Gamble Company; F. Verdonck, ARCHE; S. Gimeno, The Procter & Gamble Company; T. Delfosse, The Procter & Gamble Company, Product Safety & Regulatory Affairs; P. Sun, The Procter & Gamble Company. While terrestrial assessments may be performed less frequently than aquatic assessments, industry seeks to continuously improve experimental tools, models, and risk assessment implementation. Substances which are most likely to be of concern in the terrestrial environment include those that are persistent and lipophilic. Within new chemical management schemes such as REACh, it is anticipated that more testing will be required for such substances when a screening (and conservative) assessment indicates risk that depends greatly on screening level physical-chemical properties for prioritization. To facilitate the development of testing strategy for parameters and then refining the assessment, a sensitivity analysis for terrestrial risk assessment was conducted using EUSES (European Union System for the Evaluation of Substances) model. The key parameters for the analysis included sorptivity, biodegradability, volatility, and ecotoxicity. The focused parameters and their probability distributions were selected based on a targeted literature review. The Monte Carlo based method outputs were summarized using Spearman rank order correlation coefficients and tornado diagrams to evaluate the sensitivity of parameters contributing to the Risk Characterization Ratio (RCR). The result indicated octanol-water partition coefficient (Kow) is the most influential chemical property. Further analysis for parameters having non-linear effects on RCR (i.e., Kow, biodegradability class, vapor pressure) revealed that the trend for such effect may vary between point sources industrial release and wide dispersive use scenarios (e.g., higher sensitivity of biodegradation to RCR for hydrophilic substance in wide dispersive use, but no remarkable difference for the point sources release). Finally, look-up tables were developed for each defined class of use scenario, biodegradability, Kow and vapor pressure, with a 90th percentile RCR derived for a quick easy-to-use screening assessment purpose. Testing strategy can then be developed by targeting the most meaningful parameters that will refine the assessment and ensure the safe use of those substances.

WP126 Comprehensive Risk Assessment of a Proposed $300M Cleanup Plan at Sydney, Nova Scotia B. Magee, J. Keating-Connolly, ARCADIS; B. Chew, AMEC. Before implementing a comprehensive cleanup of 100 hectares of a former steel mill/coke oven complex, the Canadian Environmental Assessment Act required an Environmental Impact Statement, including a quantitative risk assessment of the proposed cleanup plan to ensure that the risks of the remedy did not pose unacceptable risks to human health and the environment. The risk assessment quantitated the risks of site constituents (benzene, toluene, ethylbenzene, xylenes, naphthalene, polycyclic aromatic hydrocarbons, polychlorinated biphenyls, and metals) and construction equipment related constituents (sulfur and nitrogen oxides, carbon monoxide, and fine and ultrafine particulate matter) associated with dozens of sources at dozens of specific locations. Sources included construction vehicle exhaust, dust from excavation, grading, transportation, loading and unloading, and stockpiling activities, and site-related volatile organic compounds from excavation, stabilization, and other activities. Because the proposed project was seven years in duration, many possible sequencing scenarios were evaluated to assess the impacts of different sources at different locations during different meteorological conditions. In addition, because the Final Design was not completed at the time of the assessment, different construction methods were assessed, such as ex situ versus in situ solidification/stabilization techniques and ambient stabilization versus stabilization in sprung structures to inform the Final Design. The risk assessment showed that the project could be completed safely, and it will be argued that performance of risk assessments during the design and evaluation of remedial planning can provide great value, especially at sites where the need for remedial actions is obvious. In addition, risk assessment is ongoing to ensure on a real time basis that remedial work is being done safely by the use of risk-based fenceline stop work criteria and community health criteria.

WP127 Ecological Risk Assessment & Site Management – Myths and Misunderstandings That Lead to Site Mismanagement T. Rodolakis, AMEC. Potentially responsible parties and agency regulators look at the same data when evaluating a site. Yet much of the time, the two parties draw very different conclusions as to the level of ecological risk and how that risk should be managed. Spirited discussions often ensue because one party believes that the policies and practices used by the other party to interpret the data are misguided or misapplied. Since final management decisions can be costly in terms of dollars, damage to habitat, and unintended harm to other ecosystem assets, it is critical that those decisions are technically sound. This presentation examines the myths, misunderstandings, and technical merits behind 7 ecological risk assessment and risk management practices that have costly consequences when applied incorrectly.

WP128 Residual Ecological Risk Assessment Case Study: Assessing Risk in Wetlands Habitat K. Bradley, GEI Consultants, Inc., Ecologist; C. Claytor, GEI Consultants, Inc.; A. Leifer, GEI Consultants; R.W. Gensemer, GEI Consultants, Inc, Ecological Division; R. Helfeld, Massachusetts Dept of Conservation and Recreation. A case study will be presented reviewing the challenges faced in the investigation of ecological risks in support of the selection of remedial approaches at a historic airport site in Canton, Massachusetts. The site is planned for redevelopment as a recreational park. A region of the site deemed the "Hangar Area," was not included in the ecological risk assessment (ERA) due to high concentrations of PCBs resulting in presumed risks to human and ecological receptors requiring active remediation. A residual ERA, designed to meet the requirements of both the Massachusetts Contingency Plan and the Federal Toxic Substances Control Act, focused on the potential for ecological risks beyond the footprint of anticipated remediation throughout the wetland areas located on the site. The ERA process incorporated analytical sediment, surface water, soil and tissue data, a vegetative community assessment, and sediment toxicity data associated with these areas anticipated to remain post-remediation. Results of the residual risk characterization were evaluated using a weight of evidence procedure. The ERA identified a limited potential for residual risks to ecological receptors exposed to lead and zinc, and to a lesser extent, chromium, vanadium, and PCBs in site media. However, the overall confidence in the predicted risks at the site was only low to moderate based on the weight of evidence analysis. Ecologically based remediation goals (RGs) were proposed for PCBs by compiling all toxicity reference values used in the ERA and resolving each value to a protective soil or sediment concentration. Individual location RGs (protective of sessile organisms) were determined to be 0.7 mg/kg dw of PCBs in sediments and 25 mg/kg dw of PCBs in soils. Site-wide average RGs (protective of large-range wildlife receptors) were determined to be 90 mg/kg dw of PCBs in sediments and 50 mg/kg dw of PCBs in soils. Ultimate remedial decisions regarding portions of the site outside the

Hangar area will, however, require a balance between reduction of risk to ecological receptors as identified in the residual ERA with protection of valuable wetland habitats. The site is located within an area designated as an Area of Critical Environmental Concern (ACEC) by the Massachusetts Executive Office of Environmental Affairs.

WP129 Will Ocean Acidification Affect Metal Uptake by the Marine Bivalve *Mytilus edulis*? W.E. Robinson, Univ of Massachusetts-Boston, EEOS Dept; H.C. Poynton, US Environmental Protection Agency, Molecular Indicators Research, Univ of Massachusetts-Boston, Environmental, Earth and Ocean Sciences; R.E. Hannigan, Univ of Massachusetts-Boston, EEOS. Increasing atmospheric pCO_2 has gradually lowered the pH of seawater from 8.2 in preindustrial times to 8.1 today. Some models predict that seawater pH could drop below 7.8 by 2100. These declines represent a 26 % increase in hydrogen ion concentration [H^+] since preindustrial times, and a 151 % increase in [H^+] by 2100. Studies of the biological consequences of this ocean acidification have primarily focused on reduced biocalcification (corals, pteropods, urchins and bivalves). However, an even more fundamental impact has received little attention – changes in metal speciation, uptake, and blood transport. The equilibrium speciation program MINTEQA2 was used to calculate changes in seawater free ion activity for a number of divalent metals (e.g., Ca, Cd, Cu, Ni, Zn) under a range of pH values (8.2 to 7.8). While some metals exhibited increases in free ion activity (e.g., Pb^{2+}, Cu^{2+}, Zn^{2+}), metals that are already predominantly present as free metal ion (e.g., Ca^{2+}) or that are complexed by chlorides (e.g., Cd^{2+} or Ni^{2+}) showed little change. Based on the Free Metal Ion, and the Biotic Ligand, models of metal uptake, we hypothesize that metals exhibiting an increase in free metal ion activity as a result of ocean acidification (e.g., Pb) will increase metal uptake whereas metals not exhibiting elevated free metal ion activity (e.g., Cd) will exhibit no change in uptake. To test this prediction, mussels are exposed to a mixture of metals (Cd + Pb) at three different pH levels (8.1 control, 7.8, 7.5). At Tzero, 15, 30 and 45 d, seven mussels will be dissected from each exposure tank, hemolymph removed, and the tissues analyzed for Cd and Pb concentrations. Hemolymph will be assayed for pH, protein, and free Ca^{2+} ion activity (ISE) in order to assess acid-base imbalance.

WP130 Effects of Atmospheric CO_2 on the Life Cycle and Fitness of the Mysid Shrimp *Americamysis bahia* L.S. Grear, US Environmental Protection Agency, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, Office of Research and Development, USEPA; D. Horowitz, US Environmental Protection Agency, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, Office of Research and Development, USEPA, ORD, NHEERL, Atlantic Ecology Division; R. Gutjahr-Gobell, M. Bernardo, US Environmental Protection Agency, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, Office of Research and Development. Most concern about effects of CO_2-induced ocean acidification focuses on mollusks, corals, and coccolithophores because skeletal and shell formation by these organisms is sensitive to the solubility of calcium minerals. However, many other marine organisms are likely affected by calcium availability and other acidification-related conditions such as altered cellular acid-base balance. We studied responses of the mysid *Americamysis bahia* under ambient and increased CO_2 conditions in flow-through aquariums. This included bubbling ambient and CO_2-enriched air into aquarium seawater to simulate predicted increases in anthropogenic CO_2. Our experiments included a cohort study (initiated with 1-day old groups of individuals) as well as a 5-month study of demographic responses in intact, size-structured populations. The cohort study was intended to simulate a CO_2 increase of 100-200 parts per million (partial pressure), which is within the range of that expected during the next century. Responses were monitored weekly by counting and sizing individuals. The strongest response was in the number of neonates present at the end of the third week, which was 3 times higher in the ambient control than in the CO_2 treatment (5 aquaria per treatment; each aquarium initiated with ten 1-day old individuals). The demographic study was smaller (2 tanks per treatment) but ran for twenty weeks and produced ~7500 mysid length measurements. Effects were less clear, but combined with cohort results, suggest that ocean acidification has the potential to affect the demography of marine crustacean populations. Monitoring of carbonate system characteristics in our study was limited, so further studies are needed. These studies should include a gradient of realistic CO_2 manipulations and should recognize the potential for differences between cohort-level and population-level responses.

WP131 Impacts of Ocean Acidification on Copper Speciation and Toxicity M. Grosell, Univ of Miami, RSMAS; K. Munley, A. Esbaugh, RSMAS, Univ of Miami; K.V. Brix, Univ of Miami, RSMAS, Marine Biology and Fisheries; F. Millero, RSMAS, Univ of Miami. The oceanic carbonate system (partial pressure of CO_2, pH and alkalinity) is changing rapidly due to an increased uptake of anthropogenic CO_2 from the atmosphere. Current CO_2 levels of ~380 ppm exceed pre-industrial levels of 280 ppm and have resulted in a reduction of oceanic pH by ~0.1. Furthermore, CO_2 is expected to rise to levels possibly exceeding 1000 ppm by the year 2100 and ~1900 ppm by 2300, yielding oceanic pH reductions of 0.3-0.4 and 0.7-0.8 units, respectively. Placing this in perspective, the current rate of change in atmospheric CO_2, and thus the oceanic carbonate system, is ~100-times faster than what has occurred in the past 650,000 years, posing a challenge to marine organisms and ecosystems. The predicted acidification will result in a change in inorganic copper speciation, leading to more than a doubling and nearly a three-fold increase in the fraction of copper present as ionic Cu^{2+} by the years 2100 and 2200, respectively. From this speciation change alone, copper toxicity in seawater is expected to increase significantly. Elevated CO_2 and ocean acidification challenge acid-base balance in marine organisms, a physiological parameter also affected by copper exposure. Thus, it is hypothesized that in addition to the direct effects of altered copper speciation, synergistic effects between exposure to elevated CO_2, reduced pH and substantially increased ionic copper will significantly increase copper toxicity. Ongoing embryo-larval toxicity tests on the marine pelagic fish cobia (Rachycentroncanadum) aim at testing this hypothesis under current and predicted future CO_2 and ocean acidification scenarios.

WP132 Is Sulfur in Scallop Shells an Indicator of Stress Response in Ocean Acidification? B. Broadaway, R. Hannigan, Univ Of Massachusetts Boston, Environmental, Earth, and Ocean Sciences. The burning of fossil fuels, and other natural processes, has led to an increase of carbon dioxide in the atmosphere. The equilibration of atmospheric carbon dioxide with surface waters causes the ocean pH to decrease from the current value of 8.1 through ocean acidification. Evidence suggests that as the ocean becomes more acidic, organisms such as the bay scallop, Argopecten irradians, will become more stressed due to increased energy demands to maintain shell deposition and growth. This stress, as hypothesized here, may cause an increase in the deposition of S-bearing organic macromolecules to aid in mineralization. There is also a potential for deposition of mineralized sulfate if the availability of carbonate species becomes limited. In the laboratory, Argopecten irradians were reared under air-carbon dioxide mixtures (pH = 8.0, 7.8, 7.5). Measurements of aquaria water quality (dissolved pCO_2, alkalinity, dissolved organic carbon, salinity, temperature, and pH) were measured or modeled. Fourier transform infrared spectroscopy was used to investigate the inorganic and organic shell matrix composition (pre-and post-treatment). Using principal component analysis, we identified changes in calcite, amide, and S-bearing macromolecule composition in shells of animals raised under acidic conditions. Impacts on growth and survival were also noted.

WP133 Ocean Acidification in Estuaries: Interactive Effects of Temperature, Salinity and Elevated P_{CO2} on Biomineralization and Metabolism of Oysters I. Sokolova, A. Ivanina, Univ of North Carolina at Charlotte, Dept of Biology; G. Dickinson, E. Beniash, Univ of Pittsburgh, Dept of Oral Biology. Rising atmospheric CO_2 levels lead to ocean acidification (OA), which can negatively impact calcifying organisms including mollusks. In estuaries, exposure to elevated P_{CO2} often co-occurs with other stressors, such as fluctuating salinity and temperature, that can affect seawater chemistry, alter physiology of estuarine calcifiers and modify their response to OA. We studied the interactive effects of salinity or temperature combined with elevated P_{CO2} on biomineralization and energy homeostasis in oysters *Crassostrea virginica*. In one experiment, juvenile oysters were exposed to one of two environmentally relevant salinities (30 or 15‰) either at current atmospheric P_{CO2} (~400 µatm, normocapnia) or P_{CO2} projected by moderate IPCC scenarios for the year 2100 (~700-800 µatm, hypercapnia). In a separate experiment, adult oysters were exposed to a combination of two temperatures (22 and 27°C) and P_{CO2} (~400 and 800 µatm). We found that salinity and temperature modify physiological and biomineralization responses of oysters to hypercapnia. Exposure of juvenile oysters to elevated P_{CO2} and/or low salinity led to a significant increase in mortality, depletion of tissue energy stores (glycogen and lipid) and negative soft tissue growth, indicating energy deficiency. However, tissue ATP levels were not affected by exposure to salinity and P_{CO2} stress suggesting that the juveniles maintain

their cellular energy status at the expense of lipid and glycogen stores. In adults, elevated temperature alone or in combination with high P_{CO2} did not affect respiration rate or tissue energy status. Elevated P_{CO2} at 22 or 27°C led to transient oxidative stress in adult oysters indicated by accumulation of malondialdehyde- and 4-hydroxynonenal- protein conjugates. Exposure to hypercapnia combined with low salinity or elevated temperature stress negatively affected mechanical properties of oyster shells, resulting in reduced hardness and/or fracture resistance. Overall, our data show that juveniles are more sensitive to elevated P_{CO2} than adults. Weakened shells and elevated basal energy demand in juveniles exposed to elevated P_{CO2} (especially at low salinity) can reduce their protection against predators and other stresses, and divert metabolic resources from fitness-related functions such as growth and maturation. These changes are likely to negatively affect the survival of oyster populations in the face of OA. Supported by NSF award IOS-0951079.

WP134 Ocean Acidification Inhibits Navigation of Larval Orange Clownfish, *Amphiprion percula* E. Wilcox Freeburg, Univ Of Massachusetts Boston; A. Rhyne, Roger Williams Univ; M. Tlusty, The New England Aquarium; R. Hannigan, Univ Of Massachusetts Boston, Environmental, Earth, and Ocean Sciences. Recent research into the impact of ocean acidification on marine organisms shows mixed responses in terms of calcification rate and behavioral endpoints. In particular, several studies on marine fish discuss potential susceptibility of specific fish species to olfactory sensory malfunction. Conflicting reports show earstone, or otolith, growth to be normal or accelerated. A combination of olfactory and gravitational ("hearing") cues is necessary for proper navigation and therefore survival. *Amphiprion percula*, orange clownfish, was tested for endpoint behavioral change in response to extant and predicted levels of pCO_2. We hypothesize that larval posture and post-settlement holding of station may be impacted under higher CO_2 conditions due to impacts on the growing otolith. This hypothesis is supported by some evidence that larval otoliths grow more rapidly and are possibly dominated by vaterite when raised under low pH/high CO_2 conditions. Future work will seek to elucidate the cause of the behavioral changes observed in this study.

WP135 Use of Caged Zebrafish Juveniles as Indicators of Pollutant Effect in Karstic Water Bodies G. Rodriguez Fuentes, Centro para el Estudio del Agua, Unidad de Ciencias del Agua-CICY, Centro para el Estudio del Agua, Unidad de Ciencias del Agua-CICY, Centro para el Estudio del Agua; M. Soto, Roger Williams Univ, Marine Biology, UNAM, Instituto de Ciencias del Mar y Limnologia, Roger Williams Univ, Marine Biology, UNAM, Instituto de Ciencias del Mar y Limnologia, Roger Williams Univ, Marine Biology. Yucatan Peninsula is a predominantly flat limestone region in the Southeast of Mexico. Bodies of surface water and streams are scarce or absent. Groundwater is the main source for human, industrial and agricultural consumption. Karstic areas in Yucatan are very permeable and are thus highly susceptible to aquifer contamination, some reports have already demonstrated groundwater contamination, but studies about organic pollutants are rare. A remarkable feature of the Peninsula, especially in the North, is the presence of cenotes that are water-filled sinkholes formed by the dissolution of limestone by carbonic acid. Cenotes have a high ecological value since they provide water and habitat for numerous species, some of them endemic. In this study we evaluated gene expression of vitellogenin (VTG) and cytochrome P-450 1A (CYP1A) in caged juvenile zebrafish. Cages were located in 13 different cenotes or aguadas" (obstructed cenote), organisms were exposed during 15 days. Gene expression was evaluated using quantitative RT-PCR. Results indicated over expression of VTG gene in 7 water bodies. The highest relative expression was found in an "aguada" close to a cattle farm where VTG expression was more than 3000 times higher than expression found at controls. CYP1A over-expression was located in 3 water bodies, all of them located near villages or used for tourist activities. Monitoring of pollutants and biomarkers of effect should be done in these water bodies, in order to have a better understanding of the actual levels of pollutants that are present at Yucatan's aquifer.

WP136 Sensitivity of the Vitellogenin Assay: Ability to Discriminate Among Exposure Concentrations in Adult Fathead Minnows R. Flick, USEPA, Office of Research and Development, USEPA, National Exposure Research Laboratory, USEPA, NERL; M. Crane, USEPA, National Exposure Research Laboratory; K. Jensen, USEPA, NHEERL; J. Oris, Miami Univ, Dept of Zoology. Vitellogenin is often used to infer exposure of an organism to estrogenic substances. Vitellogenin gene induction and protein levels increase, up to a point, with concentration of estrogen and duration of exposure. A biomarker such as vitellogenin should exhibit sufficient sensitivity that it can discriminate among exposure concentrations to an extent greater than simple presence/absence of a contaminant. The goals of this study were to investigate the sensitivity of the vitellogenin assay and to determine if longer exposures increased sensitivity under controlled laboratory exposures. Fathead minnows were exposed to concentrations of ethinyl estradiol ranging from 0.05 to 100 ng/L for 48 hr, 96 hr and seven days in a flow-through diluter system. Vitellogenin gene expression was quantified in liver tissue and vitellogenin protein was quantified in plasma. Gene expression patterns were similar at 48 and 96 hr, but at 7 days expression was highly variable over many concentrations and the ability of the assay to discriminate among concentrations less than at the other two time points. Shorter exposures may provide greater sensitivity than longer exposures and are likely more tractable and cheaper to perform.

WP137 Application of a Long-Established Molecular Marker in Larval Teleosts to Evaluate Estrogenic Potential in Surface Waters and Wastewater Effluents T.V. Reddy, US Environmental Protection Agency, National Exposure Research Laboratory; D. Lattier, US Environmental Protection Agency, Ecological Exposure Research Division; J.M. Lazorchak, D.A. Gordon, US Environmental Protection Agency, National Exposure Research Laboratory; M.E. Smith, The McConnell Group, Dynamac Corp., c/o United States Environmental Protection Agency. In recent years molecular indicators, diagnostic for exposure in aquatic systems, have been developed using teleostean models in laboratory and field settings. Our laboratory has previously shown that the gene for vitellogenin (VTG), a protein precursor of egg yolk in oviparous animals, can be induced to express in fathead minnow (FHM; *Pimephales promelas*) swim-up fry. FHM are widely distributed freshwater fish and fundamental among USEPA standard aquatic toxicology models. Early life stage (ELS) *P. promelas*, 48 hr post hatch and long-pec embryos, are currently being used as adult surrogates to measure transcription of Vtg, indicative for waterborne estrogen active compounds. The described ELS organisms were exposed to control (0), 0.625, 1.25, 2.5, and 5.0 ng L-1 of the synthetic estrogen, 17α ethynylestradiol (EE2). Following exposure, total RNA was isolated from single larvae in addition to statistically requisite numbers of groups comprising pooled larvae in quantities of 5 and 10. Synthetic oligonucleotide primers, specific for *P. promelas* VtgI transcripts, were used to thermally amplify RNA by way of QPCR. Analyses of data obtained thus far, suggests that use of ELS bioindicators affords a viable approach to detect estrogenic EDCs. Having yet to analyze RNA representing the range of exposure concentrations, the level of Vtg detection in FHM larvae (5.0 ng L-1) suggests that results are equal to values obtained from QPCR amplification of liver-specific RNA from adult FHM exposed to the same concentration of EE2 for 48 hrs. Although not a specific aim in development of this method, we nevertheless note that EE2 induced expression of FHM Vtg was measurable in single larva. The rationale for our bioindicator design is manifold. Use of larval organisms significantly reduces biomass, which is reflected in scale of exposure; achieved by means of fewer resources with substantial cost savings in culturing, labor, and exposure volumes. Larval fish are nevertheless regarded as 'whole animals'; however, experimental procedures carried out with limited ELS biomass, is a step toward future Agency compliance, and likely to be perceived as more palatable by those advocating for animal welfare. In addition to considerable cost and time savings, elimination of animal necropsy is a welcome facet of this protocol. This approach provides a simple, economical and transferable monitoring routine for surface waters and WWTP effluents.

WP138 Metallothionein and Vitellogenin Genes of Zacco Platypus and Their Biomarker Potential for Aquatic Contaminants S. Lee, Seoul National Univ, School of Public Health; S. Kim, Seoul National Univ, School of Public Health, Room # 736, Bldg # 220,; J. Kim, Korea Advanced Institute of Science and Technology; W. Kim, J. Kim, Korea Institute of Toxicology; H. Shin, C. Choi, Korea Maritime Univ; S. Lee, Korea Institute of Toxicology; K. Choi, Seoul National Univ, School of Public Health. *Z. platypus*, a freshwater teleost, is widely distributed in Korea and eastern Asia, and is considered as a candidate species that can be used as an indicator reflecting the regional aquatic ecology. The need for developing sensitive biomarkers that may reflect adverse impacts of chemical exposure is present for *Z. platypus*. In this study, we employed *Z. platypus* as a potential indicator species, and evaluated *metallothionein* (*MT*) and *vitellogenin* (*VTG*)

genes for the usefulness as biomarkers of exposure to metals and endocrine disrupting chemicals. For this purpose, we carried out phylogenetic study with cDNA sequences of both genes of *Z. platypus*. For phylogenetic analysis, BlastX searching was conducted to compare amino acid sequences and ClustalX, BioEdit and Mega 4 software were used to construct phylogenetic tree. Quantitative PCR analysis was conducted after the 14 d exposure to cadmium (Cd) and bisphenol A (BPA), and responses of both genes were measured. After exposure liver tissue of three individual *Z. platypus* were pooled for the quantitative PCR analysis. The phylogenetic analysis of cDNA sequences of both genes demonstrated high conformity with the genes of other teleost species, suggesting similar functions of these genes in this indigenous fish. *MT* and *VTG* mRNA expressions showed positive linear relationship with Cd and BPA exposures. The mRNA expression of *MT* showed significant dose-dependent positive trend in both male and female after Cd exposure (p for trend = 0.012 in male, and 0.013 in female). *VTG* mRNA expression also showed positive linear trend after BPA exposure (p for trend = 0.004 in female, and p for trend = 0.112 in male). Both genes were determined to be useful biomarkers of metal and endocrine disrupting chemicals exposure in *Z. platypus*.

WP139 DNA Damage in Cichlid Fish and Environmental Forensic Analysis of the Origin of PAHs at a Guatemalan Oil Field C. Theodorakis, Southern Illinois Univ Edwardsville, Dept of Biological Sciences and Environmental Sciences Program, Southern Illinois Univ Edwardsville, Environmental Sciences; J. Bickham, Purdue Univ, Center for the Environment; K.C. Donnelly, Texas A&M Univ, Dept of Veterinary Anatomy and Public Health; T. McDonald, Texas A&M Univ, Dept of Civil Engineering. This study focused on several wetlands in Laguna del Tigre National Park (Guatemala) as part of Conservation International's Rapid Assessment Program. Sediment and water samples were collected from a laguna near Xan field, Guatemala's largest oil facility, and 3 other sites for determination of levels of polycyclic aromatic hydrocarbons (PAHs). Cichlid fish (*Thorichthys meeki* and *Vieja synspila*) were collected for determination of DNA strand breakage (by gel electrophoresis) and chromosomal breakage (flow cytometry). PAHs in water and sediment were extracted with methylene chloride and analyzed by GC/MS. Environmental forensic analysis was also carried out using three metrics to draw inferences about the origin (pyrogenic, petrogenic, diagenic) of the PAHs in the sediment. These metrics included a) concentration (mg/kg) of PAHs with 4 or more rings, b) a "pyrogenic index" defined by as ∑(all other 3-6 ring PAHs)/∑(alkylated [napthalenes, phenanthrenes, dibenzothiophenes, fluorenes, and chrysenes]), and C) ratio of chrysene/ phenanthrene in sediments. Multivariate analyses were also used to analyze all three of these variates together. For *T. meeki* from Xan field, chromosomal breakage and strand breakage was greater than in at least two of the three reference sites. For *V. synspila*, chromosomal breakage and strand breakage were greater in Xan than one of the two reference sites. Patterns of aqueous PAH concentrations, suggests that fish are affected by anthropogenic contaminants. PAHs were elevated at some reference sites, but environmental forensic analysis suggested a pyrogenic or diagenic origin. The environmental forensic analysis also suggested that PAHs near the oil well injection site were primarily of petrogenic origin, and the ratio of petrogenic:pyrogenic PAHs decreased with distance from the oil field. The data are consistent with the hypothesis that oil field brines injected into the ground water caused genotoxicity in fish at Xan field, and it is also possible that pyrogenic PAHs influence levels of DNA damage in reference sites. These analyses represent one of the first efforts to examine genotoxicity in native Mesoamerican cichlids.

WP140 Evidence that Oil Droplets Contribute Only to a Limited Extent to the Overall Toxicity of Oil Dispersion to Larvae of Atlantic Cod (Gadus morhua) B. Hansen, SINTEF Materials & Chemistry, Marine Environmental Technology; P. Olsvik, NIFES; T.R. Storseth, SINTEF Fisheries and Aquaculture; D. Altin, BioTrix; A.J. Olsen, Norwegian Univ of Science and Technology, Biology; I. Overrein, SINTEF Fisheries and Aquaculture; F. De Laender, Laboratory of Environmental Toxicology and Aquatic Ecology, Ghent Univ; T. Nordtug, SINTEF Materials and Chemistry, Marine Environmental Technology. Oil exploration in the Atlantic moves towards spawning and nursery areas of fish species that sustain some of the world's largest fishery industries. Numerical models are needed to predict the fate of accidentally oil spilled and its toxic effect on local biota. Toxicity is expected to be caused by the water soluble fraction of dispersed oil, however, little is known about the possible effects of oil droplets. A custom made exposure rig was built for assessing the effects of oil droplets, and first feeding cod larvae were exposed for four days to either dispersed oil (with oil droplets) or the corresponding filtered dispersion (the water soluble fraction [WSF]) at six concentrations. The endpoints analysed for ranged from molecular (transcriptomics and metabolomics) to fitness-related (survival probability and assimilation rate). A concentration-dependent decrease in survival probability was observed following exposure to dispersed oil with EC50 of about 40 µg/L ΣPAH. Microarray analyses revealed that oil exposure affects drug metabolism, endocrine regulation, cell differentiation and proliferation, apoptosis, fatty acid biosynthesis and tissue development. A set of differentially regulated transcripts encoding proteins involved in bone development suggests that oil exposure may negatively affect skeletal system development. These observations were supported by a concentration dependent decrease in growth and assimilation rate with EC50 of about 2 µg/L ΣPAH. In conclusion, the results from this experiment indicate that numerical models that explicitly consider oil droplet toxicity – in addition to the toxicity of the WSF – on the examined endpoints are therefore unlikely to be more accurate than models that neglect oil droplet toxicity.

WP141 Enhanced Fluorescent Protein Transgenic *Daphnia magna* and Their Applications T. Le, Chonbuk National Univ, Dept of Bioprocessing Engineering; S. Lee, Korea Research Institute of Chemical Technology, Toxicology Research Center; Y. Kim, Chungbuk National Univ , School of Life Science; J. Min, Chonbuk National Univ, Dept of Bioprocess Engineering. A transgenic water flea, *Daphnia magna*, able to express a green fluorescent protein has been created to establish a novel system for a rapid detection of environmental stress. A 32bp DNA fragment containing the 18s-ribosome constitute promoter of *Daphnia* was generated by invitro annealing the commercial primers at 80oC. This *Daphnia* 18s-ribosome DNA (D18s) was inserted and replaced the CMV promoter fragment that was located ahead to the gfp gene in the EGFP vector (Enhanced Green Flourescent Protein). The successful recombinant plasmid confirmed by the DNA sequencing was introduced into the earlier developing-state *Daphnia* eggs (round shape) using microinjection technique. After 48h incubation in the 20oC chamber, the injected eggs able to develop to juveniles were observed at the 488nm wavelength by the confocal fluorescent microscope to confirm the presence of green fluorescent protein. Our results show that the green fluorescent protein was substantially found in the upper part of the transgenic organisms (e.g., head, back) while no fluorescent signal was detected in the control organism. It demonstrated that a transgenic *D. magna* expressing green fluorescent protein was firstly generated and would be promising to build a novel testing system for easily monitoring environmental stress.

WP142 Identification and Characterization of an Superoxide Dismute Genes (SOD) in *Chironomus riparius* Exposed to Environmental Pollutants S. Park, P.M. Nair, Univ of Seoul; J. Choi, Univ of Seoul, School of Environmental Engineering. Superoxide dismutase (SOD, EC 1.15.1.1) represents one kind of enzyme involved in scavenging the high level of reactive oxygen species (ROS) into molecular oxygen and hydrogen peroxide. In this study, a copper/zinc superoxide dismutase (Cu/ZnSOD) gene and a manganese superoxide dismutase (MnSOD) gene of *Chironomus riparius* (CrSODs) was identified from Expressed Sequence Tags (ESTs) database generated using pyrosequencing. A multiple sequence alignment of C. ripairus sequences revealed high homology with other insect sequences the amino acid level. Phylogenetic analysis of CrSODs grouped it with SODs of other insect taxa. CrSOD genes expression was analyzed during different in response to treatment with various concentrations of environmental stresses for variety of time interval. Cadmium dichloride (CdCl2) as heavy metal, nonylphenol (NP) as endocrine disrupting chemical (EDCs), silver nanoparticles (AgNPs) as nano material were used as stressors. These results show that SOD enzyme have important role and its potential as a biomarker to various environmental pollutants. Keywords : *C. riparius*, Superoxide dismutase (SOD) This work was supported by Mid-career Researcher Program through NRF grant funded by the MEST(2010-0027722)

WP143 Characterization of a cDNA of CYP1A1 and its Modulation by Environmental Xenobiotics in Fourth Instar Larvae of *Chironomus riparius* P.M. Nair, S. Park, G. Chung, Univ of Seoul; J. Choi, Univ of Seoul, School of Environmental Engineering. Modulation of Cytochrome P450 super family of genes by environmental xenobiotics is used as a potential biomarker in ecotoxicological studies. They are highly inducible at the

transcript and enzyme level by a variety of environmental pollutants. A 1978 bp CYP1A1 cDNA was identified by screening through a ESTs data base developed from the fourth instar larvae of *Chironomus riparius* using 454 pyrosequencing. The CYP1A1 cDNA included an open reading frame (ORF) of 1587 base pairs (bp) encoding a putative protein of a 528 amino acid protein. There was a 267 bp 5' and a 123 bp 3' untranslated region with a polyadenylation signal site (AATAAA). Alignment of the deduced amino acids of *C. riparius* CYP1A1 cDNA showed high level of sequence similarity to homologous CYP1A1 from other species and the presence of conserved amino acids. *CrCYP1A1* had a putative heme-binding cysteine at position 471 in the typical P450 signature sequence of 463- FGIGPRNCIG-473. The phylogenetic relationships of CYP1A1s among 13 fish species were analyzed by a distance method. The CYP1A1 transcript was present at all life stages. Modulation in the transcript level of CYP1A1 gene was observed after exposure to different environmental pollutants and the results are discussed. Key words: *C. riparius*; CYP1A1; Cadmium; Benzo[*a*]pyrene; BPA; Nonylphenol; Chlorpyrifos This work was supported by Mid-career Researcher Program through NRF grant funded by the MEST(2010-0027722)

WP144 Chitobiase Activity as a Measure of Recovery in *Daphnia magna*: Application to Pulsed Exposure to Glyphosate and its Formulations J.L. Rodriguez Gil, Guelph Univ, School of Environmental Sciences, Univ of Guelph, School of Environmental Sciences; K. Solomon, Univ of Guelph, School of Environmental Sciences, Univ of Guelph, Centre for Toxicology, School of Environmental Sciences; M. Hanson, Univ of Manitoba, Dept of Environment and Geography, Univ of Manitoba, Faculty of Environment; R. Prosser, Univ of Guelph, School of Environmental Sciences. Chitobiase is a chitinolytic enzyme released into aquatic systems by zooplankton during ecdysis. Previous research has shown that the activity of chitobiase in the surrounding media is positively correlated with growth in various species of freshwater and marine zooplankton. Therefore, chitobiase shows potential as measure of recovery after exposure to stressors that inhibit growth. The aim of this study was to evaluate whether chitobiase activity in the surrounding media of pre-exposed *Daphnia magna* individuals could provide similar or, preferably, better results than conventional predictors of recovery, such as time to first brood or number of neonates, as this could make the assay more rapid and cost-effective. In this study, *D. magna* were exposed for 48 hr to a range of concentrations of glyphosate, the surfactant MON 0818, and a glyphosate formulation containing the surfactant. Following exposure, individual *Daphnia* were transferred into clean reconstituted water and the activity of chitobiase released by each individual was measured every 48h for a total 14 days. Time to first brood and the number of neonates produced in the first brood were also determined during the recovery period. Chitobiase activity exhibited a hormetic response during the 96h after transfer, with greater activities observed for intermediate concentrations. Complete recovery, defined as the lack of significant differences from the control on any of the studied parameters occurred in all tested concentrations of MON0818. Chitobiase activity, number of neonates in the first brood, as well as time to first brood, were significantly lower in the daphnids exposed to high concentrations of glyphosate or the tested commercial formulation as compared to MON0818 alone. The results indicate that activity of chitobiase may be an effective measure of recovery for *D. magna* and possibly other freshwater arthropods.

WP145 Characterization of Controlled Release Formulations of Novaluron P. McManus, J. Seredy, L. Veldhuis, J. Hall, Univ of Guelph, school of environmental science. Mosquitoes pose a serious risk to public health around the globe as vectors of human pathogens such as the West Nile virus. Since 2002, about 34000 cases of West Nile viral infection in humans have been reported in Canada and the USA, resulting in hospitalizations and deaths. Consequently, it is extremely important to control mosquito populations especially at their breeding sites, i.e., standing water systems. A number of pesticides including novaluron, a member of benzoylphenyl urea family, are effective at controlling mosquitoes. Two new slow-release, wax-based formulations containing novaluron have been developed to regulate the release of the active ingredient in standing water. The goal of this research is to determine how pH, salinity, water hardness, organic matter and temperature affect the release and efficacy of novaluron. Of the parameters tested, only temperature affected the rate of release of novaluron from the formulations, while only organic matter reduced the concentration of novaluron once it partitioned into water. The slow release formulation provided effective mosquito control for at least 6 months making these formulations more effective than the EC formulation for long-term mosquito control.

WP146 Early Life Stage Toxicity of Select Pharmaceuticals to the Fathead Minnow, *Pimephales promelas* M.D. Overturf, C. Overturf, Univ of North Texas, Dept of Biological Sciences; L.A. Constantine, Pfizer Global Research and Development, Pharmacokinetics, Dynamics & Metabolism, Pfizer, Inc., Pharmacokinetics, Dynamics and Metabolism; D.B. Huggett, Univ of North Texas, Dept of Biological Sciences. Human pharmaceuticals are routinely being detected in the environment and there is growing concern whether these drugs could elicit effects on aquatic organisms. Regulatory paradigms have shifted accordingly, with a greater emphasis on chronic toxicity data as opposed to acute data. The OECD 210 Early Life Stage Test has been proposed as a good measure of the potential for pharmaceuticals to elicit chronic toxicity. To begin building a dataset regarding the early life stage toxicity of pharmaceuticals to fish, fathead minnows (FHM) were exposed to amiodarone, carbamazepine, clozapine, dexamethasone and fenofibrate. Survival and growth were used to assess chronic toxicity in FHM at 28 days post-hatch. Exposure of FHM to carbamazepine and fenofibrate resulted in no significant adverse effects at the concentrations tested. Dexamethasone exposed FHM showed a significant decrease in survival at a concentration of 576.8 mg/L; however, growth was not impacted at the concentration tested. Exposure to amiodarone and clozapine resulted in a significant decrease in survival and a significant increase in growth at concentrations of 1021.1 and 30.8 mg/L, respectively. As the effect levels derived in this study are above concentrations observed in the environment, these data suggest that these pharmaceuticals present a low risk to larval fishes.

WP147 Ecotoxicity of Sediments Sampled in Urban Rivers and Streams Dominated by Domestic Sewage: Potential Contributions of PPCPs Y. Yasuda, J. Morita, I. Tamura, Univ of Tokushima; N. Nakada, M. Narumiya, S. Hanamoto, Kyoto Univ; Y. Kameda, Saitama Institute of Environmental Sciences; K. Kimura, Saitama City Institute of Health Science & Research; H. Yamamoto, The Univ of Tokushima, Faculty of Integrated Art & Science. We have investigated the aqueous concentrations of PPCPs and their possible contributions on whole toxicity of the water samples collected in urban rivers and streams in Tokushima, Kyoto, and Saitama, Japan, dominated by treated or untreated domestic sewage. Combining the whole toxicity tests of the water samples, detected concentrations of PPCPs, toxicity tests for individual PPCPs using green algae (*Pseudokirchneriella subcapitata*), cladoceran (*Ceriodaphnia dubia*) and fish (*Danio rerio*), slight contribution on the cladceran reproduction or survival and moderate to relatively high contribution on algal growth were observed. The potentially strong contributors among the PPCPs include antimicrobials such as triclosan and triclocarban. In present study, we sampled both water and sediment at the sites we previously examined the aqueous samples, and tested the sub-chronic toxicity on benthic organisms (Chironomus yoshimatsui and *Hyalella azteca*) As results of the whole sediment toxicity, we found slight toxicities for the organisms. We also conducted toxicity tests for individual PPCPs, in particular those with relatively higher hydrophobicity and detected concentrations, such as triclosan, oxybenzone, and octylmethoxycinnamate. The contribution of these compounds are limited most of the case, and some other compounds such as heavy metals and PAHs are the possible main contributors of whole sediment toxicity. Results of our study could contribute the possible prioritization of PPCPs to be further investigated.

WP148 Applicability of Standard Antibiotic Toxicity Tests to the Ambient Aquatic Environment F.L. Hellweger, Northeastern Univ, Northeastern Univ, Civil & Environmental Engineering; X. Ruan, E. Cherchia, S. Sanchez, Northeastern Univ. The dissolved organic matter (DOM) concentration in conventional minimum inhibitory concentration (MIC) laboratory assays is typically three orders of magnitude higher than in the ambient aquatic environment. Partitioning of the antibiotic to DOM could affect bioavailability or potency. This question was investigated using laboratory experiments with *E. coli*, tetracycline and DOM varied over six orders of magnitude, which resulted in the same toxicity endpoint of 1 mg/L.

WP149 Do Antidepressant Mixtures Have Additive Effects on Fish Predatory Behavior? J.H. Bisesi, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX); K. Johnson, Southern Illinois Univ at

Edwardsville, Dept of Chemistry & Environ. Sciences; S.J. Klaine, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX), Clemson Univ, Institute of Environmental Toxicology (ENTOX) The concentrations of antidepressants detected in the effluent and receiving streams of wastewater treatment plants have been shown to be relatively non-toxic in traditional toxicity tests. But the neurochemical mode of action of antidepressants warrants investigation of the effects these chemicals may have on fish behavior. Using a predator prey bioassay previously designed in our lab, we have shown that the antidepressants fluoxetine (Prozac®) and venlafaxine (Effexor®) individually increase the time it takes for a predator to capture its prey. Concentrations that cause this effect are typically 1-2 orders of magnitude less than LC_{50}'s from traditional toxicity tests, but are still 1-2 orders of magnitude higher than those found in wastewater treatment plant effluent. In the environment these antidepressants would be found in complex mixtures with other antidepressants, as well as other chemicals. Since the effects of mixtures are not well understood the objective of the current study was to characterize the behavioral effects of a simple mixture of the two antidepressants we had previously investigated individually, fluoxetine and venlafaxine. An effect level was selected to represent one toxic unit for each of the chemicals. Levels of 0.5, 1, and 2 toxic units were tested to determine how these chemicals may interact to cause effects on fish predatory behavior. In addition to behavioral endpoints, fish brains were collected throughout exposures and analyzed for monoamine profiles. Previous work has shown that antidepressant exposure decreases brain serotonin, which can be correlated with an increase in time to capture prey. The current study will determine how multiple antidepressants interact to alter brain chemistry, and whether this interaction can cause an increased/decreased effect on fish predation behavior. Initial results indicate that fluoxetine and venlafaxine may interact in an additive manor.

WP150 Effects of Pharmaceuticals in Environment on Aquatic Organisms N. Tatarazako, National Institute for Environmental Studies, Center for Environmental Risk Research, National Institute for Environmental Studies, Endocrine Disrupter Research Laboratory; T. Oka, H. Watanabe, National Institute for Environmental Studies, Research Center for Environmental Risk; T. Suzuki, Tokyo Metropolitan Institute of Public Health; T. Nishimura, National Institute of Health Sciences, Division of Environmental Chemistry. It is concerned that environmental pharmaceuticals have on an aquatic organism recently. In our study, seven chemicals (diclofenac sodium, mefenamic acid, carbamazepine, fenofibrate, crotamiton, epinastine hydrochloride, and fumagillin) were investigated. These substances except fumagillin were detected from the Tama River (Japan), which is main river in the arcuate line between Tokyo and Kanagawa. Bioassays were carried out according to three traditional toxicity tests (algae; *Pseudokirchneriella subcapitata* growth inhibition, *Daphnia*; *Ceriodaphnia dubia* reproduction, and fish; *Danio rerio* short-term toxicity test on embryo and sac-fry stages). Each pharmaceutical showed different effects among three species. Diclofenac sodium showed weak toxicity in *Daphnia* (NOEC 2.0 mg/L) and fish (NOEC 2.5 mg/L). Carbamazepine showed weak toxicity in algae (NOEC 8.6 mg/L) and *Daphnia* (NOEC 21 mg/L). Crotamitone showed weak toxicity in algae (NOEC 5.2 mg/L) and *Daphnia* (NOEC 6.2 mg/L). Mefenamic acid showed slightly strong toxicity in algae (NOEC < 0.3 mg/L) and fish (NOEC 1.3 mg/L). Epinastine showed slightly strong toxicity in algae (NOEC 0.6 mg/L) and *Daphnia* (NOEC 2.8 mg/L). The effect of fenofibrate was not shown with all species. Fumagillin showed very strong toxicity for reproduction of *C. dubia* (NOEC 0.03 mg/L). Fumagillin is one of the anticancer drugs used as angiogenic inhibitor to a cancer cell. It is very interesting to have a strong effect for the *Daphnia* which there is not a blood vessel. Our results showed that various pharmaceutical which varied in effects had for wildlife. However, it was shown that the effects mechanism for the wildlife might be different from the effects mechanism for humans of the pharmaceutical. It is thought that it is necessary to pay its attention to the different endpoint conventionally to evaluate environmental effect of the pharmaceuticals.

WP151 Investigation of the In Vitro Metabolism of Diazepam in Channel Catfish (Ictalurus punctatus) C. Overturf, D.B. Huggett, Univ of North Texas, Dept of Biological Sciences. Many pharmaceuticals have been detected in surface waters over the past few years, which may pose adverse effects to aquatic life. Thus, the following study examined the in vitro metabolism of diazepam, a model benzodiazepine, in microsomal fractions of the liver from channel catfish. The loss of parent compound (diazepam), as well as the generation of biologically active metabolites (nordiazepam, temazepam and oxazepam) was investigated. An NADPH regeneration system was used to simulate phase I reactions and 100µM diazepam was added to the system with or without the presence of 10µM of a cytochrome P450 inhibitor. Samples were taken at selected time points and placed in methanol to stop any further reaction. The samples were then processed and analyzed using LC-MS/MS. α-napthoflavone (ANF), 17α-ethinylestradiol (EE2) and lauric acid were used as specific inhibitors of CYP1A, CYP3A27 and CYP2K1, respectively; whereas ketoconazole was used as a non-specific cytochrome P450 inhibitor. ANF resulted in no significant inhibition of diazepam or the formation of metabolites. EE2 resulted in complete inhibition of diazepam and 57% inhibition of temazepam at 60 minutes; however, did not alter nordiazepam formation. Lauric acid inhibited diazepam by 87% at 60 minutes, but did not alter metabolite formation. Ketoconazole did not significantly inhibit diazepam, but inhibited the formation of nordiazepam and temazepam by 69% and 97% at 60 minutes, respectively. Thus, it appears the CYP1A may not be involved in the metabolic pathway of diazepam in catfish. The resulting inhibition of diazepam by EE2 and lauric acid indicates that CYP3A27 and CYP2K1 may be the primary pathways that diazepam is metabolized. Additionally, EE2 inhibited the formation of temazepam, which indicates that the formation of temazepam may also be mediated through CYP3A27. The formation of nordiazepam was only inhibited by ketoconazole, indicating that its formation is mediated through cytochrome P450, but not any of the specific isoforms investigated. Thus, the inhibition of diazepam metabolism via cytochrome P450 inhibition could lead to increased concentrations of this compound. Therefore, it is recommended that co-exposure bioconcentration studies should be conducted to determine the potential to modulate the bioconcentration of diazepam.

WP152 The Change of Energy Relative Biomarkers of *Daphnia magna* Exposed to Tetracycline and its relationship to Organismal Responses in Multi-Generations H. Kim, Gwangju Institute of Science & Technology, Dept of Environmental Science and Engineering, Gwangju Institute of Science & Technology, Schoool of environmental science and engineering; S. Yu, M. Lee, Korea Atomic Energy Research Institute; T. Kim, Gwangju Institute of Science and Technology, School of Environmental Science and Engineering; S. Kim, Gwangju Institute of Science & Technology, School of Environmental Science and Engineering. The objectives of this study were to estimate the effect of tetracycline on energy relative biomarkers such as available energy contents and energy consumption and to link the biochemical indicators in the cellular level with the organismal level effect. The target compound was continuously exposed to daphnids over four successive generations at the sublethal concentrations including 0.1-10.0 mg/L. The biochemical endpoints such as available energy contents and energy consumption were measured to evaluate the effect of toxicant-induced stress on the metabolic balance of test organism. Energy reserve was calculated by measuring total protein, glycogen and lipid contents and energy consumption was estimated by measuring the activity of electron transport system (ETS). As a result, the contents of energy reserving compounds showed the concentration-dependent decrease in all generations. The concentration of protein, glycogen, and lipid in control was 32.4±4.5, 0.722±0.113, and 14.40±0.52 ug/organism, respectively. The content of each component was decreased by 25.4, 62.2, and 40.1% after 10 mg/L of exposure at parent generation. However, the rate of reduction was changed with increasing generation number. For example, the rate of glycogen reduction exposed to 10 mg/L was changed to 62.2% (F0), 61.5% (F1), 37.9% (F2), and 33.1% (F3). It suggests that the energy related biomarkers have a significant relationship with organismal effects such as growth and reproduction. Also, there is a tendency of energy related biomarkers with number of generation. It seems that trade-off mechanism might exist between the somatic growth and reproduction. Moreover, the energy content and expenditure might contribute to the organismal effect of *D. magna*, resulting in the change of population.

WP153 The Effects of Bupropion on Predation Behavior and Brain Chemistry in Hybrid Striped Bass L. Sweet, Clemson Univ, Institute of Environmental Toxicology; J.H. Bisesi, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX); S.J. Klaine, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX), Clemson Univ, Institute of Environmental Toxicology (ENTOX) The widespread use of pharmaceuticals has led to increased detection of these chemicals in wastewater effluents and receiving streams. Many of these pharmaceuticals are antidepressants,

intended to alter brain chemistry in humans; therefore, aquatic organisms with similar biochemical pathways may be vulnerable to the presence of these drugs in their environment. A bioassay has previously been developed in our lab to quantify the effects of antidepressants on predation behavior in hybrid striped bass (*Morone saxitilis* x *M. chrysops*) through measuring the time to capture prey (*Pimephales promelas*). Previous studies have shown that fluoxetine, a selective serotonin reuptake inhibitor, elicited an increased time to capture prey and a decrease in brain serotonin levels. Moreover, upon exposure to venlafaxine, a serotonin and norepinephrine inhibitor, an increased time to capture prey has also been observed. Therefore, by examining buproprion, a norepinephrine and dopamine reuptake inhibitor, we hope to elucidate the role of specific monoamines on brain chemistry and behavior. This information may be used to generate a model to evaluate the effects of antidepressants on fish predation behavior based on the targeted monoamines of the drug.

WP154 Uptake of Pharmaceuticals from Soils into Earthworms (*Eisinea fetida*) L. Carter, Univ of York, Environment Dept; J. Ryan, GlaxoSmithKline; A. Boxall, Univ of York, Environment Dept. Pharmaceutical compounds are increasingly being detected in soils due to the application of sewage sludge and use of reclaimed wastewater for irrigation. Once in soil, pharmaceuticals can be taken up by soil dwelling organisms. Accumulated pharmaceuticals may then affect the health of the organisms or be transferred up through food chains. This study therefore investigated the uptake of two pharmaceuticals, fluoxetine and diclofenac, into earthworms (*Eisinea fetida*). Diclofenac is an acidic pharmaceutical whereas fluoxetine is a basic compound. The studies were based on the OECD Guideline 317 and involved a 21 day uptake phase followed by a 21 depuration phase. Studies were performed using radiolabelled compounds to allow for a lower limit of detection thus enabling environmentally relevant concentrations of both compounds to be used in the study. A continual increase in uptake of both fluoxetine and diclofenac into worms was observed over 21 days. At the end of the uptake phase, concentrations of fluoxetine had reached 0.028 mg/kg and diclofenac had reached 0.032mg/kg. When exposed worms were transferred to clean soil, both compounds were found to depurate rapidly with only trace amounts being detected in the worms after 21 d depuration. Parallel studies, using unlabelled compounds, were run alongside the radiolabelled uptake studies to determine the extent of degradation of the parent compounds. Further Radio-HPLC investigation was also able to determine that the radioactivity detected in the earthworm and soils was that of the parent compound and not of a metabolite. This study is one of the first to explore the uptake and depuration of pharmaceuticals, commonly found in the terrestrial environment, into earthworms. Future work includes investigation into how soil properties can influence uptake. Studies are also planned to assess the uptake of pharmaceuticals from soils into plants.

WP155 Evaluating Environmental Persistence Screen C.A. Smith, Smithers Viscient, Senior Consultant; D. Sacker, S. Erler, Smithers Viscient; R. Hannah, GlaxoSmithKline, CEHS – RS 1105 To support product stewardship activities, environmental hazard classification and communication, and development of transportation criteria, Persistence, Biodegradation and Toxicity assessments are required. The scope of the above responsibilities involves developing environmental impact studies (environmental toxicology and environmental fate), ecological risk assessment and risk reduction strategies. As part of this, persistence evaluations utilizing biodegradation methods (OECD 301, 302 303 and 314) are used to determine ready and inherent biodegradation, mass balance and 1st order kinetic data. These studies are time consuming (minimum 28 days) and costly. They are run late in development and are not suitable to be run for screening purposes earlier in the development process when environmental issues could be potentially avoided. The purpose of this project is to design and implement a higher through-put, smaller scale wastewater biodegradation screening assay to assess chemical persistence in the Waste Water Treatment Facilities (WWTFs) that could be applied early in product selection and development activities to assess hazard and risk. These data along with other physical and environmental properties would be critical in developing: a PBT Profile – to facilitate early stage environmental hazard categorization. Environmental Fact Sheet--Material Safety Data Sheet – to support waste minimization and mitigation during prelaunch activities. Support development of an effective environmental testing strategy which focuses on highest intrinsic hazards and is critical to compound registration and marketing authorizations. Development of product lifecycle environmental risk profiles and site-specific manufacturing risk assessments.

WP156 Human Health and Pharmaceuticals in the Environment: A Review of Existing Practice E.S. Williams, Baylor Univ, Bayor Univ. Recent concerns over potential human and ecological risks arising from pharmaceuticals in the environment have spurred significant effort in the scientific community. The potential for adverse health outcomes associated with these substances has implications for wastewater treatment, water reuse, practices in solid and liquid waste disposal, and manufacturing. A relatively small number of human health risk assessments for pharmaceuticals in the environment have been published to date. These documents often address a small number of individual pharmaceutical substances, with carbemazepine, clofibric acid, cyclophosphamide, sulfamethoxazole, and trimethoprim being more frequent targets of study. These exercises focus on ingestion of water and fish as routes of exposure, and employ a variety of methods to assess magnitude of these potential exposures, assign safety values, and characterize risk. With a few exceptions, the risks of adverse health outcomes resulting from exposure to pharmaceuticals have been judged to be low. This presentation will summarize the methodologies used in these published exercises, and discuss the associated uncertainties.

WP157 Ketoconazole Increases the Endocrine Disruption Potential of Ibuprofen Exposure in the H295R Cells and Japanese Medaka K. Ji, Seoul National Univ, School of Public Health; K. Choi, Seoul National Univ, School of Public Health, Seoul National Univ, Dept of Environ. Health; K. Kwak, School of Public Health, Seoul National Univ; J. Khim, Korea Univ, Division of Environmental Science and Ecological Engineering; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science; X. Zhang, Toxicology centre, Univ of Saskatchewan, State Key Laboratory of Pollution Control and Resource Reuse & School of the Environment, Nanjing Univ, School of the Environment. Pharmaceuticals residues found in the aquatic environment usually occur as mixtures, while most of toxicity tests were made on individual chemicals. In the present study, we investigated whether exposure to low level ketoconazole increases the estrogenicity of ibuprofen exposure. Ibuprofen was reported to increase estrogenicity in fish. After 48 hr exposure to ibuprofen alone or in combination with ketoconazole, the production of 17β-estradiol (E2) and testosterone (T), the activity of aromatase, and the mRNA expression of steroidogenic genes and CYP2C9 gene were measured. In addition, concentrations of E2 and T in blood plasma, and the mRNA expression of two steroidogenic genes (CYP17 and CYP19b) were also determined in male Japanese medaka fish after 14 d exposure. Ibuprofen alone increased E2 production, and enhanced both aromatase activity and transcription of CYP17, CYP19 or CYP11β2 genes in the cells, which are important components of steroidogenic pathways. In medaka fish, while ibuprofen only exposure at 0.2 mg/L did not cause any significant effects on E2 concentration compared to that of control, E2 production was more elevated in combination with ketoconazole, i.e., up to 1.5-fold compared to ibuprofen only exposure. In addition, a combined exposure to ibuprofen and ketoconazole resulted in an elevated expression of CYP17 and CYP19b mRNAs in male medaka, compared to ibuprofen only exposure. This study indicates that non-effective concentrations of ketoconazole can increase the potential for endocrine disrupting effects of ibuprofen in both human adrenal cell line and the freshwater fish.

WP158 The Ecotoxicity of Photocatalytic Nano-TiO_2 Particles on Bacteria Exemplified by *E. coli* and *B. subtilis* A. Erdem, Akdeniz Univ, Environmental Engineering; C. Huang, Univ of Delaware, Civil & Environmental Engineering. Ecotoxicological effects of nanoparticles (NP) are still poorly documented while their commercialization increases in many production and manufacturing sectors. Among the various NPs, TiO_2 has being the most used nanomaterials in industry; from wall paints to cosmetic products and from textile products to children toys. Besides their advantages and they are regarded as a biocompatible material in the absence of photoactivation, nano-TiO_2 have also been shown to exhibit strong cytotoxicity when exposed to UV and solar irradiation. In order to understand the bacterial responses to nanoparticles, Gram-negative *E. coli* and Gram-positive *B. subtilis* treated with fourteen sizes and five concentrations of TiO_2 nanoparticles were studied. The end points of the microbial responses to photocatalytic nano-TiO_2 were investigated in terms of cell counting, lipid peroxidation of the cell membrane, cellular respiration, and enzymatic response, and DNA

damage. The results indicated that nano-TiO_2 particles in the absence and the presence of photoactivation induced cell inactivation, lipid peroxidation, cellular respiration disruption, increased enzymatic response, and oxidative DNA damages. In total darkness, lower levels of lipid peroxidation and DNA damage were detected than those in light condition. Results also showed that as irradiation time increased the photocatalytic effect on DNA damage and lipid peroxidation also increased. The lipid peroxidation and the simultaneous losses of both membrane-dependent respiratory activity showed that cell viability depend strictly on the presence of both light and TiO_2. It can be concluded that TiO_2 photocatalysis promoted peroxidation of the polyunsaturated phospholipid component of the lipid membrane initially and induced major disorder in the bacteria cell membrane. Subsequently, essential functions that rely on intact cell membrane architecture, such as respiratory activity, were lost, and cell death was inevitable. The results also highlight the need for caution during the use and disposal of such manufactured nanomaterials to prevent unintended environmental impacts, as well as the importance of further research on the mechanisms and factors that increase ecotoxicity to enhance risk management.

WP159 Impact of Organic Carbon on the Toxicity of Freshly Prepared and Stored Silver Nanoparticles A.J. Kennedy, US Army Engineer Research and Development Center; J.K. Stanley, US Army Engineer Research and Development Center, Environmental Laboratory; A.C. Ryan, HDR|HydroQual; B.D. Meeks, Badger Technical Services; J.G. Laird, US Army Engineer Research and Development Center; A.J. Bednar, US Army Engineer Reseach and Development Center; A. Poda, US Army Engineer Research and Development Center; J.A. Steevens, US Army Engineer Research & Development Center, Waterways Experiment Station. In a previous investigation, we determined that the concentration of total measureable silver for various nanosilver suspensions was not predictive of toxicity. However, the fraction of the concentration measured following ultracentrifugation and by integration under field flow fractogram void peaks was comparable to dissolved silver (Ag^+) toxicity. In the current study, we exposed *Ceriodaphnia dubia* to both 20 nm (hydrodymanic diameter of 27 nm) NanoComposix (San Diego, CA) citrate capped nanosilver and silver nitrate at multiple dissolved organic carbon (DOC) concentrations. A concentrated nanosilver stock was diluted to 10 mg/L using ultrapure water and was not amended with additional citrate. Using this freshly prepared stock, *C. dubia* were exposed to dissolved Ag^+ and nanoparticles at either 0 or 3.9 mg DOC/L; results suggested that both Ag^+ toxicity (significant increase in LC50 from 0.3 mg/L [0.2 – 0.3 ug/L] to 1.5 [1.3 – 1.8 ug/L] and nanosilver toxicity (LC50 increased from 16.9 [13.1 – 22.0 ug/L] to 23.7 [18.0 – 31.3 ug/L]) were reduced with higher DOC. However, when the same stored stock was reused one month later in a similar experiment, the toxicity of the nanosilver was significantly higher relative to the previous experiment, both at a lower DOC concentration of 2.0 mg/L (LC50 = 14.1 [11.1 – 18.8 ug/L]) and at 0 mg/L (LC50 = 5.1 [3.8 – 6.7 ug/L]). Dissolved Ag^+ toxicity was comparable between the two experiments. Additional experiments were conducted to test the hypothesis that nanosilver became more toxic due to dissolution caused by the dilution and storage of the stock without stabilizing the particles with additional citrate. This result, if repeatable, may have implications on the consistency of toxicity studies if stock handling and storage are not standardized. These data are being generated to consider the utility of the biotic ligand model to predict nanosilver toxicity.

WP160 The Impact of Silver Nanowire Physicochemical Properties in Environmental Media and on Nanowire Toxicity to *Daphnia magna* and Fathead Minnow Cells L.D. Scanlan, Univ of California, Berkeley, Molecular Toxicology, U.C. Berkeley, Molecular Toxicology, U.C. Berkeley, graduate student; A. Tagmount, U.C. Berkeley, Molecular Toxicology; B. Gilbert, Lawerence Berkeley National Laboratory; C. Clark, U.C. Berkeley, Molecular Toxicology; C. Vulpe, U.C. Berkeley. Nanowires are high-aspect-ratio inorganic nanomaterials that are distinct from nanoparticles (such as semiconductor quantum dots) and carbon-based materials (such as nanotubes). Nanowires are anticipated to have diverse technological applications, leading to increasing risk of environmental release during manufacture or from end products. Environmental contaminants pose particular risks to freshwater aquatic ecosystems and while there are now many studies of the environmental toxicity of nanoparticles there is very limited information on the potential toxicity of nanowires on aquatic organisms. We have performed an assessment of the environmental toxicity of silver nanowires (AgNW) by combining preliminary acute toxicity studies in the fresh water ecoindicator *Daphnia magna* with studies of AgNW reactivity and aggregation in *Daphnia* media. We also used genomic tools to analyze differential gene expression in daphnids exposed to nanowires. The toxicity of AgNWs was additionally investigated at the cellular level in fathead minnow, another aquatic eco-indicator organism. We employed cell-based assays to assess and investigate the modes of action of AgNW cytotoxicity. Classical viability assays (e.g., MTT, MTS) as well as multiplexed cell-based imaging assays (High Content Screening) were employed to tackle this question. We are currently investigating in *D. magna* and fish cells whether or not AgNW functionalization and the ratio length to diameter influence the AgNW toxicity. A cell uptake study was also carried out to correlate the cytotoxicity with AgNW internalization.

WP161 The Influence of Dissolved Organic Matter and Coating on the Toxicity of Silver Nanoparticles in *Daphnia magna* K.M. Newton, Clemson Univ Institute of Environmental Toxicology (CU-ENTOX), Biological Sciences, Clemson Univ, Clemson Univ Institute of Environmental Toxicology; L. Sweet, Clemson Univ Institute of Environmental Toxicology(CU-ENTOX), Biological Sciences; A. Bone, B. Coleman, C. Matson, Center of Environmental Implications of Nano technology (CEINT); S. Klaine, Clemson Univ Institute of Environmental Toxicology(CU-ENTOX), Biological Sciences. Silver Nanoparticles (AgNPs) are by far one of the most widely used nanomaterials in general consumer products. Their inherent antimicrobial property has greatly increased their use in health and fitness products, household cleaning products, cosmetics and personal care products. The consequence of increased use is that of increased inputs into aquatic ecosystems. To date, a lot of uncertainty still clouds the ecological impact of AgNPs. However, emerging research on their fate and behavior in aqueous systems points to the release of silver ions (Ag^+) during use and on disposal of products. Different sources of dissolved organic matter (DOM) and nanomaterial coating may affect the bioavailability of Ag^+ in aqueous systems and thus its toxicity. In order to investigate the roles that different sources of dissolved organic matter and AgNP-coating play in silver toxicity, microcosms were prepared using four different scenarios: water only, sediment + water, plants + water, and plants+sediment+water. Treatments were prepared in triplicate: Untreated controls and 2.5 mg/L Ag as $AgNO_3$ (Ag-I), Gum Arabic coated (Ag-GA) and Polyvinylpyrrolidone coated (Ag-PVP) nanoparticles for each of the scenarios. 48-hour acute toxicity tests in *D. magna* indicated $AgNO_3$ was the most toxic, that Ag-PVP was less toxic than Ag-GA in moderately hard water (MHW) and in both cases their toxicity was reduced in the presence of DOM. The presence of plant organic matter in general reduced the toxicity of AgNPs however, the reduction was not quantitatively related to DOC.

WP162 Assessment of Silver Ion Toxicity Using a Novel Method to Fish Embryos Y. Nakagame, T. Ariyoshi, T. Niwa, S. Nagasaka, H. Takei, S. Kashiwada, Toyo Univ, Dept of Life Sciences. The use of nanotechnology is increasing in both high-tech industries and medicine. While such technology offers many benefits, there are concerns regarding the potential environmental and human health risks associated with exposure to nanomaterials. Silver nanomaterials including nanocolloids and nanoparticles are ones of the most widely used materials, due to their disinfectant properties, and are likely to enter and impact the aquatic environment through municipal and other wastewater streams. Although silver is rare in the natural environment, concentrations have been elevated due to anthropogenic activities. Despite the widespread use of silver and silver ions in industry and for medical purposes, only limited information on silver toxicity is available. Existing environmental and human studies seem to demonstrate that free silver ions (Ag+) are more toxic than others. However, it is not easy to test toxicity of Ag+ only because of existence of base, a counterpart of acid, which lead to acidification of test water and cause toxic effects as well. In use of AgNO3 for sauce of Ag+, it is impossible to eliminate biological effects of NO3- from toxicity data. Herein, we will demonstrate a newly developed method for testing of Ag+ toxicity. Using a nanotechnology, Ag nanoparticles are formed on bottoms of a 6 well-plate. Using this "bottom-fixed Ag nanoparticles plate" released Ag+ (which should be pH-dependent) into ambient water from the bottom were tested and toxic effects on medaka fish embryos were estimated away from Ag nanoparticles. In case of ERM (embryo rearing medium) as ambient water, less-development of eyes, short spinal cord, vascular defects, blood clots, percardiovascular edema, ischemia, short body lengths, reduction of heart rates, and hatching delay were observed significantly more in pH4 than pH9. These features were similar to those of

Ag nanocolloids exposure. Interestingly, in case of ultrapure water instead of ERM, tested embryos exhibited complete mortality within 12 hrs in pH4, 7 and 9. If medaka embryos were incubated in ultrapure water, embryos could survive only for 2-3 days in pH4, and 13.3% and 11.1% of mortalities were shown in pH7 and pH9, respectively. This would be because ERM (Na+ and/or Ca++) could mitigate Ag+ toxicity in comparison to ultrapure water. The new developed method would be useful for elucidation of Ag toxic mechanism and assessment of Ag+ toxicity to aquatic organisms.

WP163 Multiple Fish Species and Life Stage Assessment of Nanosilver Toxicity A.D. Hawkins, Univ of Mississippi, Dept of Pharmacology, Environmental Toxicology Research Program; J.D. Laird, Us Army Engineer Research & Development Center, SpecPro Incorporated, US Army Engineer Research & Development Center, Environmental Laboratory; C. Thornton, Univ of Mississippi, Dept of Pharmacology and Environmental Toxicology Research Program, Univ of Mississippi, Pharmacology; J.A. Steevens, US Army Engineer Research & Development Center, Waterways Experiment Station; K.L. Willett, Univ of Mississippi, Environmental Toxicology Research Program, Univ of Mississippi, Dept of Environmental Toxicol. Recent advancements in nanotechnology have lead to an increase of "nanoenabled" goods on the market. Silver nanoparticles are the most widely used nanoparticles because of their antibacterial and antifungal properties. Silver is known for acute and long-term toxicity, however, little is currently known about potential developmental or gill toxicity of nanosilver exposure. Here, we investigated two species and two lifestages for effects of nanosilver relative to silver nitrate. First, adult fathead minnows (*Pimephales promelas*) were exposed for 96 hr with daily water renewals to polyvinylpyrrolidone coated silver nanoparticles (PVP-AgNPs) or silver nitrate ($AgNO_3$) at 3 different nominal concentrations (6, 80, and 214 µg/L) or (1.5, 4, and 6 µg/L), respectively. The gills were processed for histopathological detection of lesions including presence of hyperplasia, hypertrophy, circulatory disturbances, and fusion of lamellae and for enzymatic measures of oxidative stress. The CytoViva hyperspectral imaging system and ICP-MS are also being used to quantify the presence of nanosilver in the gills and assess the difference in uptake from the different silver solutions. Second, Japanese medaka (*Oryzias latipes*) embryos were exposed to 3 nominal concentrations (1, 10 and 100 µg/L) of PVP-AgNPs, $AgNO_3$, and Silver Biotics (ASAP) for 7 days. These embryos were scored at 7 days postfertilization for lethality and cardiac toxicities (blood clot, edema and tube heart using a deformity index). Associated gene expression changes of metallothionein (MT), glutathione S transferase (GST), heat shock protein 70 (HSP70), and transferrin (TF) are being measured by qRT-PCR of whole embryos. Lastly, we will consider the physiological consequences of changing pH, Ca^{2+}, Cl^-, DOC and sulfide during exposure to nanosilver. Together this work will identify both potential species and developmental stage sensitivities to nanosilver exposure and begin to identify possible mechanisms of toxicity. Supported by US Army ERDC #W912HZ-09-C-0033

WP165 Comparing Mechanisms of Toxicity and Effects of Silver Nanoparticles and Ionic Silver on *Daphnia magna* Using Non-invasive Real-time Methods M.C. Stensberg, Purdue Univ, Dept of Agricultural and Biological Engineering; E.S. Mclamore, Univ of Florida – Gainesville, Agricultural and Biological Engineering Dept; Q.C. Wei, A.C. Wei, Purdue Univ, Dept of Chemistry; D.M. Porterfield, Purdue Univ, Dept of Agricultural and Biological Engineering; M.S. Sepulveda, Purdue Univ, Dept of Forestry and Natural Resources. Silver nanoparticles (AgNPs) are becoming increasingly popular as antimicrobial agents in hundreds of products; however, the mechanisms of toxicity and potential health effects of AgNPs to other organisms are not fully understood. Many traditional toxicological studies are invasive and destructive. The goal of this research was to compare the mechanisms of toxicity and effects induced by ionic silver (as silver nitrate, $AgNO_3$) and AgNPs in the water flea, *Daphnia magna* using non-invasive real-time sensing methods. *D. magna* embryos (stages 1-2) were exposed to sublethal concentrations (130 ng/L and 650 ng/L) of $AgNO_3$ and AgNPs. Particle uptake was monitored using confocal reflectance microscopy; growth with differential imaging; and effects on physiological fluxes of oxygen and hydrogen quantified using self-referencing microsensors. AgNPs (650 ng/L) were observed inside the embryos as early as 3 hours post exposure. $AgNO_3$ (130 ng/L) significantly impaired embryo growth over the course of 25 hours. Although no changes were observed in oxygen flux after exposure to either AgNPs or $AgNO_3$, proton flux increased in both treatments within minutes after the initial exposure, but significantly more so in embryos exposed to AgNPs. Taken together these results indicate that AgNPs move into the embryos within minutes after exposure and elicit responses in proton flux that are not translated in growth effects suggesting differences in the mechanism of toxicity between $AgNO_3$ and AgNPs.

WP166 Detection of Naturally Internalized Nanoparticles in Aquatic Organisms A. Harmon, US Army Engineer Research and Develoment Center, Environmental Laboratory; A.J. Kennedy, US Army Engineer Research and Development Center; J.D. Laird, Us Army Engineer Research & Development Center, SpecPro Incorporated, US Army Engineer Research & Development Center, Environmental Laboratory; J.G. Coleman, US Army Engineer Reseach and Development Center, US Research and Development Center, Research Biologist; J.K. Stanley, US Army Engineer Research and Development Center, Environmental Laboratory; M. Hull, NanoSafe, Inc; A.J. Bednar, US Army Engineer Reseach and Development Center; B.D. Meeks, Badger Technical Services; J.A. Steevens, US Army Engineer Research & Development Center, Waterways Experiment Station. Numerous studies have investigated the toxicity and bioaccumulation potential of engineered nanoparticles. It is important to develop techniques to evaluate what form of the originally dosed nanoparticle may exist within the tissues of organisms (e.g., primary particle, aggregate, bulk, ion) to determine appropriate accumulation factors and populate environmental risk models. This investigation focuses on two different techniques that were employed to characterize the state of nanoparticles in organism tissue: hyperspectral microscopy (Cytoviva®, Auburn, AL) of tissue sections of nanoparticle exposed animals and field-flow-fractionation coupled with ICP-MS of deionized water extracted tissue. Organisms were exposed to nanoparticles (TiO_2, nanosilver) using a peristaltic pump to maintain as consistent as possible particle concentrations and suspension characteristics. Smaller and larger particle aggregate states were created by dispersing nanoparticles in low (0 – 100 µS/cm) and higher ionic strength (280 – 560 µS/cm) water. The organisms exposed included zebrafish (*Danio rerio*), fathead minnows (*Pimephales promelas*), zooplankton (*Daphnia magna*) and the Asiatic clam (*Corbicula fluminea*). Polyvinylpyrrolidone (PVP) nanosilver and TiO_2 particles were detected by hyperspectral analysis based on their unique spectral signatures on the gill filaments of *P. promelas* and *D. rerio*, respectively. Similarly, TiO_2 particles were also detected using hyperspectral imaging in cross sections of *D. rerio* and *C. fluminea* gastrointestinal tracts. The more dispersed TiO_2 particles remained in smaller aggregates that became entrapped within *D. rerio* intestinal folds or villi, with some particles potentially absorbed into the lining. The more aggregated TiO_2 particles continued to form larger aggregates that completely filled the intestines, potentially leading to an impacted gastrointestinal tract. Future studies will investigate additional particle and aggregate sizes to evaluate potential differences in uptake and assimilation efficiency of nanoparticles. Such knowledge should lead to more informed estimates of bioaccumulation and trophic transfer factors to populate databases such as NanoExPERT.

WP167 Investigating the Fate and Toxicological Effects of Nano-TiO_2 in *Daphnia magna* T. Blickley, National Institute of Standards & Technology (NIST), Surface and Microanalysis Science; C. Szakal, R. Holbrook, National Institute of Standards & Technology (NIST) The literature suggests that nano-sized titanium dioxide is acutely toxic to *Daphnia magna* at concentrations greater than100 mg/L, which is well above what is considered environmentally-relevant (0.7-16 µg/L). We are chronically exposing this freshwater invertebrate to low levels of TiO_2 (1-1000 µg/L) to determine sub-lethal toxicological effects. Nano-sized TiO_2 (NIST SRM-1898) suspensions were prepared by sonication, coated in bovine serum albumin (BSA), and dispersed in PBS, thus yielding particles that were ~80 nm in diameter. To determine particle behavior in the water column, the material was mixed into OECD *Daphnia* media, transferred to graduated cylinders, and measured for concentration via UV/VIS spectroscopy at 1, 24, 48, and 168 hours. Negligible settling occurred during the first 48 hours; however, 65% of the total suspended material had precipitated to the bottom layer by day 7. Ongoing studies involve aqueously exposing *Daphnia* neonates to these BSA-TiO_2 suspensions for 14 or 21 days. Endpoints include molting, time to first brood, and reproduction. At the conclusion of the exposures, daphnids are rinsed with clean OECD media before excising their eggs. The eggs are currently being evaluated for TiO_2 deposition with Focused Ion Beam/Secondary Ion Mass Spectrometry (FIB/SIMS). Additionally, adult *Daphnia* are being aqueously exposed to 1 mg/L BSA-TiO_2 for 7 days and the gut tract contents are examined for transformation of the particles with

SIMS. The goal of these studies is to determine where the nanoparticles reside in the aquatic environment as well as where and in what form the particles exist within the organism.

WP168 Photo Enhanced Toxicity of Nano Titanium Dioxide (Anatase) on Freshwater Zooplankton M. Alloy, Univ of North Texas, Dept of Biological Sciences; A. Roberts, Univ of North Texas. Classic photo-enhanced toxicity is focused around PAHs closely associated with petroleum use, internal combustion engines, oil refining, and oil spills. The majority of nanotoxicology has been focused on effects of nanomaterials in acute exposures. Titanium dioxide has been used for decades as a paint pigment, food coloring, sun screen, the active portion of self-cleaning surfaces, fog free mirrors, and in many more roles prior to the use of nano-scale TiO_2 crystals. The first reports of TiO_2 photocatalytically decomposing compounds in the aqueous phase by generating reactive oxygen species was reported in the late 1970s. Toxicology of nano TiO_2 is not new, but few studies have looked at aquatic toxicity of nano TiO_2 under exposure to UV light. The goals of this study are: to determine if nano TiO_2 is more toxic to aquatic organisms in the presence of UV light, if it follows classic phototoxicant patterns of reciprocity, and to what magnitude does UV exposure mediate toxicity. Time to failure tests using *Daphnia magna* neonates as model organisms were run and LC_{50} values established under a variety of exposure conditions. Results of these tests indicate that TiO_2 is phototoxic to zooplankton in aquatic environments at relatively low concentrations.

WP169 Influence of Functionalization on the Suspension Stability of Titanium Dioxide Nanoparticles in Aqueous Matrices S.P. Yang, Univ of Wisconsin, Molecular and Environmental Toxicology; K.M. Louis, Univ of Wisconsin; O. Bar-Ilan, Univ of Wisconsin, Division of Pharmaceutical Sciences; R.J. Hamers, Univ of Wisconsin, Chemistry; R.E. Peterson, W. Heideman, Univ of Wisconsin, School of Pharmacy; J.A. Pedersen, Univ of Wisconsin, Soil Science. The ability of titanium dioxide (TiO_2) nanoparticles (NPs) to adsorb ultraviolet light and generate reactive oxygen species has led to applications ranging from cosmetics to wastewater treatment to photovoltaics. As such, production volumes are expected to surpass 10,000 tons per year by 2014. Many applications require stable NP suspensions, and the addition of organic ligands during synthesis can increase stability through electrostatic and steric repulsion. Upon release into aquatic environments, NP stability can be modified by solution conditions (e.g., pH, ionic strength, dissolved organic matter (DOM)). These factors are expected to impact NP environmental fate and bioavailability. Here, we examine the influence of functionalization on TiO_2 NP suspension stability as a function of ionic strength and composition, DOM concentration, and sunlight exposure. We synthesized TiO_2 NPs from $TiCl_4$ and were functionalized with various organic ligands (e.g., citrate, dihydroxybenzaldehyde (DHBA), polyethylene glycol). Dynamic and electrophoretic light scattering were employed to assess suspension stability and a metal halide lamp designed to mimic sunlight at an underwater depth of 1-2 m. Suspensions of DHBA- and citrate-functionalized TiO_2 NPs (primary particle size: 5-6 nm) were stable in NaCl concentrations up to 1 M. However, suspensions were destabilized by low concentrations (0.1 mM) of Ca^{2+}. For the DHBA and citrate functionalizations, dissolved organic matter (Suwannee River natural organic matter isolate; 10 mg L^{-1}) increased suspension stability in the presence of Ca^{2+} ions (0.1 mM). In the absence of DOM, exposure to simulated sunlight increased the aggregate size of DHBA- and citrate-functionalized NPs. These results suggest the TiO_2 NPs can photocatalytically degrade the functionalizations. Changes in TiO_2 NP aggregate size through these various mechanisms are expected to impact uptake by aquatic organisms.

WP170 Effect of ZnO and TiO_2 Nanoparticles on Larva and Embryo of *Oryzias latipes* Under Continuous Ultraviolet Irradiation Y. Shin, Konkuk Univ; Y. An, Konkuk Univ, Dept of Environmental Science. We investigated the effect of zinc oxide and titanium oxide nanoparticles on the early development of *Oryzias latipes* when the fish embryo rearing media were continuously illuminated by ultraviolet irradiation during exposure period. UV irradiation was conducted in a controlled photoreactor where the intensity of UV was low enough not to influence the test species. Control experiment was conducted in visible light condition. We observed that abnormal development of bladder was increased in nanoparticle solutions. No significant decrease in hatchment was found under the UV irradiation. This study indicates that zinc oxide and titanium oxide nanoparticles can influence on the larval development of *Oryzias latipes* in aquatic ecosystem when they are exposed to sunlight having UV region. This work was supported by the National Research Foundation Grant funded by the Korean Government (NRF 2009-0079204).

WP171 Effect of ZnO and TiO_2 Nanoparticles to the Green Microalgae *Pseudokirchneriella subcapitata* Under Visible Light, UVA, and UVB Irradiations W. Lee, Konkuk Univ, Konkuk Univ, Dept of Environmental Science; Y. An, Konkuk Univ, Dept of Environmental Science. Metal oxide nanoparticles have been widely used in a variety of industries. ZnO and TiO_2 nanoparticles are photoreactive substances that are of raising concerns regarding phototoxicity. We assessed the ecotoxicity of ZnO and TiO_2 nanoparticles to green microalgae Pseudokirchneriella subcaputata under different irradiation conditions. Nanoparticles were dispersed in OECD algae medium, and the test units were preilluminated by UVA and UVB light in a photoreactor. Visible light irradiation was served as a control. Inhibition of algae growth was related with the ZnO and TiO_2 NPs concentrations. The growth of *P. subcapitata* was found to be inhibited under visible light, UVA, and UVB irradiation conditions, with no significant differences in results among the light conditions. This reason was attributed to the photocatalytic activity of ZnO and TiO_2 NPs in both UV and visible ranges. This study provides us with an better understanding of toxicity of photoreactivce nanoparticles as related to the effects of light. This work was supported by the National Research Foundation Grant funded by the Korean Government (NRF 2009-0079204)

WP172 Assessing Genotoxicity of Nanosized ZnO and TiO_2 in the SOS Chromotests S. Nam, Konkuk Univ; Y. An, Konkuk Univ, Dept of Environmental Science. Zinc oxide nanoparticles (ZnO NPs) and titanium dioxide nanoparticles (TiO_2 NPs) are widely used in cosmetic products such as colorants and sunscreens. These NPs can be absorbed to users' bodies through oral, inhalation, or dermal contact pathways. The presence of genotoxics entering into the body can induce a probable problem since they cause DNA damage of the receptors. The SOS chromotest with *Escherichia coli* PQ37 has been used for the screening of a variety of chemicals because of its practicality. However, available SOS chromotest data for nanomaterials is extremely limited. In this study, we investigated the genotoxicity of ZnO NPs and TiO_2 NPs by the SOS chromotest with the *E. coli* PQ37 strain. The exposure concentrations of chemicals were 0-100 mg/L ZnO NPs and TiO_2 NPs. Additionally, zinc ion were assessed in the same ways of ZnO NPs. The genotoxicity of Ti ion was not assessed because of extremely low solubility of TiO_2 NPs. ZnO, TiO_2, and Zn ion in a range of tested concentrations (between 0 and 100 mg/L) exerted no effects on the SOS response in the SOS chromotest, evidencing IFmax values of 0.90, 1.24, and 0.68, respectively. Therefore, nanoparticles of ZnO and TiO_2 and zinc ion are classified as non-genotoxics. This is, to the best of our knowledge, the first report to evaluate the genotoxicity of ZnO NPs and TiO_2 NPs using a SOS chromotest. This work was supported by the National Research Foundation Grant funded by the Korean Government (NRF 2009-0079204)

WP173 Toxicity of ZnO Nanoparticles to Estuarine Amphipod (*Leptocherius plumulosus*) S.K. Sundaray, Chonnam National Univ, Dept of Oceanography; B. Lee, Chonnam National Univ, Oceanography; S. Yang, S. Lee, N. Kim, Chonnam National Univ, Dept of Oceanography. Zinc oxide nanoparticles (ZnO-NPs) are now widely used in many industrial, household, and cosmetic products, and there are increasing concerns of their environmental fate and potential toxicities in aquatic organisms. The objective of the present study was to evaluate the potential toxicological effects of ZnO-NPs (< 30 nm) compared to ionic zinc (Zn^{2+}, $ZnCl_2$) in the estuarine amphipods (*Leptocheirus plumulosus*). In the present study, 10-d amphipod sediment acute toxicity test was conducted referred to the USEPA guidelines, using estuarine sediments spiked with 5 nominal Zn concentrations of 5, 10, 15, 30 and 60 mmol/g for both types of Zn. No significant mortality was observed in this 10 d acute toxicity test, when the amphipods were exposed up to 5 µmol Zn/g as ZnO-NPs. Toxicity experiments revealed comparable toxicity for ionic Zn^{2+} (in terms of pore water, PW) spiked as $ZnCl_2$ (5–15 µmol/g), with a 96-h median lethal concentration (LC50) value (60 mM), attributable solely to dissolved zinc. 100% mortality was observed in 60 µmol Zn/g for spiked ZnO-NPs with 40-49 mM Zn in PW, while that for spiked $ZnCl_2$ it was 15 µmol Zn/g as $ZnCl_2$ with 166-434 mM Zn in PW. Based on total Zn concentration, toxicity was 3-4 times higher for $ZnCl_2$ than for ZnO-NPs. However, when compared as a function of the Zn^{2+} concentration in PW, toxicity of ZnO-NPs appeared to be

much higher than that of $ZnCl_2$. These results suggest that ZnO-NPs play a significant and critical role in acute toxicity. During the 10 d experiments, Zn concentration was increased (up to two fold) in overlying water (OW) for spiked ZnO-NPs, whereas that for spiked $ZnCl_2$ remained relatively constant. This may be caused by the release of Zn^{2+} from spiked ZnO-NPs sediments into the OW. Concentrations of Zn in PW decreased significantly in case of spiked $ZnCl_2$ (by 2.3 to 3.2- fold) as compared to spiked ZnO-NPs (by 1.2 to 2.1- fold). The apparent partitioning coefficient (*K*pw, ratio of [Zn] in SEM to PW) increased with increased Zn^{2+} in spiked $ZnCl_2$ sediments and decreased with time, whereas that for spiked ZnO-NPs remained relatively constant. These results reveal that dissolution of ZnO-NPs from spiked sediments relatively increases with time and leads to potential toxicity

WP174 Biodistribution of Quantum Dots in Fathead Minnows, *Pimephales promelas*, Using a Fluorescence Based Assay C.M. Lavelle, Univ of Florida, Center for Environmental Health and Toxicology; M. Hahn, Univ of Florida, Particle Engineering Research Center; K.J. Kroll, Univ of Florida, Physiological Sciences; K. Powers, Univ of Florida, Particle Engineering Research Center; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology. The abundant use of nanomaterials in a variety of applications including cosmetics, electronics, and biomedicine necessitates the understanding for their interactions in biological systems. Of specific importance are the biological transport and fate of nanomaterials in aquatic organisms, as the aquatic environment is a common sink for environmental contaminants. Furthermore, aquatic vertebrates may serve as a model species for the effects of nanomaterials in other organisms. Previous research has shown that particle characteristics such as size and surface chemistry influence biological fate and transport and ultimately effects. One class of nanomaterials of specific interest are the semiconductor quantum dots (QD) which consist of a semiconductor core and shell that can be modified by the addition of different functional groups ultimately changing their surface chemistry. Here we investigated the transport and fate of QDs by utilizing the inherent fluorescent qualities of commercially available quantum dots (QD 705, Invitrogen) with the development of a fluorescence based assay. Biotransportation of QDs was elucidated by dosing of QDs with different surface properties by oral gavage into fathead minnows, *Pimephales promelas*. At multiple time points post dosing, tissues were harvested and homogenized by sonication and later digested with 5N NaOH. Digested tissues were analyzed for QDs by measuring fluorescence (filters: 355excitation, 685 emission). Standard curves were constructed using spiked control tissue pools for each tissue type examined. Results show that most of the dosed QDs are passed through the gut and detectable in the feces at 12 hours post gavage, however, some are able to cross the gut membrane resulting in higher fluorescence readings in the blood as well as in various other tissues in a manner dependent upon QD type and fish sex. Comparison of this fluorescence assay with another widely used technique using the Xenogen platform highlights the increased sensitivity of the fluorescence assay. Results of the fluorescence assay can be further validated with the use of other techniques including confocal microscopy, TEM, and ICP-MS.

WP175 Interactions of Free Chlorine with nC_{60} Differs Between Aged Versus Fresh Aqueous nC_{60} Assessed by Differences in Chlorine Toxicity in Zebrafish J. Park, Univ of Tennessee, Center for Environmental Biotechnology; M. Barham, F. Menn, The Univ of Tennessee, Center for Environmental Biotechnology; Q. He, Univ of Tennessee, Center for Environmental Biotechnology; T. Henry, Univ of Plymouth, School of Biomedical and Biological Sciences, Univ of Plymouth, School of Biology, Univ of Plymouth, School of Biological Sciences; G.S. Sayler, Univ of Tennessee, Center for Environmental Biotechnology, Dept of Microbiology, Dept of Ecology and Evolutionary Biology. A substantial release pathway for manufactured nanoparticles (NPs) is via wastewaters, and passage through wastewater treatment plants (WTPs) will occur before NPs enter surface waters. The C_{60} fullerene is a NP that is present in the aqueous phase as aggregates of many C_{60} molecules (nC_{60}), and nC_{60} are expected to arrive and pass through WTPs; however, little is known about the effects of treatment processes on nC_{60} aggregate characteristics or the fate of substances (e.g., co-contaminants) that are associated with nC_{60} as they pass through WTPs. One treatment process of WTPs is chlorination, and the main objective of the present study was to investigate the interaction of aqueous nC_{60} with free chlorine and evaluate the toxicity in larval zebrafish. We prepared 6 treatments; 1) control (no chemical addition), 2) positive control (5 mg/L of free chlorine), 3) aged nC_{60} (nominal 3 mg/L nC_{60} suspended in water for 3 years), 4) fresh nC_{60} (nominal 3 mg/L nC_{60} solution suspended in water for 2 days), 5) aged nC_{60}+free chlorine, and 6) fresh nC_{60}+ free chlorine. Aqueous nC_{60} and free chlorine were mixed overnight prior to exposure. Mortality and hatching rates were monitored over 5 d in zebrafish eggs (1-day post fertilization) exposed to the above solutions. The presence of aged or fresh nC_{60} did not affect hatching rate. As expected, free chlorine was acutely toxic in zebrafish with dose- and time-dependence (100% mortality within 1 h at 0.24 mg/L free chlorine). However, the acute toxicity of chlorine was significantly reduced with the co-exposure of aged nC_{60}, but not with that of fresh nC_{60}, suggesting different associations between nC_{60} and free chlorine for aged and fresh aqueous nC_{60} preparations. To investigate the physicochemical factors underlying the differences in toxicity, ongoing efforts are studying aged and fresh nC_{60} with Fourier Transformation Infrared Spectroscopy (FT-IR), Nuclear Magnetic Resonance (NMR), and Scanning Electron Microscope (SEM). The reduction in the acute toxicity of free chlorine when mixed with aged nC_{60} but not fresh nC_{60} is further indication that that physicochemistry of aqueous nC_{60} changes with time.

WP176 Impacts of Chronic Exposures to C_{60} and C_{60}-0H Nanoparticles on *Daphnia magna*: Relating Gene Expression and Mortality for Ecological Risk Assessments B.J. Blalock, Univ of Massachusetts, Boston, Environmental, Earth, and Ocean Sciences; D. Arndt, R. Klaper, Univ of Wisconsin-Milwaukee, Great Lakes WATER Institute, School of Freshwater Sciences. Fullerene (C_{60}) and hydroxylated fullerene (C_{60}-OH) nanoparticles have a wide range of applications and a great potential for medical benefits. However, the increasing manufacturing and production of fullerenes has led to the need for more research to assess the associated environmental impacts and determine which nanoparticles are safer for industry, consumer goods, and medicine. Since chronic exposures are more representative of the field this study aims to relate mortality data and Glutathione-S-transferase (GST) and Catalase (CAT) gene expression levels to use genomic data as biomarkers for fullerene exposure. This experiment is a 19-day static renewal chronic toxicity assay using *D. magna* as the indicator species. *D. magna* are exposed to 1 mg/L, 10 mg/L, and 50 mg/L treatments of C_{60}-stir and C_{60}-OH nanoparticles. At the end of the exposure mRNA is extracted and reverse transcribed into the more stable cDNA and the gene expression levels are examined for the selected primers and normalized to Actin. C_{60}-stir and C_{60}-OH nanoparticles are characterized by TEM and Zetasizer. The results of this experiment indicate significant GST and CAT gene expression levels and percent mortality at 10 and 50 mg/L concentrations of C_{60}-stir. Therefore, GST and CAT gene expression levels can potentially be used as biomarkers of C_{60}-stir exposure. Since it is difficult to quantify the concentration of nanoparticles in aquatic systems, GST and CAT gene expression levels can potentially be used as a threshold to rank and characterize nanoparticle risk in aquatic environments.

WP177 The Occurrence of Lead in Soil and Vegetables at a Community Garden in Omaha, Nebraska J. Sangster, Univ of Nebraska – Lincoln, Dept of Civil Engineering; S. Bartelt-Hunt, Univ of Nebraska, Civil Engineering; A. Neilson, Univ of Nebraska – Lincoln, Civil Engineering. Lead is a persistent and ubiquitous soil pollutant in urban environments and is of significant public health importance as it acts as a neurotoxin, particularly to children. Elevated lead concentrations in soil may be due to the use of lead-based paint, emissions from combustion of leaded gasoline, industrial emissions, waste incineration, and pesticide application. One potential pathway for exposure can be consumption of produce grown in lead-contaminated soil, although there is relatively little information available about what types of produce accumulate more lead relative to others and the relationship between soil lead concentrations and concentration of lead in produce. The purpose of this project was to utilize undergraduate students in the environmental engineering laboratory course at the Univ of Nebraska to sample soil and vegetables obtained from City Sprouts, a community garden, located in Omaha, Nebraska. The garden is located within the boundaries of the Omaha Lead Superfund site, which consists of a 27 square mile area in Eastern Omaha with elevated lead concentrations in soil. This area encompasses 15,000 residential properties and was placed on the National Priorities List in 2003. Students collected, dried, and extracted total lead from soil and vegetable samples using a nitric acid/ hydrogen peroxide extraction procedure. The liquid extracts were analyzed for total lead using atomic absorption spectroscopy (AAS). The concentrations of lead measured in soil ranged from 4 to 574 parts per million (ppm). With a few exceptions,

most of the soil samples had lead concentrations below the action level set by the United States Environmental Protection Agency (USEPA) for Omaha, NE at 400 ppm. There was some variability in lead concentrations in soil samples obtained from a single bed. Some of the variability may be due to wind-blown soil contamination from an off-site location. Based on the limited number of vegetable samples tested, it is difficult to draw conclusions based on this data. There is not currently any regulatory limit on lead in food, however, a limit of 0.5 ppm has been established by the FDA for lead in glazed dinnerware. Based on this limit, the samples of leafy greens, eggplant, okra, and one of the tomato samples would be over this limit. Additional testing of vegetables, including more replicate samples would be appropriate.

WP178 Biochar Amendment for Reduction of Bioavailability of Toxic Chemicals in Biosolids H. Hwang, Univ of California, Davis, Dept of Civil and Environmental Engineering, Univ of California, Dept of Civil and Environmental Engineering; H. Kim, Univ of California, Civil and Environmental Engineering. Large fraction of sludge from municipal wastewater treatment plant is being converted to biosolids to use as fertilizer. Most biosolids are being applied to farmland but a certain portion of biosolids is mixed to soils for household gardening and municipal landscape. Biosolids are highly enriched with variety of hydrophobic toxic chemicals, including PBDEs, pyrethroid pesticides, phthalates, perfluorinated compounds, pharmaceuticals, personal care products, and trace metals. To investigate desorption and bioavailability of toxic chemicals in biosolids and potential of biochar amendment for reduction of their bioavailability, grass growing tests were conducted. Biochar is known to have greater capacity to hold organic contaminants and trace metals so plant uptake rate is expected to be reduced when biochar is mixed with biosolids before soil amendment. Biosolid amendment significantly increased the growth rate of grass. Biochar amendment also significantly increased the growth rate of grass. When both biosolids and bioachar are added together, grass growth rate was slightly higher compared to that in soil amended with biosolid only. Next step is to measure toxic chemicals, including PBDEs, PAHs, pesticides, pharmaceuticals and trace metals accumulated in grass tissue to evaluate whether biochar amendment can reduce bioavailability of toxic chemicals in biosolids. The chemical measurement data will be added for the presentation.

WP179 PCBs, PBDEs, and PAHs in the Urban Atmosphere: Spatial and Seasonal Trends and Implications for Contaminant Transport L. Melymuk, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry; M. Robson, Univ of Toronto, Dept of Geography and program in planning; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch; M.L. Diamond, Univ of Toronto, Dept of Geography and program in planning, Univ of Toronto, Dept of Geography. We have examined the distribution of polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), and polycyclic aromatic hydrocarbons (PAHs) in the atmosphere of Toronto, Canada and the surrounding suburban/rural area. A series of temporally- and spatially-distributed air samples were collected over a 1-year period with polyurethane foam passive air samplers and high-volume active air samplers. Bulk air concentrations of ΣPAHs ranged from 0.27 ng/m3 up to 51 ng/m3. Concentrations of ΣPCBs ranged from 6.0 pg/m3 to 1300 pg/m3, and concentrations of ΣPBDEs ranged from 0.47 pg/m3 to 110 pg/m3. All compounds exhibited highest concentrations in the urban core, and lowest concentrations in the surrounding rural areas. Urban-rural gradients were modeled using a radial dilution model, and the comparison between measured and modeled gradients was used to estimate the distribution of POP sources across the urban area. The measured gradient of PCBs in air followed the radial dilution model well, indicating that the dominant PCB source region in Toronto is the downtown core. However, the radial dilution model significantly underestimated atmospheric concentrations of PAHs at distances from 10-40 km from the downtown core, indicating a significant influence of diffuse PAH sources located throughout the urban/suburban region. Comparison between measured and modelled distributions of PBDEs indicated that the majority of sources were in the downtown area, with a lower source density in the suburban regions, and emphasized the importance of particle movement in the transport of PBDEs from the urban to surrounding regions. Relationships between atmospheric concentrations and meteorological parameters were also examined. A strong inverse relationship existed between temperature and partial pressure of the gas-phase PCBs and PBDEs, indicating the dominant influence of temperature-controlled processes on air concentrations, in particular volatilization from local sources of PCBs and PBDEs. The relationship between temperature and gas-phase PAHs varied along the urban-rural gradient, which we believe indicates that in highly urbanized areas, such as downtown Toronto, volatilization from paved surfaces has a significant impact on air concentrations, while in areas with less impervious surface coverage the emissions from domestic heating have a greater influence on atmospheric concentrations of PAHs.

WP180 Reconnaissance Study of Sealcoat Application in Toronto, Canada and an Estimate of Related PAH Emissions E. Goosey, Univ of Toronto; M.L. Diamond, Univ of Toronto, Dept of Geography and program in planning, Univ of Toronto, Dept of Geography; S.A. Csiszar, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry; S. Verkoyeon, C. Catching, Univ of Toronto; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch. Coal tar sealcoats (CTS) are a significant source (i.e., ~50%) of PAH to urban surface waters in many Eastern US cities. This study reports the concentrations of PAH identified in paved surface materials collected from Toronto, Canada. These data are compared to different PAH environmental sources and are used to examine the importance of CTS use across the Toronto region in comparison to the impact from more widely used asphalt materials. Over 100 samples taken across the city fell into four main categories of CTS, asphalt sealcoats (AS), asphalt, and other material. PAH concentrations in CTS ranged from 54 – 24 000 mg kg^{-1}, in comparison to uncoated asphalt (0.1-0.9 mg/kg) and concrete areas of driveways and parking lots (0.02-0.15 mg/kg). Quinoline concentrations ranged from 0.2 to 1700 mg kg^{-1}. We estimated that only 20 % or 14.8 km^2 area of a total of 630 km^2 impervious surface was coated in CTS. The Multimedia Urban Model (MUM) is also used to assess the main transportation mode for the PAH from the sealcoat into other environmental matrices. Results from the model indicated that the use of CTS in Toronto could contribute between 24 – 14 000 kg y^{-1} PAH to nearshore Lake Ontario concentrations with the wide range due to uncertainties in CTS removal rates. This compares to total PAH loadings to Lake Ontario via surface waters of 35 000 kg y^{-1}. Thus, 0.07 % – 40 % of PAH loadings from Toronto to Lake Ontario could be from CTS use.

WP181 Is a Standard Method Desirable for Avian Egg Injections in Toxicological Assessments? T. Augspurger, US Fish and Wildlife Service, Ecological Services; G.H. Heinz, Patuxent Wildlife Research Center, USGS, USGS, PWRC – Beltsville Lab. Injection of toxicants into the avian egg is a common approach for assessing early lifestage effects, but there is no standard method. Age of the embryo at dosing, portion of the egg receiving the dose, vehicle, vehicle volume, and incubation conditions can influence toxicological endpoints. Differences among studies in each of these aspects of experimental design limit integration of results into previous work. A standard method would facilitate comparing the relative toxicity of chemicals to a particular avian species and comparing the relative sensitivity of various bird species to a particular chemical, but standardization would best follow from objectives of the assessment. We suggest four distinct objectives which may facilitate development of one or more standard methods: 1) comparison of chemical (or chemical mixture) toxicity within a species; 2) comparison of chemical or mixture toxicity among species; 3) prediction or reproducing the toxicity observed with maternal deposition of the contaminant; and 4) examination of mechanisms of embryo toxicity. For the first two objectives, development and adherence to standard methods may aid in synthesis of results among studies and increase confidence in results among labs (and therefore support regulatory acceptance of results). For the third and fourth objectives, optimizing experimental design for the specifics of the chemical and species being evaluated likely outweigh the value in applying a standard method. An experimental design framework for each of these objectives is proposed.

WP182 Some Reflections on Egg Injections G.H. Heinz, Patuxent Wildlife Research Center, USGS, USGS, PWRC – Beltsville Lab; T. Augspurger, US Fish and Wildlfie Service. Scientists have been injecting eggs with toxic substances for decades, but there are still many questions that need to be answered in order to fully understand how applicable the results are in terms of protecting the embryonic stage of egg laying animals. This presentation addresses some of those questions, largely through our own experiences in conducting egg injection studies with many species of birds. The biggest

question one faces is whether the administration of a contaminant by way of an egg injection mimics the toxicity when the mother deposits that contaminant in her eggs? If it doesn't, can we make adjustments to the LC50s egg injection studies generate? Egg injections may work better for certain classes of contaminants than others, but at present, we don't know which ones it works best with. Even simple questions, such as where should a given contaminant be injected – into the yolk, albumen, or air cell – have not been adequately addressed. More complicated issues, such as which solvent to use, how much of the solvent to inject, and when to inject are even less studied. The same can be said for what happens at the molecular level; when a contaminant is injected does it just float around in the egg or does it bind to compounds in the egg? Normally, one might collect eggs from animals in nature to inject, but if those wild eggs contain some of the same contaminant, how do you add together the naturally bound and injected concentrations and assess their effects? When eggs are injected and incubated artificially in the lab, hatching success of the eggs, even the control eggs, can be very poor. How can this be improved to give better dose response results? Could the results from egg injection studies ever fit into the setting of regulatory guidelines? Can egg injections become an acceptable way to conduct otherwise impossibly costly interaction studies with two or more contaminants? All of these questions, and more, are deserving of discussion and research.

WP184 Body Distribution of Mercury in the Chicken Embryo Following Methylmercury Chloride Egg Injection J. Rutkiewicz, Univ of Michigan; D. Nam, Univ of Michigan, Dept of Environmental Health Sciences; J. Head, Univ of Michigan, Cooperative Institute of Limnology and Ecosystem Research, Univ of Michigan, Cooperative Institute for Limnology and Ecosystem Research; N. Basu, Univ of Michigan, Dept of Environmental Health Sciences, Univ of Michigan, Dept of Environmental Health. Methylmercury (MeHg) is a potent environmental toxicant that is associated with decreased reproductive success in wild and captive birds. Although females deposit methylmercury into their eggs, few studies have investigated exposure and subclinical toxic effects in the developing embryo. Even fewer have characterized the toxicokinetics of mercury (Hg) deposition across organs during development. The goal of this study was to examine the body distribution of Hg in embryos exposed at the start of incubation in order to gain a better understanding of potential sites of toxicity. To mimic maternal deposition, fertilized white leghorn chicken eggs were injected at day 0 with 0, 0.17, 0.62, or 2.0 mg/g egg MeHg chloride in corn oil. Following injection, eggs were artificially incubated in the laboratory until day 19, when embryos were dissected. Samples from the brain (cerebrum, cerebellum, optic lobe), liver, heart, kidney, muscle, and feather were collected and stored at -80°C until wet tissues were analyzed on a direct mercury analyzer (DMA-80) for total Hg. Embryos in the 0 mg/g vehicle control group did not accumulate appreciable concentrations of mercury in their tissues. Regardless of Hg dose group, Hg concentrations were highest in feathers, followed by liver, kidney, muscle, heart, and brain of Hg exposed embryos. However, embryos in the 0.62 and 2.0 mg/g dose groups accumulated a higher burden of Hg in the feathers and liver (feather Hg=12-14X brain Hg; liver Hg=3-4X brain Hg) relative to the brain than did embryos in the 0.17 mg/g dose group (feather Hg =7X brain Hg; liver Hg=2X brain Hg). In all dose groups, Hg concentrations did not differ significantly between brain regions. These results indicate that chicken embryos accumulate a body distribution of Hg similar to that of adult birds, and may similarly sequester Hg in the liver and feathers to protect against toxicity in the brain.

WP185 A Field Egg Injection Study to Evaluate Methylmercury Toxicity in Common Loons (*Gavia immer*) K. Kenow, USGS; M.W. Meyer, Wisconsin Dept of Natural Resources; R. Rossmann, USEPA; A. Gendron-Fitzpatrick, Univ of Wisconsin; B. Gray, US Geological Survey, Biological Resources Division. To determine the level of in ovo methylmercury exposure that results in detrimental effects on fitness and survival of common loon (*Gavia immer*) embryos and hatched chicks, we adapted egg injection techniques for field use. Eggs were injected with methylmercury chloride solutions on day 4 of incubation to achieve targeted increases in egg mercury concentrations of 0.0 (control, corn oil carrier only), 0.5, 1.3, and 2.9 µg mercury/g of wet-weight egg content. Eggs were injected at a rate of 0.5 µl solution/g egg content. Eggs were collected following about 23 days of natural incubation and then artificially incubated to observe hatching. Reduced embryo survival was evident in eggs injected at a rate of ≥1.3 µg mercury/g wet-mass. When maternally deposited mercury and injected mercury were considered together, the median lethal concentration of mercury (LC50) was estimated to be 1.78 µg mercury/g wet-mass. We also observed increased length of incubation period, differences in chick organ mass patterns, and behavioral changes (chicks less responsive to a frightening stimulus) with increasing egg mercury concentrations. The results of this work contribute to our understanding of a critical exposure component needed to assess the risk of mercury to common loons.

WP186 Effects of an Environmentally Relevant PCB Mixture on Embryonic Heart Development in *Gallus domesticus* (Domestic Chicken) T. Carro, Univ of Maryland, graduate student; L. Taneyhill, Univ of Maryland, Dept of Animal & Avian Sciences; M. Ottinger, Univ of Maryland, Dept of Animal and Avian Sciences. Polychlorinated biphenyls (PCBs) are synthetically made chemicals that consist of biphenyl rings with one to ten chlorine substitutions. Mixtures of PCBs were commercially used in the US from the 1920's until their ban in the 1970's and desirable due to their overall general inertness. PCBs have been linked to adverse health conditions such as carcinogenicity, endocrine disruption, reproductive interruption, and decreased neurological function. In 2007, a study conducted in a wild bird population determined that embryonic exposure to a single PCB congener did not affect survivability of the population, but did affect heart morphology in hatchlings. To examine whether PCBs adversely affected heart development in ovo, an environmentally relevant PCB mixture was administered to broiler chicken embryos. The results of this study showed that the PCB mixture decreased survivability at increasing concentrations, affected heart rate during embryonic development, and produced a variety of cardiomyopathies in hatchling hearts; including absence of the heart wall compact and trabeculated layers, enlarged ventricular cavities, and abnormal septal formation. The effects noted in this hatchling study suggested a disruption of protein essential in heart muscle formation during embryonic heart development. Among the protein candidates was ventricular myosin heavy chain (VMHC), which is a major structural component of heart muscle that is expressed throughout the entire heart field during early heart tube formation. To explore the possibility of spatial-temporal disruption of VMHC in the embryonic heart due to PCB exposure, embryos were exposed to a low and high concentration of the PCB mixture and collected at three significant stages of chick heart development. Immunohistochemistry with a VMHC antibody was used to categorize morphological abnormalities in whole mount and on sections. The results from this study will determine the stage(s) of early cardiac development most vulnerable to PCB exposure and will potentially delineate the molecular basis of underlying cardiomyopathies observed in PCB-treated hatchling hearts. The conclusions and opinions presented here are those of the authors, they do not represent the official position of any of the funding agencies, the Hudson River Trustees or the United States.

WP187 Apparent Tolerance of Common Tern (*Sterna hirundo*) Embryos to a Pentabrominated diphenyl Ether Mixture (DE-71) R.S. Lazarus, Patuxent Wildlife Research Center, USGS; B.A. Rattner, Patuxent Wildlife Research Center, USGS, USGS-Patuxent Wildlife Research Ctr, Beltsville Laboratory; G.H. Heinz, Patuxent Wildlife Research Center, USGS, USGS, PWRC – Beltsville Lab; S.E. Warner, N.K. KarounaRenier, S.L. Schultz, Patuxent Wildlife Research Center, USGS; R.C. Hale, Virginia Institute of Marine Science, Environmental & Aquatic Animal Health. Recent polybrominated diphenyl ether (PBDE) embryotoxicity studies with American kestrels (*Falco sparverius*) suggest the lowest-observed-effect-level (LOEL) for pipping and hatching success to be 1.8 µg total pentaBDE/g ww (~32 µg/g lw). Concentrations of total PBDEs in Forster's tern (*Sterna forsteri*) eggs from the San Francisco Bay range up to 63 µg/g lw, and thus exceed this LOEL. As a surrogate for west coast terns, 60 recently laid common tern (COTE) eggs were collected from Poplar Island, MD. Six eggs (vehicle injected controls that failed to hatch) were chemically analyzed and all were found to contain low levels of organochlorine pesticides (< 0.08 µg/g ww), total PCBs (< 0.5 µg/g), and total PBDEs (< 0.05 µg/g), indicating that sample eggs from this mid-Bay location could be used for studying DE-71 embryotoxicity. Eggs were artificially incubated, and on day 4 of development, corn oil vehicle (n=19, controls), 0.2 µg/g (n=12), 2 µg/g (n=12), or 20 µg/g (n=17) of a pentaBDE mixture (DE-71) was injected into the air cell at a constant volume (0.5 µl/g egg). There were no significant effects of DE-71 on survival to 90% of incubation (DE-71: 63.6-90.9% vs. 87.5% for controls), to pipping (63.6-81.8% vs. 81.8%), and to hatching (63.6-75.0% vs. 81.3%). Controls hatched on average 0.44 days earlier than the DE-71

groups ($p < 0.015$). No gross deformities were observed, and the lengths of the tibiotarsus, metatarsus, femur, humerus, and ulna in cleared skeletal preparations did not differ among groups. Crown-rump lengths in the 0.2 and 2 µg/g treatments were greater ($p < 0.01$); however, the magnitude of change did not seem to be biologically significant. Weights of hatchlings, yolk sac, liver, bursa, thyroids, and organ to body weight ratios were not affected by DE-71, although the spleen:body weight ratio of the 2 µg/g group differed ($p = 0.03$) from other groups. Histopathological examinations of liver, kidney, spleen, bursa of Fabricius, and thyroid were unremarkable. Oxidative stress and genotoxicity assays are being conducted on liver tissue. These results suggest that COTE embryos, and perhaps other tern species, are no more sensitive (and probably less sensitive) to PBDEs than kestrel embryos. A similar pattern of sensitivity between terns and kestrels has been observed in egg injection studies involving PCB-126 and methylmercury.

WP188 Gonadal Structure and Development of Turtle Malayemys Macrocephala After Topical Application of Environmentally Relevant Dose of Cadmium to Eggshell N. Kitana, Chulalongkorn Univ, Dept of Biology; S. Keithmaleesatti, Khon Kaen Univ, Dept of Environmental Sciences; M. Chiewchanchai, J. Kitana, K. Thirakhupt, Chulalongkorn Univ, Dept of Biology, Faculty of Science. In Thailand, cadmium (Cd) contamination at Mae Tao river basin, Tak Province raise concerns over potential impacts to human. The contamination is so severe that cadmium can be found in sediments, soil and grains of rice that grew in that area. However, there is still limited information on impacts on biological systems, especially animals living in the area. As a result, the monitoring system for potential effects on human populations is thus unlikely. In this study, a freshwater turtle, *Malayemys macrocephala*, was used as a sentinel species to monitor the effects of exposure and, by inference, the potential for human health impacts. Since contaminant may affect turtle by exposing through eggshell as well as maternal transfer via yolk, effect of cadmium on turtle embryos was thus examined. Freshly laid eggs were collected from a reference site with no history of Cd contamination. Representatives of eggs were subject to an ICP/ES analysis to verify that the Cd content in egg yolk is non-detectable. The effect of cadmium was determined in eggs subjected to topical exposure to $CdCl_2$. The doses used (0, 3, 30 and 300 µg total Cd/g egg weight) were based on Cd content in soil at Mae Tao areas (3.4-284 µg/g). Eggs were kept in an incubator at 29°C, the temperature that yields 1:1 sex ratio, until hatch. Cadmium content carried across the eggshell was estimated by GFAAS analysis in different egg compartments two weeks after exposure. It was found that 0.07% of the applied dose could be transferred to egg yolk. Hatching success (31.43%-48.57%) and hatchling weight (6.11-6.55 g) were not significantly different among groups. However, low dose of cadmium significantly prolonged the incubation time compared to those of the control (147 vs. 113 days). Sex ratio of hatchlings from the control showed 1:1 sex ratio while the increasing dose of cadmium produced the male-biased sex ratio, although the *G* test did not show significant difference from expected ratio (1:1) in any groups. Gonadal structure of neonate turtle was examined histologically, and the results will be presented. Potential interference of cadmium with gonadal structure and development of the freshwater turtle after topical exposure through eggshell will be discussed.

WP189 Estrogenic Activity Assessment of Propylpareben in Water During Photochemical Degradation T. An, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, State Key Laboratory of Organic Geochemistry; H. Fang, Graduate School of Chinese Academy of Sciences, ; G. Li, Guangzhou Institute of Geochemistry,Chinese Academy of Sciences, State Key Laboratory of Organic Geochemistry; X. Nie, Institute of Hydrobiology, Jinan Univ. Pharmaceutical and personal care products (PPCPs) have recently been classified as pollutants because of their ubiquitous detection in surface water and water treatment systems. One of the widely used PPCPs is propylparaben, which is applied as preservative in products such as cosmetics and shampoo. There are many references that have reported the estrogenic activity of propylparaben, which has raised a concern about its potential impact on environment and human health. However, the information on the environmental fate of propylparaben residues is limited. Thus, its environmental fate and effect on the organisms are of great concern. Photochemical degradation is an efficient process for most of PPCPs. Organic compounds could be mineralized through a series of complex reactive ways, such as reacting with •OH, 1O2, and the triplet state of compound itself or other sensitizers. Thus, in this work, photochemical degradation of propylparaben in water was studied in detail. It shown that degradation rate of propylparaben decreased with the increasing of initial pH. To better know the role of different reactive oxygen species (ROSs) during photochemical degradation, different specific scavengers were used. Results indicated that triplet state of propylparaben had the major contribution in the degradation of propylparaben in aqueous solution. In addition, the transient spectrum of triplet state of propylparaben was examined to probe the degradation mechanism. The photochemical degradation mechanism of propylparaben was tentatively proposed based on several identified degradation intermediates by LC/MS/MS. Furthermore, the change of toxicity and estrogenic activity during the photochemical degradation were also attempted. Acknowledgments: Financial supports from Knowledge Innovation Program of CAS (No. KZCX2-YW- QN103) and NSFC (No. 40973068).

WP190 Is This Dirt Hazardous? Identification and Differentiation of Contamination Sources in the Environment C. Yang, Z. Wang, Z. Yang, B. Hollebone, C. Brown, Environment Canada. Petroleum-related contamination is one of the most widespread environmental issues in Canada, North America, and worldwide. Remediation of the contaminated sites to meet the regulatory standards for agricultural, commercial and residential uses is usually very costly. Ubiquitous organic contaminants in the environment are generally originated from three main sources, i.e., petrogenic (PHCs), pyrogenic and biogenic (BOC). The naturally biogenic organics in soils and sediments can be easily misidentified and quantified as regulated hazardous petroleum hydrocarbons if not properly determined. In some cases, these non- or low hazardous biogenic interferences can exceed regulatory levels, resulting in unnecessary remediation. The paper introduces methodologies for the characterization and differentiation of the contribution of various sources to environmental contamination. Chromatographic analysis provides fingerprints of petroleum-related hydrocarbons such as alkylated PAHs (APAHs) and biomarkers, and biogenic compounds (BOCs) such as waxes, sterols, fatty acids and fatty alcohols. Because biomarker compounds including bicyclic sesquiterpanes and diamondoids are naturally absent from modern soils and sediments that are free from petroleum contamination, in addition to the signatures of determined APAHs and traditional biomarker terpanes and steranes, their presence provides further evidence of petroleum contamination. A series of diagnostic ratios are found to be effective in distinguishing biogenic source from others in environmental samples.

WP191 Fate of Airborne Cyclic Organic Siloxanes in the Presence of Ozone and UV Lights and Its Implications Z. Gao, Health Canada, Exposure and Biomonitoring Division, Healthy Environments and Consumer Safety Branch; Y. Feng, J. Zhu, Health Canada; J. Zhang, Syracuse Univ, Dept of Mechanical and Aerospace Engineering. The objective of this study is to investigate the effects of environmental factors (ozone and UV light) on fate of airborne cyclic organic siloxanes, and potential formation of secondary compounds. Octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5) were selected for the study. The tests were carried out in a full-scale stainless steel environmental chamber with an interior volume of 56.4 m3. The chamber air conditions were set at 23°C (± 2°C) and 50% (± 10%) RH. Four UVA and four UVB lamps were placed at the corners in the chamber. For UVA lamps, the max light intensity at the lamp surface was 20.5 mW/cm2 by UVA meter and 0.12 mW/cm2 by UVB meter. For UVB lamps, the max light intensity at the lamp surface was 5.5 mW/cm2 by UVA meter and 2.48 mW/ cm2 by UVB meter. The light intensity decreased below 1mW/ cm2 for both UVA and UVB at 1 m away from the lamp. Ozone was generated by an ozone generator and its concentration was monitored continuously by an ozone analyzer. D4 or D5 was spiked into the chamber to create a concentration of 1 mg/m3. Formaldehyde concentration was monitored by 1412 gas monitor while other VOCs (including D4 or D5) were analyzed by GC/MS. Significant ozone consumption accompanied with measurable formaldehyde production was observed when D4 (and D5) was mixed with ozone in the presence of UV lights. A clear decrease of D4 (and D5) concentration in the chamber was also observed when the compound was exposed to a combination of UV light and ozone. D4 and D5 were however, found to be stable in the presence of either ozone or UV light alone. It appears that UV light promoted the production of ozone in the chamber thereby promoted reduction of airborne siloxanes. The identification and quantification of reaction products need to be further investigated.

WP192 Alternate Approaches to Assessment of Benthic Health in Sediment Limited Systems W.J. Reese, J.R. Flanders, URS Corporation;

C. Mancini, URS Corporation, Manager-Ecosystems Management Team; R.G. Stahl, DuPont Company, Corporate Remediation Dept, Principal Consultant, DuPont Corporate Remediation Group. Benthic macroinvertebrate community structure has been used as to measure habitat integrity and the effect of environmental stressors over time in a variety of regulatory and environmental settings. The benthic macroinvertebrates inhabiting fluvial systems include a range of trophic levels, providing information for potential cumulative effects of stressors as well as a detailed understanding of the benthic macroinvertebrate component of the aquatic food web. In order to assess benthic community structure and colonization dynamics along a gradient of mercury, a benthic colonization study was designed and implemented in the South River, Virginia, which has elevated levels of mercury compared with regional background levels due to historic uses of mercury in the watershed. The study design included deployment of uniform substrate types, standardized deployment parameters, and controlled exposure times to minimize variability between treatments. Substrate-filled colonization trays were deployed in riffles at four study sites downstream of the historic point source of mercury and two reference sites, and will be sampled after 14, 28, and 42-day colonization periods. Co-located benthic samples will also be collected using a Surber sampler to characterize resident benthic community structure by means of a traditional method. Additionally, co-located interstitial sediment samples will be collected and analyzed for total mercury (THg) and methylmercury (MeHg) to establish potential concentration gradients in physical media. Specific community metrics will be evaluated to characterize the colonized and resident community samples. Statistical analyses may include analysis of variance (ANOVA) and correspondence analysis to evaluate differences in benthic colonization community structure in the South River, Virginia.

WP193 Arsenic Speciation and Biotransformation in Highly Contaminated Marine Benthic Macroinvertebrates K. Whaley-Martin, I. Koch, K. Reimer, Royal Military. College of Canada, Environmental Sciences Group. The ability to predict and mitigate toxic effects of arsenic in marine environments is dependent on knowledge of how arsenic is biochemically transformed and the factors controlling these mechanisms. Arsenobetaine, a non-toxic arsenic compound, is commonly found in marine animals, and recent studies point to the possibility that the formation or uptake of this compound is compromised in organisms exposed to high concentrations of arsenic in severely contaminated environments. In such environments, we hypothesize that arsenic is taken up unchanged, as toxic inorganic arsenic. The first part of this investigation measured the proportion of inorganic arsenic, using complementary techniques (high performance liquid chromatography – inductively coupled plasma mass spectrometry and x-ray absorption near edge structure analysis) in three common marine benthic macroinvertebrates (Blue Mussels (*Mytilus edulis*), Edible Periwinkles (*Littorina littorea*) and Shore Crabs (*Carcinus maenas*)) as a function of an arsenic concentration gradient. Preliminary results show strong positive correlations between the increase in the proportion of inorganic arsenic and the increase in total arsenic present in all three marine benthic organisms. This may have significant implications with respect the health of marine biota and humans consuming them. The second part of this investigation examined the bioaccumulation and metabolism of arsenic more closely in *Mytilus edulis* by in situ elemental mapping the arsenic distribution in a fully intact organism from a contaminated site. The gills, mantle and digestive gland, which are organs that are important for analyte absorption and uptake, were targeted. Mapping was carried out at the known k-edge absorption photon energies of three arsenic species: As(V) (11875.3 eV), AB (11872.6 eV) and As(III) (11871.7 eV), as well as at 11868 eV for total As, Se, Br, Zn, Cu, Ni, Fe, Mn, Ti, Ca, Cr, K, Hg, S and P mapping. Preliminary results revealed interesting As(III) and As-S hotspots in the digestive gland which do not seem to correlate with any other elements, indicating the hot spots are biological and not mineralogical.

WP194 Dietary Arsenic Toxicity in Subadult Rainbow Trout: Growth Effects, Nutrient Absorption, and Tissue Bioaccumulation D. Hoff, T.L. Highland, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; J.R. Hockett, USEPA, Mid-Continent Ecology Division; C. Jenson, M. Poe, USEPA. Dietary arsenic toxicity in subadult (~200 g.) rainbow trout was evaluated in a 70 day test using arsenic-spiked pellet diets containing 50, 104 and 162 ppm arsenite. All organisms in all treatments survived the exposure. Dose dependent effects on percent weight gain, with commensurate changes in feed conversion and efficiency, were noted in all arsenic-spiked diets. Growth, as measured by standard length, was similarly affected in a dose-dependent manner. Chromic oxide was also spiked into all pellet diets at a concentration of 0.3% and was used as a marker for measuring absorption of gross lipid and protein in the contaminated diets. Weekly fecal samples were collected to detect changes in nutrient digestion throughout the 10 week exposure. Little to no change in protein absorption was noted throughout the exposure period. While lipid absorption was similar for the first 4 weeks across all treatments (91-94%), they subsequently decreased progressively in arsenite-spiked treatments through the end of the experiment to as low as 80% in the higher doses. Liver, kidney, pyloric caecum, gall bladder and muscle tissue were harvested at the termination of the study allowing for the calculation of tissue-specific bioaccumulation factors. Findings are discussed in the context of previous studies of arsenic effects and the potential for developing residue-based assessment approaches. This abstract does not necessarily reflect EPA policy.

WP195 Evaluating the Effects of Sub-lethal Copper Exposure on Ammonia Excretion in the Euryhaline Guppy, *Poecilia vivipara* A.M. Zimmer, McMaster Univ; I.F. Barcarolli, Universidade Federal do Rio Grande – FURG; C. Wood, McMaster Univ; A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. Copper is a common toxic pollutant in aquatic environments and though Cu is known to be lethal at elevated levels, the physiological effects of non-lethal Cu exposure are not well understood. To date, studies seem to suggest that Cu exposure disrupts Na^+ uptake and ammonia excretion (J_{amm}). These observations are very interesting physiologically as these processes are thought to be linked to one another in the current molecular model for ammonia excretion. Acute 96 h exposure to 20 µg/l Cu using *Poecilia vivipara*, a euryhaline guppy collected at a creek flowing into the sea at Cassino Beach (Southern Brazil), demonstrated that fish acclimated to saltwater (SW; 25ppt) are more sensitive than those acclimated to freshwater (FW; 0 ppt). Though Cu exposure elicited a transient inhibition of J_{amm} in both FW- and SW-acclimated fish, the exposure resulted in a reversal of J_{amm} in the SW-acclimated fish. However, following 84 h of Cu exposure, both acclimation groups were able to recover J_{amm} to control levels. To further understand the mechanism of the compensatory responses displayed by both fish groups, 24 h and terminal activity of carbonic anhydrase (CA), Na^+/K^+-ATPase, and H^+-ATPase will be measured to assess if these enzymes play a role in the observed inhibition and recovery of J_{amm}. Furthermore, the effect of copper on Na^+ homeostasis will be assessed by measurements of terminal whole-body $[Na^+]$ in both fish groups.The ultimate goal is to develop a model for understanding the physiological effects of non-lethal Cu exposure in both SW- and FW-acclimated fish. [Supported by the International Research Chair Program of the International Development Research Centre, the Canada Research Chair Program and the Brazilian CNPq (INCT-TA)].

WP196 Investigation of Arsenic Speciation in Plankton Organisms from Contaminated Lakes by HPLC-ICP-MS and XAS G. Caumette, I. Koch, K. Reimer, Royal Military. College of Canada, Environmental Sciences Group. Arsenic is mainly found as a toxic inorganic compound in water, while aquatic organisms contain organoarsenicals, with the non-toxic arsenobetaine being the main compound found in marine organisms. For health and safety reasons, such as the exposure of local populations, there is still a need to understand the cycling of arsenic through the food chain, and the pathways of formation of the non-toxic arsenobetaine. The marine environment has been widely studied and arsenobetaine is found as the major arsenic compound in most animals, including zooplankton, which is at a low trophic level of the marine food chain. Marine algae and phytoplankton, on the other hand, contain mainly arsenosugars. A hypothesis to explain these findings describes arsenobetaine as an osmolyte needed in saline environments (Clowes et al. 2004). The present work studies arsenic speciation at the base of the freshwater food chain, in plankton. Although the osmolyte requirements are not the same, arsenobetaine has been found in freshwater fish (Miyashita et al. 2009). Phytoplankton and zooplankton species were collected from gold-mine contaminated lakes in Yellowknife, NT, Canada. Arsenic speciation was measured in phytoplankton and the different zooplankton species isolated (*Cyclop* sp. and *Daphnia pulex*). HPLC-ICP MS (high performance liquid chromatography – inductively coupled plasma mass spectrometry) was used on water-extracts and XAS (X-ray absorption spectroscopy) was used on the whole solid samples and residues from extraction, in order to assess speciation of the unextracted arsenic. The results show that unlike marine phytoplankton (which contain

arsenosugars), freshwater phytoplankton only contain inorganic AsV. However freshwater zooplankton contain several organoarsenicals, with the sulphate arsenosugar as the most abundant, up to 47% of total arsenic. The other arsenic compounds identified were the phosphate arsenosugar, the glycerol arsenosugar, MMA (monomethylarsonic acid) and DMA (dimethylarsinic acid). The proportion of these compounds in zooplankton organisms varies according to the species analyzed and the arsenic concentration in the lake. In uncontaminated lakes, arsenobetaine was found in Cyclop sp. as a minor compound, less than 8% of total arsenic measured but it was not present in organisms from contaminated lakes. This information supports the likelihood that arsenobetaine is not required, by freshwater organisms as much as in the marine environment.

WP197 Metal Accumulation from Dietary Intake in the Sea Urchin, *Strongylocentrotus droebachiensis* T. Jarvis, Valdosta State Univ, Biology; G.K. Bielmyer, Valdosta State Univ, Biology, Valdosta State Univ, Dept of Biology. Heavy metal contamination is an increasing problem in aquatic environments; however, little research has focused on the effects of dietary metal exposure to macroinvertebrates. The seaweeds, *Ulva lactuca* and *Enteromorpha prolifera*, readily uptake metals, are widely distributed, and are often used as bioindicators in ecological studies. Additionally, these species serve as vital components in aquatic food chains. *U. lactuca* and *E. prolifera* were exposed to five metals (Cu, Ni, Pb, Cd, and Zn) and fed to the green sea urchin, *Strongylocentrotus droebachiensis*, for two weeks. Body mass, test length, and total length were measured, the sea urchins were dissected and their organs (esophagus, stomach, intestine, gonads, and rectum) were digested and analyzed for metal content using graphite furnace atomic absorption spectrophotometry. The results demonstrated that metal accumulation and distribution varied between seaweed species and among metals. All of the metals accumulated within at least one organ of *S. droebachiensis*, with Cu being most significant. In general, there were higher levels of metals within the sea urchins fed *E. prolifera* as compared to those fed *U. lactuca*. These results indicate that *E. prolifera* may accumulate metals in a more bioavailable form than within *U. lactuca*, which may substantial impact metal toxicity in the consumer. No significant differences in body length or growth were detected between the control and metal-exposed sea urchins after the two week testing period, despite the observed increase in tissue metal accumulation. However, increased exposure duration may lead to more substantial effects.

WP198 A Multi-media Approach to Stream Metal Contamination in Canada's "Chemical Valley": Implications for the Aamjiwnaang First Nation D. Cryderman, L. Letourneau, N. Basu, School of Public Health, Univ of Michigan, Environmental Health Sciences. Approximately 40% of Canada's petrochemical industry lies near the Aamjiwnaang First Nation Reserve, in Sarnia, Ontario. Previous work has shown the possibility that various metals, among other pollutants, in a local stream may pose threat to wildlife species and human residents. Here we initiate a broader study (spatially and temporally) to address the levels of multiple metals (e.g., cadmium, cobalt, lead, manganese, and zinc) in stream water on and near the Reserve, as well as mercury levels in sediment and soil collected from those streams. The purpose was to determine if sites on Reserve have higher concentrations of these metals than off Reserve, and to identify any site at which levels exceed benchmark values. Surface water, sediment and soil were collected from twenty-five stream sites were analyzed for metals during the fall of 2010 and spring of 2011. Three out of twenty-five stream sites showed elevated levels of lead(ranging from below LOD to 379 ppb), one site had elevated levels of cobalt (ranging from below LOD to 7ppb), and four sites had elevated manganese levels (ranging from 4ppb to 1924ppb) in stream water. In general, stream water concentrations of metals were higher in the fall than the spring. Levels of mercury in sediment (0.2ppb-1830ppb) and soil (1.2 ppb – 646ppb) collected near sites were elevated in multiple streams, with concentrations in the fall tending to be higher than in the spring. Overall, these findings suggest that metals contamination is ubiquitous in the region, and that spatial and temporal variation exists. Future work is needed to determine the bioavailability (and possible health effects) in resident wildlife and humans.

WP199 Benthic Macroinvertebrates Community and Sediment Toxicity in an Metropolitan Water Supply Reservoir in Brazil F. Lage, A.L. Brandimarte, Universidade de São Paulo – USP, Dept of Ecology ; C.M. Botta, E.L. Espindola, Universidade de São Paulo – USP, Escola de Engenharia de São Carlos – EESC. The high demand for water supply led Guarapiranga reservoir, built primarily for power generation, became a relevant public water supply to Sao Paulo city (Brazil) since 1928. Moreover, due to high urbanization, nowadays more than half of its basin area is modified, sewage and diffuse pollution are the main pollution sources. The relationship between benthic community and sediment features was evaluated in three sites, in each one of four sampling stations (one near the dam and three in the main reservoir tributaries: Embu-Mirim, Embu-Guacu and Parelheiros). In July 2010, 6 sampling units for benthic fauna analysis and 3 for sediment bioassays were collected with an Ekman-Birge grab in each sampling site. Fauna samples were washed into a 500 µm mesh sieve and preserved in 4% neutralized formalin in the field. In the laboratory, samples were transferred to 70% alcohol and stained (Rose Bengal). Two sediment samples of each site were collected with an Ambühl & Bührer corer for physical and chemical measures. All sites had 7 *taxa*, except Embu-Guacu with 9. Oligochaeta was the most abundant group in all the sites, except in Parelheiros where Chaoboridae was most abundant. Silty sediment predominated, except in Embu-Guacu where was a sandy site. The average organic matter sediment content was 35%, with higher value in the dam region. Extremely reducing conditions were observed in Embu-Mirim and near the dam, especially in the drinking water catchment area. Another author found the highest values of the relationship (Σ [SEM] – [AVS]), TOC, the highest concentrations of metals and concentrations above PEL for chromium, copper and lead, and above VRR for all metals analyzed, except nickel around the dam. Presence of Oligochaeta and Ostracoda was associated with the organic matter content and presence of silt. Besides Chaoboridae, other insect larvae were found, including Tanypodinae, *Chironomus decorus* and Ceratopogonidae. The test with *Daphnia similis* showed significant sediment acute toxicity in all regions except in Embu Guacu. The test with *Chironomus xanthus* showed significant sediment acute toxicity in all regions except for one site in Embu Guacu and one in Embu-Mirim. The test for porewater with *Daphnia similis* showed significant acute toxicity in the dam region. Spatial heterogeneity, due to many of the variables analyzed, divided Guarapiranga reservoir in 2 compartments: Embu Guacu and Parelheiros; Guarapiranga-dam and Embu-Mirim.

WP200 Can Freshwater Toxicity Models (FIAM and BLM) Be Applicable to Marine Ecosystems? Y. Dong, Denmark Technical Univ, Section of Quanlitative Sustainability Assessment, DTU Management Engineering; M. Owsianiak, Technical Univ of Denmark, Dept of Management Engineering; K.S. Christiansen, Univ of Copenhagen, Dept of Basic Sciences and Environment, Faculty of Life Sciences, Denmark Technical Univ, Section of Quantitative Sustainability Assessment, DTU Management Engineering; M.Z. Hauschild, Denmark Technical Univ, Section of Quanlitative Sustainability Assessment, DTU Management Engineering. Metal toxicity in freshwater ecosystems is relatively well documented and predictive models such as biotic ligand models (BLM) or free ion activity models (FIAM) are available. However, toxicity of metals in marine and estuarine waters has attracted less attention, despite the fact that these waters receive a large share of total metal emission from industrial activities. While recent studies report that metal uptake rates for marine fish are comparable to those for freshwater fish, they also reported on higher sensitivities of freshwater organisms to toxic metals when compared to marine species. We hypothesize that the observed differences are a result of differences in water compositions, with elevated concentrations of cations in marine waters reducing metal toxicity by competitive binding to biotic ligands, and the presence of anions to form complexes with toxic metal ions. If this hypothesis is true, it should be possible to extrapolate ecotoxicity models developed for freshwater organisms to marine ecosystems by taking differences in ionic composition into account. The aim of this work is to test the applicability of freshwater FIAMs and BLMs for predicting metal toxicity in marine and estuarine ecosystems. Firstly, published BLMs for freshwater fish are employed to calculate the activity of free metal ion corresponding to EC50 in freshwaters spanning a wide range of water characteristics. Results show that toxicity of metals to fathead minnow varies about 1 order of when expressed as free ion concentrations (4.9E-09–7.8E-08 mol /l for Cu^{2+}). The predictions made with FIAM fall within the range of values predicted by BLMs. Next, assuming that intrinsic sensitivity of marine fish to toxic metal is similar to that of freshwater fish, freshwater BLMs are employed to predict EC50 of metals in salt waters. The calculated free ion EC50 values are up to two orders of magnitude higher than in freshwaters. To test the accuracy of the predictions, FIAMs for marine fish are derived from published EC50 values for salt

waters by means of speciation modeling. The results show a good correlation between freshwater BLMs extrapolated to marine ecosystem, and marine FIAMs. This highlights the importance of taking metal speciation and water composition into account in predicting metal toxicity. It also suggests that existing toxicity parameters for freshwater organisms can be extrapolated to marine ecosystems.

WP201 Chromium(III) Exposure is Toxic to Developing Zebrafish Altering Expression of Genes Critical to Matrix Metabolism (MMP) and Metal Detoxification (MT) A.A. Rucki, K.R. Cooper, L.A. White, Rutgers, the State Univ of New Jersey, Dept of Biochemistry and Microbiology. We hypothesize that chromium (III) is a potential teratogen that exerts its effects through alteration of matrix metabolism. Furthermore, we hypothesize that metallothionein can be used as a marker for aquatic contamination with chromium (III). Chromium (III) is an essential element required for fat and protein utilization; however, at higher concentrations it can be toxic. Approximately 2,300 metric tons of chromium (III) are released to the atmosphere in the United States from a variety of sources (leather tanning, wood preserving) each year. This released chromium does not remain in the atmosphere, but is deposited into soil and water resulting in exposure of aquatic species. We exposed zebrafish embryos to chromium (III) from 2 hour post fertilization (hpf) at concentrations ranging from 0.2μM to 5.0μM, and embryos were observed at 24, 48, and 72 hpf. We found that chromium (III) exposed zebrafish showed a statistically significant increase in mortality at 2 μM, as well as increased incidence of hemorrhaging, edema, tail curvature and yolk sack dysmorphia at 1 μM chromium. To determine whether these changes may relate to disruption in matrix metabolism, we determined whether chromium exposure altered expression of the matrix metalloproteinases (MMPs), endopeptidases that are critical for extracellular matrix remodeling. Our data, using real time RT-PCR to analyze MMP gene expression, show that chromium exposure results in an increase in the expression of MMP-2, MMP-9, and MMP-13 at 0.2 μM and 2 μM, suggesting that some of the developmental effects of chromium (III) exposure may be through alterations in MMP expression. We also examined whether metallothionein could be used as markers for chromium (III) exposure. Metallothioneins (MT's) are a family of highly conserved, low molecular weight, cystein-rich, metal binding proteins, with critical roles in heavy metal detoxification and protection against reactive oxygen species (ROS). For this study we focused on MT-1 and MT-2 and found that exposure as low as 0.2 μM chromium (III) (ten times below the current acceptable limit in water) resulted in a significant increase in MT-1/-2 expression in developing zebrafish.

WP202 Copper Effect on Energy Metabolism in the Sea Anemone *Actinia bermudensis* N.L. Yano, M.M. Lauer, A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. Copper is an essential metal, but excessive concentrations in water can be toxic to aquatic animals. In general, its mechanism of toxicity in fresh water species is associated with ionic and osmoregulatory disturbances. However, little is known about its effect in marine osmoconformers like echinoderms and cnidarians. Therefore, the aim of the present study was to evaluate the effect of copper on energy metabolism in the sea anemone *Actinia bermudensis.* Animals were exposed (96 h) to copper (5, 10, and 50 μg Cu/L) in seawater (30 ppt). Temperature (20°C) and photoperiod (12h L: 12h D) were fixed. A control test (no copper addition) was also run. No mortality was observed. Following copper exposure, sea anemones were cryoanesthetized and dissected for enzymatic analysis [hexokinase (HK), phosphofructokinase (PFK), pyruvate kinase (PK), and citrate synthase (CS)]. Control animals showed reduced HK activity respect to those exposed to 5 μg Cu/L. PFK activity was higher in sea anemones exposed to copper than in those kept under control conditions. On the other hand, sea anemones exposed to 5 μg Cu/L showed a higher PK activity than the control ones, while those exposed to 50 μg Cu/L showed an inhibited enzyme activity. CS activity was also inhibited in all copper-exposed sea anemones when compared to control ones. This copper-induced impairment may lead to a disruption of the energy metabolism in the sea anemone, since a smaller production of citrate leads to a lower production of NADH and FADH2, the co-enzymes responsible for ATP production. Our results show that even low copper concentrations (5 μg Cu/L) may impair sea anemones physiology, suggesting that other species from neglected phyla such as Cnidaria should be used to establish safe levels of copper in marine environments. [Supported by Brazilian CNPq (INCT-TA) and CAPES (Ciências do Mar) and Canadian International Development Research Centre (IDRC)].

WP203 Copper Effects on Energy Metabolism in the Sea Cucumber *Trachythyone crassipeda* M. Lauer, C. Oliveira, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas; R. Cagnin, B. Cantarela, L. Fernandes, Universidade Federal do Espirito Santo; A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. Marine organisms have being neglected about metals effects since it is believed that sea water chemistry provides a high protection against these pollutants. However, recent studies showed that they are indeed very susceptible to metal exposure. Sea cucumbers belong to an exclusive marine phylum, the Echinodermata, and very little is known about metal effect on their metabolism. Copper is usually considered an iono-osmoregulatory toxicant to aquatic animals. Since echinoderms are osmoconformers another mechanism (respiratory or energetic impairment) could be involved in copper toxicity. In light of the above, the aim of this study was to evaluate the effects of copper exposure on the energy metabolism of *Trachythyone crassipeda*, a sea cucumber found in Brazilian marine waters. Adult animals were exposed to 5, 9, and 20 μg Cu/L for 96h at 30 ppt under fixed temperature (24ºC) and photoperiod (12h L: 12h D). A control test (no copper addition) was also run. No mortality was observed during test period. After exposure, sea cucumbers were cryoanesthetized and their respiratory trees were dissected and collected for enzymatic analyses [hexokinase (HK), phosphofructokinase (PFK), pyruvate kinase (PK), lactate dehydrogenase (LDH), citrate synthase (CS)]. HK activity was higher in sea cucumbers exposed to 9 and 20 μg Cu/L than in control animals and those exposed to 5 μg Cu/L. No difference in PFK and CS activities were observed between control and copper-exposed animals. PK activity was lower in control animals than in those exposed to copper. However, organisms exposed to 20 μg Cu/L showed higher PK activity than those exposed to 5 and 9 μg Cu/L. In contrast, LDH activity was higher in control animals, with sea cucumbers exposed to 5 and 20 μg Cu/L showing higher activities than those exposed to 9 μg Cu/L. Even though HK and PK are more active, neither LDH nor CS is raising its activity, which could imply in a reduction of NADH and FADH2 production, and a consequently smaller ATP production. Taken altogether, these findings show that sea cucumbers rely on an anaerobic metabolism that is compromised by copper exposure since LDH, a key enzyme in this process, was impaired by all copper concentrations tested. It is clear that copper affects marine organisms such as echinoderms even at low concentrations (5 μg Cu/L). Therefore, more attention should be paid to these animals in order to establish safe levels of copper in marine environments.

WP204 Copper Toxicity and Bioavailability to *Mytilus galloprovincialis* in Shelter Island Yacht Basin, San Diego, CA C. Capolupo, R.S. Kaufmann, Univ of San Diego; M. Colvin, San Diego State Univ Research Foundation; G. Rosen, SPAWAR Systems Center Pacific, Environmental, SPAWAR Systems Center Pacific, Scientist; P. Earley, B. Swope, I. Rivera, SPAWAR Systems Center Pacific. Copper concentrations in bays and marinas have the potential to reach relatively high levels due in part to leaching from copper-based antifouling paints used on aquatic vessels. These high levels may or may not be toxic depending on the chemistry of the water which affects copper bioavailability. Shelter Island Yacht Basin (SIYB), a recreational marina and harbor located near the mouth of San Diego Bay, is frequently elevated for copper, but the bioavailability and toxicity of this contamination is not well understood. It is important to examine the biological effects and chemical activity of copper in order to predict potential effects of its loading on biological communities, and to make environmental decisions about copper regulation. This study assessed the temporal and spatial variation of total and dissolved copper concentration, complexation capacity, and toxicity in SIYB. Samples were collected from 15 stations at two different depths during both wet and dry seasons (March and July 2011, respectively). Samples from four of these stations were spiked with up to 10 concentrations of copper in laboratory toxicity exposures for deriving a site-specific criterion for the Basin using the EPA's water effect ratio (WER) procedure. Toxicity tests were 48-h embryo-larval development tests with the mussel *Mytilus galloprovincialis*. The results of the ambient and WER studies will be compared to the results predicted based on water chemistry alone using the marine Biotic Ligand Model. The areas at the head of SIYB had copper concentrations above the EPA's water quality criterion of 3.1 μg/L; however, no toxicity was observed during the wet season sampling.

This result attests to the importance of including bioavailability of the metal in regulatory decision making.

WP205 Effect of Cations on Toxicity of Ni to Duckweed (*Lemna minor*): A Mechanistic Study Y. Gopalapillai, Univ of Guelph, School of Environmental Sciences, Natural Resources Canada, CANMET Mining and Mineral Sciences Laboratories, Natural Resources Canada, Metal and Mineral Sciences Laboratories; B. Hale, Univ of Guelph, School of Environmental Sciences; B. Vigneault, Natural Resources Canada. Major cations (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}) are generally known to reduce toxicity of Ni^{2+} by competing for uptake at the biotic ligand in aquatic organisms such as fish (BLM framework), while soil plant studies have shown lack of competition. In the present study, the effect of cations on toxicity of $\{Ni^{2+}\}$ in water (i.e., $IC25_{Ni2+}$) and Ni accumulated in tissue (i.e., $IC25_{NiTiss}$) were examined using the aquatic plant, *Lemna minor*. Ni accumulation kinetics was used to provide mechanistic explanations for the observed effects. The results indicate that major cations do not significantly affect Ni^{2+} toxicity in the tested range. However, kinetic analysis of Ni accumulation showed an anti-competitive effect of Ca^{2+} on Ni^{2+} accumulation (K_d and B_{max} decreased linearly). $IC25_{NiTiss}$ increased linearly with $[Na^{+}]$ (indicating reduced sensitivity of *L. minor* to $[Ni]_{Tiss}$ in the presence of Na^{+}) but was not affected for the other cations. For pH, $IC25_{Ni2+}$ decreased linearly with pH (BLM type model); unexpectedly, $IC25_{NiTiss}$ also decreased linearly (not a BLM-type model and indicates that plant is more sensitive to Ni at higher pH). In addition, Ni accumulation kinetics did not show 'pure' competitive relationship between H^{+} and Ni^{2+}. Thus, increased toxicity at higher pH may be due to other physiological or chemical changes with pH (e.g., presence of Ni hydroxides/carbonates, change in availability of micronutrients). The results of the present study suggest that toxicity of Ni in aquatic plants is dominated by homeostatic control and a model based on simple competitive cation effects is not sufficient.

WP206 Effect of Natural Organic Matter Quantity and Quality on the Acute Toxicity of Cu to the Aquatic Amphipod *Hyalella azteca* K. Livingstone, Wilfrid Laurier Univ, Dept of Biology; S. Smith, Wilfrid Laurier Univ, Dept of Chemistry, Wilfrid Laurier Univ, Chemistry; N. Yan, York Univ; J. McGeer, Wilfrid Laurier Univ, Dept of Biology. The aim of this study is to examine the influence of NOM quantity and quality (NOM source) on acute copper toxicity and bioaccumulation in the freshwater amphipod *Hyalella azteca*. Toxicity tests (96h) were done according to standard methods with 2-9 day old organisms added to solutions of Cu (0.25-2 uM) and dissolved organic carbon (0-11.5 mg C/L). The pH of test solutions was 7.1 ± 0.1 and temperature was maintained between 20-21 ºC. Test solutions had a water hardness of 40 mg $CaCO_3$/L and consisted of the following salts: 0.31mM $CaCl_2$, 0.31mM $NaHCO_3$, 0.031mM NaBr, 0.0153mM KCl, and 0.0763mM $MgSO_4$. Test solutions were equilibrated for 24 h before initiating exposures. The LC50 for dissolved Cu, with no added NOM, was determined to be 1.2 uM Cu (± 0.9 uM). Tests designed to understand the time course of accumulation (at 0.25 uM Cu) showed that the saturation of tissues (whole body dry weight basis) occurred quickly, at 9 h following Cu exposure. Short term exposure to Cu that the body burden sharply increased then levelled to a maximum at 1.0 uM, demonstrating saturable uptake and suggesting a Cu-regulating mechanism. Testing with NOM sources established a clear protective relationship between NOM quantity and toxicity. For example, Brandy Lake NOM added (0-11.5 mg C/L) at various Cu concentrations indicated a DOC concentration-dependent relationship with survival, directly related to Cu^{2+}. Tests to compare the quality (based on toxicity mitigation) of NOM sources demonstrated clear differences that could be related to Cu binding capacity (measured by Cu^{2+} selective electrode) and optical (absorbance and excitation emission matrix spectroscopy) characteristics. For example, the survival of *Hyalella* in test solutions with 4 uM Cu and 5 mg DOC/L improved from 25% with Daisy Lake NOM to 55% with Allard River NOM. This difference in protection was associated with the increased Cu binding capacity (Bmax of 1.07 compared to 1.61 uM Cu/mg C,) and the increased humic-like content of Allard River (56% compared to 82%). Currently the Biotic Ligand Model (BLM) includes NOM as a single homogeneous entity however; sources vary in their protective abilities. This research provides some progress toward understanding NOM quality characteristics which may be used to improve BLM predictions of Cu impacts in fresh water. This project is part of the TALER (Terrestrial Aquatic Linkages for Ecosystem Recovery) Research Program supported by NSERC, Vale and Xstrata.

WP207 Effects of Copper on Sodium Content in Mitochondria-rich Cells of the Freshwater Mussel *Lasmigona costata* L. Nogueira, Federal Univ of Rio Grande – FURG, Instituto de Ciências Biológicas; A. Bianchini, Federal Univ of Rio Grande – FURG; C.M. Wood, McMaster Univ; P.L. Gillis, Environment Canada – Canada Center for Inland Islands. Gill tissues in aquatic animals are composed of various cell types, each with specific functions such as respiration, excretion, acid-base balance and ionic regulation. Among the gill cells, mitochondria-rich cells (MRCs) are considered to be the primary sites responsible for ion transport. In bivalves, the gill is the main route of contaminant uptake and metals can be absorbed through specific transporters in cell membranes. In order to determine the effects of copper on sodium content in MRCs, gill cells from *Lasmigona costata* were isolated and layered in a discontinuous Percoll gradient. The pavement cells (PVCs) and MRC populations were confirmed by a specific mitochondrial dye (DASPEI) and Na,K-ATPase activity. MRCs were then exposed to a range of copper concentrations (5, 10 and 20 µg/L) for 3 hours. Following exposure, copper accumulation and sodium content were measured. Copper accumulation increased in all copper exposures with saturation-type kinetics. In contrast, the sodium content did not change in low exposures and increased significantly when cells were exposed to high copper concentrations. To further explore this result, both sodium and copper were measured after specific pharmacological blockade of Na,K-ATPase and carbonic anhydrase enzymes. Carbonic anhydrase inhibition had no effect, suggesting that sodium and copper uptake mechanisms are not dependent on a supply of protons. However, the inhibition of Na,K-ATPase by ouabain resulted in an increase in sodium and copper content in the MRCs. This enzyme is responsible for sodium extrusion from the cell, and the results suggest that it is also a route for copper extrusion. (Supported by the International Research Chair Program of the International Development Research Centre and the Canada Research Chair Program).

WP208 Environmental Causes and Phenotypic Consequences of Gene Copy Number Variation: A Metal Perspective J.R. Shaw, Indiana Univ, The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics, Dartmouth College, Dept of Biology; S.P. Glaholt, R. Keith, Indiana Univ, The School of Public and Environmental Affairs. Recent studies indicate copy number variation (CNV) represents a large source of the genetic variation observed in human populations and have uncovered strong associations between CNV and disease, including complex phenotypes. However, the environmental contributions to CNV remain unknown, in part because there are few animal models available for environmental genomics studies, which seek to understand how genome structure and function evolve in response to environmental change. Our group makes use of the NIH model, *Daphnia*, to test the central hypothesis that exposure to environmental contaminants increase the rate of mutations giving rise to CNV, and that this variation has functional consequences on gene expression, phenotype, fitness, and population structure. To accomplish this goal we are developing mutation accumulation (MA) lines derived in the absence and presence of cadmium in order to define the spectra of CNV and measure the per generation rate at which they spontaneously arise in individuals. We are studying past populations that have been captured and preserved in lake sediments. Here we scan genomes from populations that have adapted to over a century of mining pollution in order to characterize the magnitude, distribution, functional consequences, and evolutionary path of CNV in relation to the metal adapted phenotype. Finally, we are conducting quantitative trait loci experiments to determine the functional significance of CNV by establishing cause and effect relationships between copy number variants and metal tolerance. Collectively, these studies quantitatively assess whether environmental exposure affects the risk for spontaneous CNV, and do so in context of their contributions to individual health parameters that influence tolerance (i.e., adaptation and susceptibility) and disease. Answers to these questions have profound implications for the long-term health of human populations that are living longer and doing so in the presence of a greater diversity of chemicals that can modify DNA.

WP209 Estimating Population-level HC5 for Copper Y. Iwasaki, Tokyo Institute of Technology, Dept of Civil Engineering; M. Kamo, Advanced Industrial Science and Technology, Research Institute of Science for Safety and Sustainability. Estimating the "safe" concentration (e.g., predicted no effect concentration), below which unacceptable effects will not occur, is essential in ecological risk assessment (ERA) of chemicals. ERAs have been generally performed based on the individual-level effects derived from

laboratory toxicity tests. In this context, the species sensitivity distribution (SSD) approach (Posthuma et al. 2002) is widely used to determine the safe concentration. The SSD is a statistical distribution describing the sensitivity of species to a chemical substance, and its 5th percentile concentration (HC5) has been frequently applied as the safe concentration. The typical goals of ecological risk managements are to protect populations, communities, and ecosystems. Although the SSD approach can be used to predict the effects at such levels, the estimated HC5 is still based solely on the individual-level effects. Therefore, more ecologically-relevant methods, such as population modeling, are required to directly assess the impacts at the population and higher levels. The population-level ERA is often conducted by calculating the threshold concentration of a target chemical, which leads to the zero-net population growth. Using the SSD approach with such threshold concentrations for several biological species, population-level HC5 (PHC5) proposed by Kamo and Naito (2008, Hum Ecol Risk Assess) can be estimated. This approach may provide useful information to determine the safe concentration at the population and higher levels. However, since PHC5 was estimated only for zinc (Kamo and Naito 2008), the utility of the approach is not well examined. In the present study, we estimated the PHC5 for copper using the population-level SSD and examined the utility of this approach by comparing it with the HC5 and field-derived safe concentrations.

WP210 Evaluating the Relative Contributions of Dietary and Waterborne Lead to Toxicity in Rainbow Trout D. Alsop, McMaster Univ, Biology; J. Chowdhury, International Lead Zinc Research Organization, Inc.; C. Wood, McMaster Univ, Biology. The toxic interactions between waterborne and dietary metals have received little attention in fish, although aquatic animals commonly face multiple routes of exposure. The purpose of this study is to determine the toxic contributions of waterborne and dietary Pb to juvenile rainbow trout over 7 weeks. For the waterborne portion of the experiment, trout were exposed to control water and six concentration of Pb ranging from 4 to 800 ug/L in moderately hard water. Fish were fed 10% body weight per day with live aquatic worms (*Lumbriculus variegates*). Mortalities were observed in the highest Pb exposure (800 ug/L) over the course of the experiment. Even so, there were no effects of waterborne Pb on specific growth rate at any concentration of Pb over 7 weeks. With a view to developing dietary Pb-exposure doses for trout, *Lumbriculus* were maintained in control water and exposed to the same six concentrations of waterborne Pb. Metal accumulation in the worms was concentration-dependent and increased linearly without reaching steady-state over 7 weeks. These experiments set the stage for the current work that is directly addressing the interactions of dietary and waterborne metal exposures. Trout will again be exposed to waterborne Pb, and will be fed unexposed or Pb-exposed *Lumbriculus*. Fish in control waters will also be fed control and Pb-exposed worms. Survival, growth, Pb tissue accumulation and a variety of physiological endpoints will be monitored in the fish. These experiments should elucidate the relative toxic contributions of these two routes of metal exposure; the findings will be discussed in the context of environmental water quality criteria (supported by ILZRO).

WP211 Evaluation of Mn and As Exposure of a Goby Fish (*Gymnogobius isaza*) in the Bottom of Hypoxic Lake – Analytical and Experimental Approaches T. Itai, D. Hayase, Y. Hyobu, Ehime Univ, Center for Marine Environmental Studies (CMES); S.H. Hirata, Tottori Univ, Dept pf Regopnal Environment; M. Kumagai, Lake Biwa Environmental Research Institute; S. Tanabe, Ehime Univ, Center for Marine Environmental Studies. In December 2007, mass mortality of Isaza (*Gymnogobius isaza*), an endemic goby fish in Lake Biwa, Japan, was observed. As dissolved oxygen (DO) level in lake bottom was low (< 1 mg/L) due to incomplete vertical mixing of lake water caused by warm winter, oxygen deficiency might be the most plausible reason for mass mortality. However, we found that average concentrations of Mn and As in dead Isaza during the mortality event (MI) were 96 and 16 times higher than that of live Isaza (LI), respectively. Since Mn and As have toxic properties for organism and can be mobilized from sediment under reducing condition, exposure to these elements in the lake bottom with progressing hypoxia should also be verified. A critical rebuttal to the theory of Mn and As enrichments in MI was the secondary accumulation scenario stating that Mn and As have been accumulated from surrounding media after mortality. We considered three approaches to test the secondary accumulation scenario: (i) organ distribution analysis, (ii) speciation approach using X-ray absorption fine structure (XANES), (iii) absorption test for dead Isaza. If significant secondary accumulation occurred, concentration of As and Mn should be higher in the surface tissues such as skin and gill rather than internal organs. In our organ distribution analysis, however, higher level of Mn and As in MI than LI was not only observed at skin and gill, but also at viscera. Speciation of Mn and As measured by XANES indicated that predominant Mn species were Mn^{2+} ion, whereas high proportion As were associated with S such as As-glutathion. Since As in the lake bottom water and sediment were mostly arsenate, presence of As-S bonding from internal tissues suggested possible transformation of As after exposure. Finally, the results of absorption test showed that Mn levels in the organs increased depending on the Mn concentration in test water, whereas As levels in the organs did not increase even if the arsenate or arsenite levels in test water were 10 times higher than the naturally observed level. These results suggest that secondary accumulation of Mn cannot be ruled out, whereas high As levels in mortality Isaza reflects possible exposure before mortality. The results of this study suggest that hypoxia-induced mobilization of trace metals and its effect on aquatic organisms is an important issue in environmental toxicology.

WP213 Influence of Humic Acid on Ag Uptake and Toxicity to Green Algae Z. Chen, N. Paquet, C. Porcher, P.G. Campbell, INRS – Eau, Terre et Environnement; C. Fortin, INRS – Eau, Terre et Environnement, Universite du Quebec. Over the years, the biogeochemical cycle of silver has been disturbed by different anthropogenic activities, from photographic processes to nanoparticles. To better understand the relationship between silver speciation and bioavailability in natural freshwaters, short-term and long-term silver uptake and toxicity experiments were carried out with two species of green algae (*C. reinhardtii* and *P. subcapitata*) in the laboratory over a range of silver concentrations (1 to 200 nM) and in the presence or absence of well characterized natural dissolved organic matter (Suwannee River Humic Acid). The presence of DOM added a layer of complexity since Ag-DOM interactions cannot be predicted accurately with thermodynamic models. We thus determined the free Ag+ concentration in the exposure solutions using an equilibrium ion exchange technique (Fortin & Campbell 1998 Int J Environ Anal Chem 72:173-194). The Biotic Ligand Model (BLM) predicts that for a given free metal ion concentration metal uptake should remain the same, in the presence or absence of a metal-complexing ligand such as DOM. However, short-term Ag uptake in the presence of DOM was greater than would be anticipated on the basis of the measured free Ag+ concentration. For the long-term toxicity experiments with *P. subcapitata*, the intracellular concentration of silver required to inhibit growth by 50% (EC50 based on Ag cell quota at 48 and 72 h) was lower in the presence of DOM than in its absence; in other words, internal Ag is more toxic in the presence of DOM. Possible explanations for these results are discussed, including kinetic limitations on silver uptake and direct effects of DOM on the test algae.

WP214 Influences of Salinity on Acute Copper Toxicity in Blue Crab, *Callinectes sapidus* K. Chan, Univ of Miami, Rosenstiel School of Marine and Atmospheric Science; M. Grosell, Univ of Miami, RSMAS. Copper targets mainly the osmoregulatory processes and sensitivity to copper is influenced by ambient salinity. Osmoregulating organisms, like the killifish, *Fundulus heteroclitus* has been demonstrated to be least sensitive to acute copper toxicity when exposed in salinities iso-omotic to their extracellular fluids. For this fish, sodium gradients across the gill epithelium are the key parameter that determines the sensitivity to acute copper exposure across salinities. However, there is limited information regarding acute copper toxicity in euryhaline invertebrates such as crustacean at different salinity. The blue crab, *Callinectes sapidus*, like *F. heteroclitus* is a strong osmoregulator, yet display different osmoregulatory strategies by being isoosmotic in seawater and hyperosmotic at intermediate and low salinities. Thus, the prediction currently being tested is that blue crabs will be least sensitive in seawater and show a gradual increase in sensitivity with decreasing salinity. *C. sapidus* are acclimated to different salinities and subjected to standard 96h LC50 copper tests. Result from blue crabs to date indicate little, if any, need to transport sodium at higher salinities (20-30 ppt) but copper exposure at high concentrations nevertheless cause toxicity. At high salinities a dose dependent increase of hemolymph total CO_2 was observed following 96h of exposure indicating a metabolically compensated respiratory acidosis. Sensitivity of blue crabs at lower salinity as well as mechanisms of toxicity is currently being tested.

WP215 Interactions of Waterborne Cadmium and Dietary Calcium on Fitness and Mitochondria Bioenergetics in Vivo in Rainbow Trout, *Oncorhynchus mykiss* R.C. Adiele, Univ of Prince Edward Island, Dept of Biomedical Sciences, Atlantic Veterinary College, Univ of Prince Edward Island, Graduate Student -Toxicology; C. Kamunde, Univ of Prince Edward Island, Associate Professor, Univ of Prince Edward Island, Assistant Professor. Rainbow trout were exposed to sublethal waterborne Cd (5 and 10 µg/l) and dietary Ca (60 mg/g), individually and in combination, for 30 days to elucidate the interactive effects and evaluate the toxicological significance of mitochondrial responses to these cations in vivo. Indices of fish condition and mortality were measured and livers, centers of metabolic homeostasis, were harvested to assess mitochondrial function and cation accumulation. All indices of condition assessed (body weight, hepatosomatic index and condition factor) were reduced in all the treatment groups. Mortality occurred in the Cd-exposed groups with dietary Ca partly protecting against or enhancing it depending on the Cd exposure concentration. State 3 respiration was inhibited by 30, 35 and 40% in livers of fish exposed to Ca, Cd and Cd+Ca, respectively, suggesting reduced ATP turnover and/or impaired substrate oxidation. While the phosphorylation efficiency was unaffected, resting (state 4) and state 4+ (+ oligomycin) respirations were inhibited by all the exposures. Mitochondrial coupling was reduced and transiently restored denoting partially effective compensatory mechanisms to counteract Cd/Ca toxicity. The measured respiratory dysfunction was associated with accumulation of both Cd and Ca in the mitochondria. Although fish that survived acute effects of Cd and Ca exposure apparently made adjustments to energy generation such that liver mitochondria functioned more efficiently albeit at reduced capacity, reduced fitness was persistent possibly due to increased demands for maintenance and defense against toxicity. Overall, interactions between Cd and Ca on mortality, condition indices and mitochondrial responses were competitive or cooperative depending on exposure concentrations.

WP216 Metal Accumulation and Sublethal Effects in the Sea Anemone, *Aiptasia pallida*, After Waterborne Exposure to Metal Mixtures G.K. Bielmyer, Valdosta State Univ, Biology, Valdosta State Univ, Dept of Biology; J. Brock, Valdosta State Univ. Metal contamination is common in marine environments, predominantly due to anthropogenic inputs, yet the effects of metals on symbiotic cnidarians are largely understudied. To further understand the impact of elevated metal concentrations on marine symbiotic organisms, a toxicity study was performed using the model sea anemone, *Aiptasia pallida*. *A. pallida* were exposed to a control or a metal mixture (Cu, Zn, Ni, and Cd) at three exposure levels (low, medium, high) for 7 d. Anemones were then transferred to clean seawater for an additional 7 d after the metal exposure to assess depuration and recovery. Metal accumulation, behavior, protein concentration, activity of the oxidative stress enzymes, catalase and glutathione reductase, and activity of the enzyme carbonic anhydrase were measured at 0, 1, 3, 5, 7, and 14 d. Additionally, algal photosynthetic parameters and density of the symbiotic algae, *Symbiodinium* sp., within the anemone were also quantified at the beginning and end of the metal exposure. *A. pallida* rapidly accumulated all of the metals in a time and concentration dependent manner. Enzyme activity followed a similar pattern and varied with exposure concentration. Understanding how this organism deals with toxicity after mixed metal exposure in the laboratory may allow better understanding about how symbiotic cnidarians respond to metal polluted aquatic environments.

WP217 Metal Partitioning Among Pools of Cytosolic Ligands in Larvae of *Chaoborus punctipennis* Living Along an Environmental Trace-metal Gradient M. Rosabal, INRS – Centre Eau Terre Environnement, Eau Terre Environnement (INRS-ETE); L. Hare, P. Campbell, INRS – Centre Eau Terre Environnement. Larvae of the dipteran insect *Chaoborus punctipennis* are an effective sentinel for estimating the exposure of lake-dwelling animals to cadmium (Cd) and nickel (Ni), in part because they are very tolerant to these metals. Heat-stable proteins play an important role in the intracellular sequestration and detoxification of metals in these sentinels. However, the distributions of metals among ligand pools within this cytosolic fraction are unknown. Metal-binding proteins are included in this fraction, especially metallothioneins and metallothionein-like proteins which have been associated with enhanced metal tolerance in species living in metal-contaminated environments. We set-out to measure the distributions of Cd, Cu, Ni and Zn among various cytosolic ligand pools in *C. punctipennis*. Larvae of *C. punctipennis* were collected from nine lakes located on the Canadian Precambrian Shield in the vicinity of metal smelters located in Rouyn-Noranda (Quebec) and Sudbury (Ontario). To evaluate metal partitioning, the cytosol was fractionated by size-exclusion high-performance liquid chromatography to obtain three metal-ligand pools: a high molecular weight pool,"metallothioneins" and a low molecular weight pool. Metals in each pool were measured by ICP-MS. Our results highlight the importance of the "metallothionein" pool in metal sequestration in the intracellular environment of this insect, presumably contributing to the presence of *Chaoborus* larvae in highly metal-contaminated environments

WP218 Metal Partitioning Among Pools of Cytosolic Ligands in Larvae of the Insect *Chaoborus punctipennis* Living Along an Environmental Trace-metal Gradient M. Rosabal, L. Hare, P. Campbell, INRS – Centre Eau Terre Environnement, Eau Terre Environnement (INRS-ETE). Larvae of the dipteran insect *Chaoborus punctipennis* are an effective sentinel for estimating the exposure of lake-dwelling animals to cadmium (Cd) and nickel (Ni), in part because they are very tolerant to these metals. Heat-stable proteins play an important role in the intracellular sequestration and detoxification of metals in these sentinels. However, the distributions of metals among ligand pools within this cytosolic fraction are unknown. Metal-binding proteins are included in this fraction, especially metallothioneins and metallothionein-like proteins which have been associated with enhanced metal tolerance in species living in metal-contaminated environments. We set-out to measure the distributions of Cd, Cu, Ni and Zn among various cytosolic ligand pools in *C. punctipennis*. Larvae of *C. punctipennis* were collected from nine lakes located on the Canadian Precambrian Shield in the vicinity of metal smelters located in Rouyn-Noranda (Quebec) and Sudbury (Ontario). To evaluate metal partitioning, the cytosol was fractionated by size-exclusion high-performance liquid chromatography to obtain three metal-ligand pools: a high molecular weight pool,"metallothioneins" and a low molecular weight pool. Metals in each pool were measured by ICP-MS. Our results highlight the importance of the "metallothionein" pool in metal sequestration in the intracellular environment of this insect, presumably contributing to the presence of *Chaoborus* larvae in highly metal-contaminated environments.

WP219 Pb and Zn Toxicity to Mussel and Echinoderm Larvae: Effects of Salinity and DOC S. Nadella, McMaster Univ, Biology; S. Smith, Wilfrid Laurier Univ, Chemistry; A. Bianchini, Federal Univ of Rio Grande; M. Tellis, McMaster Univ, Biology; R. Diamond, Wilfrid Laurier Univ, Chemistry; C. Wood, McMaster Univ, Dept of Biology. We investigated the influence of DOC and salinity on the toxicity of Pb and Zn to early life stages of two blue mussel species (*Mytilus galloprovincialis*, *Mytilus trossolus*) and one echinoderm, the sea urchin (*Strongylocentrotus purpuratus*) in 48or72h development tests. In the absence of Pb or Zn, salinity thresholds for normal development were 30 ppt for *S. purpuratus*, 25 ppt for *M. galloprovincialis*, and 20 ppt for *M. trossolus*. For Pb in 100% seawater (33 ppt), the three species exhibited comparable sensitivity. EC50's were 63 (36-94) µg Pb/L for *M. galloprovincialis*, 45 (22-72) µg Pb/L for *M. trossolus*, and 74 (50-101) µg Pb/L for *S. purpuratus* respectively, from dissolved Pb concentrations. Salinity (21 – 33 ppt), evaluated in *M. trossolus*, had no significant effect on Pb toxicity. The addition of DOC from fresh water (Nordic Reservoir) and a marine DOC collected inshore in Brazil decreased the toxicity of Pb moderately in both *M. galloprovincialis* and *M. trossolus*, with EC50 values approximately doubling. However, the effect was not concentration-dependent over the range 2.1-10.5 mg C/L. Low salinity (21ppt) did not enhance the protective effect of DOC. DOC additions actually increased the toxicity of Pb to *S. purpuratus*. Good correlations were observed between whole body Pb burden and % mortality in both *M. galloprovincialis* and *S. purpuratus* embryos with a 48-h LA50 (BLM parameter) of 575 (251-1000) µg Pb/g in the mussel and a 72-h LA50 of 316 (141-741) µg Pb/g in the sea urchin. For Zn in 100% seawater (33 ppt), the three species again exhibited comparable sensitivities. EC50s were 172 (126-227) µg Zn/L for *M. galloprovincialis*, 135 (103-170) µg Zn/L for *M. trossolus*, and 151 (129-177) µg Zn/L for *S. purpuratus*, from dissolved Zn concentrations. Thus Zn was somewhat less toxic than Pb. The addition of the same two DOCs (2 – 12 mg C/L) had no significant effect on Zn toxicity to blue mussels, but exacerbated Zn toxicity to urchin larvae. As with Pb, good correlations were again observed between whole body Zn burden and % mortality in both *M. galloprovincialis* and *S. purpuratus* embryos with a 48-h LA50 of 759 (617-776) µg Zn/g in the mussel and a 72-h LA50 of 398 (347-575) µg Zn/g in the sea urchin. Thus despite differences in EC50's between Pb and Zn, LA50's were

comparable. These data will be useful in developing BLM's for Pb and Zn in estuarine and marine environments (ILZRO, IZA, NSERC CRD program, IRC program of CIDA/CRC).

WP220 Quantification of Toxic Metals Carried by Plastic Litter Over a Beach E. Nakashima, A. Isobe, S. Kako, Ehime Univ; S. Magome, Sanyo Techno Marine, Inc.; N. Deki, Ehime Univ; T. Itai, Ehime Univ, Center for Marine Environmental Studies (CMES); S. Takahashi, Ehime Univ. In East China Sea, an amount of marine litter was found on the beaches, due to rapid economical growth in the neighboring countries. Although this litter poses a great threat to marine wildlife by ingestion of plastics and entanglement in drift nets, few reports on chemical pollution have also been reported. This background prompted us to establish a study to quantify the chemical substances carried by litter in Ookushi beach, Goto Island, Nagasaki, Japan. Firstly, the weight of beach litter was estimated 716±259 kg in Ookushi beach, Goto Island. This was calculated from both the coverage area of beach litter (123.5 m^2) using balloon camera and the weight measurement of litter in 4 m^2 unit area (5.8 kg/m^2). Among randomly collected beach litters, Plastics prevail among various materials on the ten boxes of the Ookushi beach, the mass of plastics accounts for 74% (i.e., 530±201 kg), in which five polymers such as PE, PP, PET, PVC and PS accounted for 98%. Secondly, the levels of heavy metals were estimated in litter. Among them the toxic metals, lead (Pb) was the most common toxic metal detected in plastic litter on Ookushi beach. Therefore, we had estimated the total weight (*M*) of Pb carried by plastic litter by multiplying the estimated the mass with the concentration of Pb in each polymer type: On the other hand, Pb contained in plastic PVC fishing floats exceeded 100 mg/kg which is regulated by EU regulation on packaging and packaging waste. This Pb in polymers is used for pigments and might be released into the beach environment when the plastic undergoes degradation. In order to examine Pb leaching from PVC fishing floats, we had conducted several leaching tests. Although the leaching rate (μg/h) of lead from fishing float declined exponentially with time, Pb is leaching from PVC floats. This fact suggested that these Pb may affect the marine environment in the long term.

WP221 Reducing Metal Mine Effluent Effects on Fathead Minnows (*Pimephales promelas*) Through Water Chemistry Modifications J.D. Ouellet, Univ of Saskatchewan, Biology; S. Niyogi, Univ of Saskatchewan, Dept of Biology; M. Dube, Univ of Saskatchewan, School of Environment and Sustainability. Treated metal mine effluents (MMEs) are discharged into waterways and may impact invertebrate and fish populations in those receiving environments. Past studies have shown elevated tissue metal concentrations and altered reproduction in fathead minnows [FHMs (*Pimephales promelas*)] exposed to an environmentally relevant concentration of a Canadian nickel mine effluent [45% process water effluent (45% PWE)]. Alteration of the water chemistry parameters, such as increased pH and DOC, is known to reduce the toxic effects of metals under acute exposures. A 21-day multi-trophic exposure was performed using FHMs and *Chironomus dilutus* to determine if these protective effects continue under chronic exposures to a metal mixture (45% PWE). Six treatments were assessed: (1) normal reference water (pH=7.7), (2) reference water with pH increased to ~8.1, (3) reference water with humic acid added, (4) normal 45% PWE (pH=7.2), (5) 45% PWE with pH increased to ~8.1, and (6) 45% PWE with humic acid added. Increasing the pH to 8.1 and increasing humic acid concentrations in both reference water and 45% PWE each resulted in higher cumulative total egg production relative to normal reference and normal 45% PWE exposed FHMs. Normal 45% PWE exposed FHMs showed a decrease in cumulative total egg production relative all other FHMs. However, tissue metal concentrations remained similar between all 45% PWE exposed FHMs regardless of the increase in pH and humic acid. These results suggest that increasing pH and DOC may mitigate some effects of metal mine effluent under chronic conditions. Further work will explore the pathways under which these water chemistry parameters reduce the reproductive effects.

WP222 Selenium Bioaccumulation in Littoral and Pelagic Food Webs in Lakes Near Metal Smelters D.E. Ponton, INRS – Centre Eau Terre Environnement, Eau, Terre et Environnement, Institut National de la Recherche Scientifique, ETE, Institut National de la Recherche Scientifique, Eau, Terre et Environnement; L. Hare, INRS-ETE. Aquatic animals are reported to take up selenium (Se) mainly from their diet. Thus changes in diet can alter Se exposure. Within a lake, changes in diet can occur as animals grow and as they move between the littoral and pelagic zones to feed. Among lakes, food chain structure and Se exposure can be influenced by industrial emissions. All of these factors likely influence Se concentrations in predatory midge larvae (*Chaoborus*) and in yellow perch (*Perca flavescens*), both of which can survive in metal-contaminated lakes. To explain Se concentrations in these predators, we measured Se in various compartments of the pelagic and littoral zones in lakes located at various distances from metal smelters in northern Ontario (Sudbury) and Quebec (Rouyn-Noranda); that is, lake water (selenite, selenate and organic selenium), suspended particulate matter (bacteria and microalgae < 64 μm), zooplankton (prey of *Chaoborus*), littoral invertebrates (prey of yellow perch) and the predators themselves. In all food-chain components, we measured the isotopic signatures of stable nitrogen, so as to estimate trophic position, and carbon and sulphur, so as to determine the source of energy and Se for the food chains. These data allowed us to explain the influence of trophic position and contaminants on Se bioaccumulation by animals in lakes on the Canadian Shield.

WP223 Sensitivity of White Sturgeon (*Acipenser transmontanus*) and Rainbow Trout (*Oncorhynchus mykiss*) to Copper, Cadmium, and Zinc in Acute Exposures R.D. Calfee, USGS, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center; E.E. Little, H.J. Puglis, USGS, Columbia Environmental Research Center; E. Beahan, US Geological Survey. Larval recruitment failure resulting from chemical contamination is thought to be a factor in the endangered status of white sturgeon populations of the Upper Columbia River (UCR). Previously we determined that early lifestages of Kootenai and Columbia River sturgeon were sensitive to very low concentrations of copper that may occur as a result ofmetals extraction and smelting activities in sturgeon habitats. To confirm these observations we conducted 96-hour exposures of white sturgeon from the Upper Columbia River at various stages of development from 2 to 98 days post-hatch to copper, cadmium and zinc under flow-through conditions. We also conducted similar exposures with rainbow trout to determine sensitivity of a commonly tested species. Companion studies evaluated the chronic toxicity of copper, cadmium, zinc and lead to sturgeon and trout and the toxicity of whole-sediments from the UCR to sturgeon. The acute data indicate that sturgeon sensitivity to copper decreases markedly during development with the most sensitive stages occurring between 16 and 30 dph. Sturgeon were less sensitive to cadmium and zinc with LC50 values well above environmental concentrations, however sublethal effects were evident with changes in behavior. Sturgeon were most sensitive to cadmium and zinc at 61 dph .Rainbow trout proved to be less sensitive during the very early lifestages (1-46 dph) with LC50 values up to 7 times less toxic for copper, but were more sensitive to cadmium and zinc than white sturgeon. Our results indicate that exposure to metals may be a factor in early lifestage survival of white sturgeon.

WP224 Sensitivity of White Sturgeon (*Acipenser transmontanus*) and Rainbow Trout (*Oncorhynchus mykiss*) to Selected Metals in Chronic Water-only Exposures N. Wang, US Geological Survey, Columbia Environmental Research Center; C.G. Ingersoll, USGS, Columbia Environmental Research Center; W. Brumbaugh, US Geological Survey, Columbia Environmental Research Center; J.L. Kunz, USGS; R. Consbrock, D.K. Hardesty, US Geological Survey. White sturgeon (*Acipenser transmontanus*) in the trans-boundary reach of the upper Columbia River (UCR) in eastern Washington State, USA are experiencing poor recruitment. Limited toxicity data indicated that early life stages of white sturgeon might be more sensitive to copper, cadmium, or zinc than test organisms used to derive the USEPA ambient water quality criteria. However, insufficient information is available to define toxicity thresholds for these metals. The objective of this study was to evaluate the sensitivity of white sturgeon to copper, cadmium, zinc, and lead in chronic water-only exposures conducted for up to about 8 weeks. Rainbow trout (*Oncorhynchus mykiss*) were also conducted under similar test conditions to determine the sensitivity of white sturgeon relative to this commonly tested species. Companion studies evaluated the acute toxicity of copper, cadmium, and zinc to sturgeon and trout and the toxicity of whole-sediments from the UCR to sturgeon. For each of the four tested metals, three chronic toxicity tests were conducted in flow-through diluter systems: (1) Continuous Exposures (about 8 weeks) starting with 1 day post-hatching (dph) fish, (2) Stage 1 Exposures (2 to 3 weeks) with 1 dph fish, and (3) Stage 2 Exposures (4 weeks) with about 28 dph fish. Preliminary results based on survival endpoint indicate that white sturgeon were 8- to 32-fold more sensitive to copper or lead, and were equally or slightly more sensitive

to cadmium or zinc compared to rainbow trout. Larvae of both species in Stage 1 Exposures were equally or more sensitive to the metals than juveniles in Stage 2 Exposures, except that rainbow trout juveniles were ≥4-fold more sensitive to cadmium or zinc than larvae. Analyses of growth data (length and weight) are ongoing.

WP225 Sodium Loss is the Acute Toxic Mechanism of Metals and Other Contaminants in Zebrafish: Implications for Additive Toxicity D. Alsop, C. Wood, McMaster Univ, Biology. Zebrafish larvae (*Danio rerio*) were used to examine the mechanisms of action and acute toxicities of metals and other contaminants. Larvae had similar physiological responses and sensitivities to waterborne metals as adults. While cadmium and zinc have previously been shown to reduce Ca^{2+} uptake, copper and nickel also decreased Ca^{2+} uptake, suggesting that the epithelial transport of all these metals is through Ca^{2+} pathways. However, exposure to cadmium, copper or nickel for up to 48 h had little or no effect on total whole body Ca^{2+} levels, indicating that the reduction of Ca^{2+} uptake is not the acute toxic mechanism of these metals. Instead, mortalities associated with metal exposure were effectively related to whole body Na^+ loss, which decreased up to 39% after 48 h exposures. Additive toxicity was observed between metals. For example, exposure to sublethal levels of nickel (10% of the nickel 96 h LC_{50}) decreased the copper 96 h LC_{50} by 58%. In addition, exposure to fluoxetine and other contaminants decreased whole body Na^+. Fluoxetine also showed additive toxicity with copper. We have demonstrated that the acute toxicity of a number of contaminants is effectively related to Na^+ loss, possibly stemming from stress hormone signaling. This common impact on Na^+ may underlie additive toxicity. Understanding mechanisms will help predict the toxicities of mixtures for water quality criteria, a necessity given that the vast majority of polluted environments are impacted by multiple contaminants (supported by NSERC discovery).

WP226 Sublethal Effects on Behavior of White Sturgeon (*Acipenser transmontanus*) and Rainbow Trout (*Oncorhynchus mykiss*) Exposed to Copper, Cadmium, and Zinc E.E. Little, USGS, Columbia Environmental Research Center; R.D. Calfee, USGS, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center; H.J. Puglis, USGS, Columbia Environmental Research Center; E. Beahan, US Geological Survey. White sturgeon (*Acipenser transmontanus*), in the trans-boundary reach of the Upper Columbia River have experienced poor recruitment. The potential for contaminant effects on sturgeon spawning behavior and larval mortality is considered a data gap, and raises concerns about additional threats to the rapidly declining populations. Previous studies have shown severe behavioral impairments observed among early life stage white sturgeon during acute (Calfee et al) and chronic (Wang et al) toxicity tests with copper, cadmium and zinc. These behavioral changes occurred rapidly during exposure most often during the first 24 hours, and were similar to those observed when fish were exposed to slag-contaminated sediments from UCR sites (Little et al). Sturgeon behavior was rapidly impaired and to the extent that survival in the field would be jeopardized, as fish would be swept downstream, or readily captured by predators. The objectives of this investigation are to conduct behavioral observations during a series of acute metals exposures to determine time to effect during early lifestage development, and to understand the significance of these responses relative to survival of these vulnerable early lifestage fish.

WP227 The Bioavailability and Toxicity of Metals to the Larvae and Juveniles of the Freshwater Unionid Mussel, *Utterbackia imbecillis* B. Dubansky, Louisiana State Univ, Dept of Biological Sciences, Louisiana State Univ, graduate student; B. Whitaker, Louisiana State Univ, Dept of Biological Sciences; F. Galvez, Louisiana State Univ, Dept of Biological Sciences. Freshwater unionid mussels are the most imperiled group of animals in the world with approximately 70% of known 300 North American species in decline. We are currently investigating the effects of waterborne metal exposures on the larval and juvenile stages of *Utterbackia imbecillis*, and on the mitigating effects of competing and complexing ligands on bioavailability and toxicity metal in this species. We are currently using a novel methodology to infect fish hosts with mussel larvae (glochidia) after exposure of both the host and parental mussel to metals, followed by assessing the efficacy of glochidial attachment and metamorphosis. Additional studies are accessing the metal bioavailability and toxicity in varying water chemistries to juvenile unionid mussels. Our goal is to provide insight into the influence of host physiology on glochidia metamorphic success, and to develop and utilize this model system to monitor the effects of toxicants on freshwater environments.

WP228 The Effects of Ca^{2+}, Mg^{2+}, and Natural Organic Matter Quantity and Quality on Ni Toxicity to *Hyalella azteca* K. Chan, Wilfrid Laurier Univ; J. McGeer, Wilfrid Laurier Univ, Dept of Biology. The focus of this study is to determine the effects of Ca, Mg and natural organic matter (NOM) on the acute toxicity of waterborne Ni to *Hyalella azteca*. Organisms were cultured in artificial soft water (0.3 mM Ca, 0.075 mM Mg, 0.3 mM Na, 0.3 mM Cl, pH of 7.0 and 20C) and tests followed standard methods. Two sources of amphipods were compared, a commercially available source (Aquatic Research Organisms (ARO)) and organisms collected from Hannah Lake (HL), a lake in Sudbury, ON that was severely impacted by acid and metal inputs from nearby smelters but has since recovered to a significant degree. Lab cultures of HL *Hyalella* were established over 6 months prior to testing and acclimated to very soft water (0.1 mM Ca, 0.025 mM Mg, 0.1 mM Na, 0.1 mM Cl). In addition to survival, the short term uptake of Ni was assessed (whole body dry weight basis) to establish linkages between accumulation and effects in the context of biotic ligand modeling principles. The effects of Ca were tested across a range of concentrations: 0.1, 0.3, 0.75 and 2.0 mM Ca. The LC50 concentrations of ARO *Hyalella* varied from 1.0 mg/L (95% confidence interval of 0.55 to 1.83) to 3.1 mg/L (95% confidence interval of 2.4 to 4.1), demonstrating protective effects of Ca^{2+} competition against Ni^{2+}. The HL source of *Hyalella* showed similar protective responses of Ca with Ni LC50 increasing from 0.56 mg/L to 3.2 mg/L at Ca concentrations of 0.1 mM and 2.0 mM respectively. Increased waterborne Mg at 0.5 mM did not provide protective effects on acute Ni toxicity and appeared to act as a stressor as survival of unexposed controls was reduced. Sources of NOM were collected across a gradient of smelter impacted sites in the Sudbury area and unimpacted reference sites (Muskoka region of Ontario). The protective effects of NOM were assessed on the basis of both quantity (dissolved organic carbon (DOC) concentration) and quality. NOM source quality was assessed biologically (protective effect of DOC on Ni toxicity) as well as spectrophotometrically (absorbance and excitation emission matrix spectroscopy). These results are considered in the context of validating and extending the BLM for Ni and understanding the importance of NOM source differences. This project is part of the TALER (Terrestrial Aquatic Linkages for Ecosystem Recovery) Research Program and is supported by NSERC, NRCan, Vale and Xstrata.

WP229 The Physiological Implications of pH Manipulation Methods and Their Impact on Observed Toxicity A. Esbaugh, Univ of Miami, Rosenstiel School of Marine and Atmospheric Science; K.V. Brix, Univ of Miami, RSMAS, Marine Biology and Fisheries; M. Grosell, Univ of Miami, RSMAS. It is well established that environmental pH is an important factor when assessing dissolved metal toxicity in aquatic environments. This is largely due to the effects of pH on metal speciation, which affects the concentration of a toxic metal species relative to the total dissolved metal concentration. To properly evaluate the impacts of pH on metal toxicity, the pH of test media must be experimentally manipulated. Currently three methods are used for such pH manipulation: buffers, carbon dioxide, and acid/base solutions. Although all three methods are effective at altering pH, and consequently metal speciation, they can have dramatically different effects on the physiology of aquatic animals. Since toxicity is the result of cumulative stress owing to metal exposure and other environmental parameters, it seems likely that variable stress stemming from different methods of pH manipulation could impact observed toxicity. The present study employed acute Pb toxicity in the fathead minnow to examine this question, by determining the relative toxicity at pH 7.4 (control), 6.4 and 8.3 using the respective pH manipulation methods. Using the organic buffer MOPS, 96 h LC50 values were 15% and 29% of the control value at pH 6.7 and 8.3, respectively. In contrast, experiments using HCl or NaOH resulted in LC50 values that were 42% and 54% of the control value at pH 6.4 and 8.3, respectively. Experiments investigating the effects of carbon dioxide at pH 6.4 will also be performed. Differences in observed acute toxicity between treatments will be discussed with respect to the physiological implications of the various methods.

WP230 Toxicity of Smelter Slag-contaminated Sediments and Associated Metals from Lake Roosevelt to White Sturgeon E.E. Little, USGS, Columbia Environmental Research Center; R.D. Calfee, USGS, Columbia Environmental Research Center, US Geological Survey, Columbia

Environmental Research Center. The toxicity of smelter slag-contaminated sediments from the upper Columbia River and metals associated with those slags were evaluated with early lifestage white sturgeon (*Acipenser transmontanus*) in 96-hour exposures. Behavioral observations were made to determine if the sturgeon avoided contact with the sediments or avoided dissolved metals. Leachates resulting from holding 75 gms of sediment in 2 liters of water for 96- hours to 2 weeks were nonlethal to sturgeon that were 8 day post hatch (dph), but were toxic to fish that were about 30 dph, suggesting that the latter lifestage is highly vulnerable to copper exposure. The toxicity of copper alone was similar to the toxicity of a mixture of copper, cadmium, and zinc. The latter metals were not lethal, but induced adverse behavioral changes including a loss of equilibrium. Fish maintained consistent and prolonged contact with sediments and did not avoid contaminated sediments when provided a choice between contaminated and uncontaminated sediments. Nor did they avoid aqueous mixtures of copper and zinc. The results suggest that metals associated with smelter slags may pose harm to early lifestage sturgeon if they occur in areas contaminated by slags and support the need for further investigation of slag toxicity to early lifestage white sturgeon.

WP231 Understanding the Influence of Micronutrients on Cd Uptake and Toxicity in Algae: Refinement of the Biotic Ligand Model M. Lavoie, INRS-ETE, Biogeochemistry; P.G. Campbell, C. Fortin, INRS-ETE. Within the biotic ligand model (BLM) construct, cations are considered to be simple competitors for metal binding to uptake sites and may offer some protection against metal-induced toxicity. The influence of essential trace metals and cell pre-conditioning to different micronutrient concentrations on metal uptake and toxicity is assumed to be negligible. In order to test this assumption, we monitored Cd uptake and toxicity in a green alga (*Chlamydomonas reinhardtii*) during long-term exposures (60 h) to a range of environmentally realistic free Ca^{2+}, Fe^{3+}, Mn^{2+}, Co^{2+} and Zn^{2+} concentrations buffered with NTA. A 200-fold increase of $[Mn^{2+}]$ as well as a 100-fold increase of $[Fe^{3+}]$ did not affect Cd uptake and toxicity while Ca^{2+} effectively offered some protection. Interestingly, we found that a 100-fold increase of $[Zn^{2+}]$ and $[Co^{2+}]$ decreased Cd toxicity about 3- and 2-fold respectively. Cd uptake and toxicity was not affected by acclimation to the lowest and highest $[Fe^{3+}]$, $[Mn^{2+}]$, $[Co^{2+}]$ or $[Zn^{2+}]$ used. Short-term (30 min) Cd uptake experiments in the presence of varying $[Cd^{2+}]$ reveal the presence of two Cd transport sites of different affinities; one of low affinity (KCd 1 = 10^5.5 M-1) and one of high affinity (KCd 2 = 10^7.4 M-1). The competitive binding affinity of Ca^{2+} to the high affinity Cd^{2+} transport sites was only 10^2.4 M-1 but was much greater for the low affinity Cd binding sites (>> 10^2.4 M-1). Slight non-competitive inhibition of Ca^{2+} on Cd^{2+} uptake by the low affinity Cd^{2+} transport system was also observed. We conclude that low $[Co^{2+}]$ and $[Zn^{2+}]$ should be taken into consideration as competitors for Cd uptake in *C. reinhardtii*. Furthermore, the protective effect of Ca^{2+} on Cd^{2+} uptake seems to be more complex than initially anticipated.

WP232 Site Specific Implications of Mining Regulations: The Case of Zinc in Ross Lake, Manitoba S. Yacoob, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry; M. Diamond, N. Gandhi, Univ of Toronto; C. Gueguen, Trent Univ. Ross Lake in Flin Flon, Manitoba, CA has received zinc enriched mine tailing effluents for over 50 years. Due to resuspension of sediments, Ross Lake remains an overall net source of zinc to downstream waterbodies. Recent sampling campaigns, conducted to update fate and speciation models at Ross Lake, have found significant changes in the environmental conditions over the last 10 years. Sediments have gone from anoxic to oxic conditions. pH in the water column has dropped from 8.3 due to the mine operators liming the tailings outflow to ~ 6.5 due to acidifying the outflow to achieve circumnetural pH. This latter change is demanded by recently implemented regulations for the mining sector. The low pH is also due to the breakdown of thiols in the lake where the sulphur originates from the intentional acidification and from the treated tailings effluent. Low pH and dissolved oxygen impact speciation and thus toxicity and bioavailability of metals. In order to assess the overall implications of the regulations we are quantifying the bioavalaible fraction of metal using modelling and field in situ testing. The Windermere Humic Aqueous Model (WHAM) was employed to model speciation in Ross Lake, and Diffusion Gradients in Thin Films (DGT) were deployed to measure in situ labile metals concentrations. Field measurements confirm estimates from WHAM of high metal bioavailability under current conditions. This raises questions about the effectiveness of the application of the regulations at the site specific level.

WP233 Are Free Ion Activity Models Sufficient Alternatives to Biotic Ligand Models in Evaluating Metal Toxic Impacts in Terrestrial Environments? M. Owsianiak, Technical Univ of Denmark, Dept of Management Engineering; R. Rosenbaum, Technical Univ of Denmark, Section for Quantitative Sustainability Assessment; H.F. Larsen, M.Z. Hauschild, Technical Univ of Denmark. Metal partitioning between solid and aqueous phases and speciation in soil pore water control the bioavailability of toxic forms of metals, while protons and base cations can mitigate metal ecotoxicity by competitive interactions with biotic ligands. The employment of BLMs to evaluate toxicity potential of metals in soils results in site-specific toxicity scores due to large variability of soil properties and differences in ionic composition. Unfortunately, terrestrial BMLs are available only for few metals and few organisms, thus their applicability to hazard ranking or toxic impact assessment is low and alternatives must be found. In this study, we compared published terrestrial BLMs and their potential alternatives such as free ion activity models (FIAM), for applicability in addressing metal toxic impacts in terrestrial environments. A set of 1300 soils representative for the whole world is employed to calculate EC50 and thereafter hazardous concentration HC50 (geometric mean of all EC50) for these terrestrial organisms, for which both TBLMs and FIAMs are available. Results showed that median HC50 for all soils predicted with BLMs range 2 and 3 orders of magnitude for copper and nickel, respectively. In all cases, predictions of FIAMs fall within the range of values predicted with BLMs, and toxicity ratio of copper to nickel is accurately predicted with both models. Thus, both models are able to distinguish between the two metals in terms of their average toxicity. Given that the calculated toxicity scores show large variability even for soils located in close proximity to each other, selection of FIAMs is also justified in deriving soil quality criteria. It remains to be investigated at what spatial scale the FIAMs are a good alternative to TBLMs in evaluating metal toxic impacts in terrestrial environments.

WP234 Copper Accumulation and Toxicity in the Lamellae of the Eurhyhaline Isopod *Excirolana armata* at Different Salinities I.F. Barcarolli, Universidade Federal do Rio Grande – FURG; A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. Copper is ubiquitous in aquatic environments, being required for several physiological functions. However, high environmental copper concentrations are proved to be toxic, leading to structural and molecular injuries. In the present study, copper accumulation and effect on sodium regulation and enzyme activities were evaluated in the lamellae of the eurihaline isopod *Excirolana armata*. Isopods were collected at the Mar Grosso Beach (São José do Norte, RS, Southern Brazil) and acclimated to different salinities (3, 6, 15 and 30 ppt). They were exposed to 0.673, 12.37, 12.42 and 18.94 mg Cu/L at salinities 3, 6, 15 and 30 ppt, respectively. Copper concentrations used corresponded to the 48-h LC_{50} values previously determined under the same conditions. After copper exposure, isopods were collected, washed with an EDTA (12 mM) solution to remove the copper loosely bound on the isopod surfaces, and blotted dry in filter paper. Lamellas were then dissected and frozen (-80°C) until analysis. An aliquot of samples were dried, digested in concentrated nitric acid, diluted with MilliQ water for copper and sodium concentration measurement (atomic absorption spectrophotometry). Another aliquot of samples was homogenized in a buffer solution and Na^+,K^+-ATPase and carbonic anhydrase activities were determined (spectrophotometry). Significant lamellar copper accumulation was observed in all salinities tested paralleled with a decrease in the lamellar sodium concentration. A reduced lamellar Na^+,K^+-ATPase activity was also observed in isopods exposed to copper in salinities 3 and 30 ppt. In turn, carbonic anhydrase activity was inhibited in isopods exposed to copper in salinities 6, 15 and 30 ppt. These findings suggest that copper accumulates in the isopod lamellae and that the mechanism of acute copper toxicity at very low salinity (3 ppt) is associated with an inhibition of the lamellar Na^+,K^+-ATPase activity paralleled with disturbances in tissue sodium regulation. At higher salinities, this mechanism seems to be associated with an inhibition of the carbonic anhydrase activity, which also leads to disturbances in the lamellar sodium concentration. Data presented are relevant in the scope of the development of a Biotic Ligand Model for brackish and seawater environments (Supported by the International Copper Association, the Brazilian CNPq, and the Canadian International Development Research Centre).

WP235 The Relationship Between Chemical Extractability and Bioaccessibility of Arsenic in a Former Smelter Site S. Jeong, Seoul National Univ, Dept of Civil and Environmental Engineering; H. Moon, Seoul National Univ.; K. Nam, Seoul National Univ, Dept of Civil and Environmental Engineering, Seoul National Univ, Dept of Civil and Environmental Engineering. The present study was conducted to determine the bioavailable fraction of arsenic in four different types of soils with organic matter content 1.6 to 4.1% collected from a former smelter site. The main objective was to investigate how the in vitro bioaccessibility could be related to the existing form of arsenic in soil. The five-step extraction method developed by Tessier et al (Analytical Chemistry, 1979, 51(7):844-851) was employed as a means of determining the existing form of arsenic in soil. With the extracted soil samples obtained from each extraction step, in vitro bioaccessibility of arsenic was determined by using the stomach-phase extraction test method developed by the Solubility/Bioavailability Research Consortium (Solubility/Bioavailability Research Consortium, 1999, Appendix C). Total arsenic concentrations in the four soils ranged from 100.1 to 1063.7 mg/kg, and most of them (> 94%) were present as residual form (i.e., arsenic remaining after 4th extraction step), probably due to the long contamination history. The stomach-phase extraction test suggests that the arsenic recovered from 1th to 4th extraction steps, which corresponded to from 0.68 to 7.26% of total concentration, may be bioaccessible. More importantly, some portion of the arsenic which remained in the soil samples after 4th extraction step was also likely to be bioaccessible (i.e., from 0.64 to 11.33% of total concentration). Further analysis indicated that the residual arsenic existed in two forms such as remaining organic matter-bound form and mineral-bound form and the remaining organic matter-bound arsenic probably contributed to the bioaccessible fraction. About 64 – 92% of the arsenic present in the remaining organic matter was bioaccessible whereas only 1.98 – 7.25% was bioaccessible in the mineral-bound form, suggesting that the arsenic associated with organic matter was more bioaccessible. The composition of the residual organic matter (i.e., the organic matter remaining after 4th extraction step) seemed to be also important. A soil sample with 1.6% of organic matter showed higher bioaccessibility compared to another sample with 1.7% of organic matter (i.e., 11.9 and 0.64%, respectively). Humic substance fractionation study revealed that the former had higher humic and fulvic acids content than the latter (i.e., 1,083 and 83 mg/kg, respectively) while the two samples had similar humin contents.

WP236 Bioavailability of Metals at a Missouri Mine Waste Area J. Kountzman, Black & Veatch Special Projects Corp, Federal Services Division. The bioavailability of metals in the environment is of great concern particularly near former mine sites, dumps, tailings piles, and impoundments. Soil in these areas may contain higher than average concentrations of many metals (e.g., arsenic, cadmium, chromium, cobalt, copper, lead, nickel, selenium, zinc). In order to evaluate ecological risks associated with elevated concentrations of these metals, the fraction of the total concentration in soil that is bioavailable must be identified. Often, very high percentages (near 100%) of total metals are assumed to be bioavailable. While this assumption is conservative in terms of being protective of human and ecological receptors, it may not be a reasonable estimate of site conditions because the actual bioavailability of metals is often not assessed. The resulting risk may overestimate the true risk of exposure to site media. Overestimation of risk may result in lengthy and costly site remediation that may not be warranted. In order to understand metal bioavailability in soils, chemical and/or biological techniques must be used to measure the portion of metal that is bioavailable to humans and soil organisms. Techniques can range from direct measures of bioavailability such as concentrations in soil organisms to indirect measures such as chemical extractions. For this study, direct measures of metal concentrations were made from samples of plant and earthworm tissue collected from former mine sites, dumps, tailings piles in southeast Missouri. Plant and earthworm tissues were selected because they are important food items for sensitive ecological receptors. Measured results were used to develop site specific uptake factors. Single-variable (e.g., soil concentration) regression models were developed for raw data, as well as ln-ln and log-log transformed data. Multiple regression models including soil pH and fraction organic carbon were also evaluated to determine the effect on model predictions. The best fit estimates (based on the measured concentrations) were compared to default uptake factors used in the development of the EPA Eco Soil Screening Levels (EcoSSLs). Recommendations for incorporating site-specific bioavailability data in ecological risk assessments of mine waste sites are presented and discussed.

WP237 A Stable Isotope Approach to Investigating Zinc Toxicity and Internal Transport in Barley (*Hordeum vulgare* L.) J.J. New, J.W. Snodgrass, D. Ownby, Towson Univ, Urban Environmental Biogeochemistry Laboratory; R. Casey, Towson Univ, Urban Environmental Biogeochemistry Laboratory, Towson Univ, Dept of Chemistry; S.M. Lev, Towson Univ, Urban Environmental Biogeochemistry Laboratory. Trace metal in a soil is divided among mineral bound, surface bound and dissolved fractions. These pools can vary significantly among soils and as a result, there may not be a linear relationship between the total metal concentration in a soil and toxicity. Further complicating this relationship is trace metals acting as micro-nutrients (e.g., Zn) for terrestrial organisms. Plants will display a micronutrient exposure response to Zn in the environment. This will not be a linear response to increasing Zn but more of a polynomial response with poor health in Zn limited or excess conditions and good health over a range of optimal Zn. As a result, there is focus on the impact of low soil Zn on crop yields for plants like *Hordeum vulgare* L. (barley) but little attention to the negative impacts at excess Zn, including Zn uptake and storage in soils with elevated Zn. To characterize the Zn effect on barley and the potential for uptake into the roots and shoot, we conducted exposure experiments in OECD soil and concluded Zn within the plant tissue was concentration dependent, with Zn accumulation in the roots and shoots increasing with exposure concentration. Zn uptake in the shoots appears to be well regulated until the exposure concentration approaches the EC_{50} of 1500 mg kg^{-1} at which point Zn tissue concentrations become correlated with the exposure concentration. Root uptake exhibits a linear response with increasing exposure concentration and is highly correlated with acid extractable Zn in the soil. These results are expected because the roots act as the point of regulation of Zn in *H. vulgare* L. In order to track flow of Zn in *H. vulgare* L. between soil and roots and from roots to shoots, we germinated barley seedlings in a ^{68}Zn enriched OECD soil for 7 days and transplanted the seedlings into OECD soils with a range of Zn concentrations (100-3750 mg kg^{-1}) and a natural isotopic abundance for 7 days. Zn^{68} in shoot tissues was rapidly 'lost' as evidenced by the uniformly low fraction of Zn^{68} remaining in shoot tissues at all exposure levels. Efflux of ^{68}Zn to the roots is the most likely pathway. The $^{68}Zn/^{66}Zn$ ratio in the roots remained elevated and constant despite increasing Zn exposure concentrations. This suggests that the Zn entering the roots must be derived from the shoot, the only ^{68}Zn enriched source post-transplant. The lack of ^{68}Zn dilution in the roots is a direct result of the regulation of Zn uptake in the shoots.

WP238 Assessing Bioavailability of Lead from Soil and Earthworms to Small Mammals Using the Relative Bioaccessibility Leaching Procedure: Study Design S.R. Beganyi, The Ohio State Univ, Evolution, Ecology, and Organismal Biology; R. Lanno, Ohio State Univ, Dept of Evolution, Ecology, and Organismal Biology. Ecological soil screening levels (SSLs) are based on total lead (Pb) in soil, assuming that 100% of Pb is absorbed by the receptor and reaches target organs. However, this does not give an accurate estimate of Pb risk because not all Pb in the soil is absorbed in the digestive tract and reaches target organs. Bioavailability, or the amount of metal that is absorbed from the digestive tract into the blood stream, is a better estimate of Pb concentrations that may affect receptors. The goal of this study is to assess the bioavailability of lead from soil and earthworms to shrews using the Relative Bioaccessibility Leaching Procedure (RBALP) to determine if bioavailability is less than the assumed 100%. The study site is a private shooting range located in central Ohio. Areas of interest for this study include the main shotfall area that receives spent ammunition from clay pigeon practice, an area where Pb pellets were excavated (Fall 2009), and a reference area that does not receive a significant amount of spent Pb shot. Surface soil from each area will be collected and analyzed for total Pb and extractable Pb. Earthworms will be reared in the three soils for 28 days. After 28 days, soil samples and prey items will be analyzed using the Relative Bioaccessibility Leaching Procedure (RBALP). Lead in tissue samples from field caught mammals will be measured using inductively-coupled plasma mass spectrometry (ICP-MS). Mammal tissue Pb values will be compared to total soil Pb and bioaccessible Pb determined by RBALP to estimate bioavailability. If there is a correlation between field Pb levels in mammals and the relative bioaccessibility, then RBALP may be a useful non-invasive tool for exposure estimates in ecological risk assessment.

WP239 Elements of Green Energy Technology: Preliminary Hazard Analysis of Rare Earth Metals D.B. Mayfield, A.S. Lewis, K.R. Reynolds Reid, Gradient. The United States and other western nations are rapidly

expanding mineral resources in order to provide the necessary materials for emerging technologies, particularly green energy technologies. Rare earth elements (lanthanides) are critical to many components (e.g., magnets and batteries) of green energy technologies (e.g., wind turbines, hybrid vehicles). The process of bringing these resources to market (e.g., mining, milling, product development and disposal) may have unintended environmental consequences that may result in exposure to humans and ecological receptors. However, limited studies have been performed to evaluate the potential hazards associated with this group of metals. Further, few regulatory standards are available to manage occupational exposures or environmental releases. Using an existing green chemistry assessment framework, we performed a hazard analysis for rare earth elements. Acute and chronic toxicity studies were also reviewed and summarized to evaluate the potential health effects of lanthanides on humans and the environment. Our preliminary analysis of the more recent studies indicates that rare earth metals demonstrate moderate to elevated toxicity depending on the route of exposure, compound formulation, and/or species tested. These results suggest that further evaluation is warranted due to the growing utility of these elements in technology. Critical data needs, that can provide the basis for guidelines that will be protective of human health and the environment, are also discussed.

WP240 Hepatic, Renal and Reproductive Effects of Cadmium Contamination in Frog *Microhyla fissipes* Living Downstream of Zinc Mining Area in Thailand J. Kitana, Chulalongkorn Univ, Dept of Biology; O. Achayapunwanich, P. Thammachoti, Chulalongkorn Univ, Dept of Biology; M. Othman, Universiti Kebangsaan Malaysia, Environmental Health Program; W. Khonsue, N. Kitana, Chulalongkorn Univ, Dept of Biology. Cadmium is a toxic heavy metal contaminated in environment and caused adverse effects in animal. In Mae Sot District of Tak Province, Thailand, concerns have been raised over the cadmium contamination, potentially due to zinc mining activities. Although there is no report of acute toxicity on animals in this area, the impact of long-term environmental exposure to cadmium on their health are of attention. Water and sediment collected from two potentially cadmium contaminated field sites (low-Cd site and high-Cd site) in Mae Sot during 2008 were analyzed by graphite furnace atomic absorption spectrometry. Year round cadmium contamination in water ranged from 0.0015-0.002 mg/L in low-Cd site to 0.0019-0.0023 mg/L in high-Cd site, while higher levels were found in sediment ranged from 0.1013-0.2206 mg/kg in low-Cd site to 2.9260-3.2888 mg/kg in high-Cd site. *Microhyla fissipes* (n = 20) was collected from each site in 2-month interval during wet season. Detectable level of cadmium residue was found only in the frog collected from high-Cd site. Gravimetric analysis showed that hepatosomatic indices were significantly lower in low-Cd site compared to those of the high-Cd site. Histological analysis showed similar alterations in liver of the frog from both sites including lipid accumulation, necrosis, and fibrosis of the liver tissues. Distinctive melanomacrophage aggregations were found in frog's liver from both sites. Although the number of cells counted was higher in high-Cd site (672.53 cells/mm2), the difference was not significant compared to those of the low-Cd site (381.87 cells/mm2). Renosomatic indices as well as kidney histology were not significantly different between two sites. Degeneration and pyknosis of renal tubular cells were observed in some area of the kidney tissues. These evidences indicate that environmental cadmium contamination in Mae Sot, even at low level, may cause hepatotoxic and renotoxic effects on the frog living in this area. Reproductive health in term of gonadosomatic indices were significantly different between two sites with the lower GSI in both male and female found in frogs from the high-Cd site. Since exposure to low levels of an endocrine disruptor such as cadmium may induce changes in gonadal development and differentiation resulting in adverse effects on reproduction. Gonadal development will be histologically examined for the assessment of reproductive effects of low level cadmium contamination on this frog species.

WP241 Advantages to Using Site-specific KOC Values When Assessing Ecological Risk at MGP Sites R. Devries, T. Rodolakis, AMEC. USEPA guidance advocates organic carbon partition coefficients (KOC), in concert with Equilibrium Partitioning (EqP) theory, to develop ecological screening benchmarks for organic compounds in sediment (USEPA, 2003). As part of the site investigation and ecological risk assessment of a former MGP site in Massachusetts, AMEC derived site-specific KOCs for polyaromatic hydrocarbons (PAHs) using advanced analytical techniques. Following the USEPA guidance, ΣESBTUs were calculated first using EPA default KOCs and then using site-specific KOCs. Results from the two approaches were then compared to each other. The partitioning of PAHs from riverbed sediment to porewater using site-specific KOC was a factor of 12 (for alkylated PAH) to 38 (for parent PAH) lower than what was predicted by default KOC. In the context of this MGP site, use of site-specific KOC amounted to a difference of approximately 100,000 sq ft of river bottom that were screened out of the risk assessment with respect to the ESBTU measurement endpoint. This comparison shows that relying on default Koc values may lead to risk estimates that are biased high.

WP243 Application and Critical Analysis of Brazilian Dredging Regulations M.C. Lamparelli, CETESB – Companhia Ambiental do Estado de São Paulo, Hidrobiology Laboratory; J.E. Bevilacqua, CETESB – Companhia Ambiental do Estado de São Paulo. The application of the 2004 Brazilian regulation, which established an Action List with a lower and upper chemical Action Level for the characterization and destination of dredged material to aquatic environments, and the S.Paulo State regulation for destination on land, resulted in suggestions for their improvement. Although the regulations were not established on simple pass/fail Action Levels, allowing the use of a weight-of-evidence approach, the lack of professional expertise of the stakeholders involved, impaired the integration of all measured physical, chemical and biological characteristics into the final decision. Few alternatives for dredged material other than open water disposal are considered in brazilian harbors, except for few cases where the material was confined, and practically no beneficial use or treatment exist. Data on sediment quality, available for harbors in several States, and the experience as regulators indicated the necessity to make more explicit the use of bioassays in whole sediments and the adjustment of Action Level 1 to sediment background concentrations of arsenic and nickel on the southeastern coast. It was also verified that the guidelines values adopted, mainly based on ecotoxicological data sets from North American, couldn't be considered restrictive, since values superior to them were rare. Dredging operations in Santos harbor, the largest one in South America, have produced enough knowledge as to establish the minimum requirements for its monitoring. The relationship between quality and quantity of dredged materials at the disposal site, located at 6 miles from the coast, showed that the current direction distributed particles for an area of 7 miles around the site, with C/N ratio indicating a significative continental influence; subletal effect for organisms and alteration of the benthic community were also verified. Modeling of dredged material transport, indicated that it didn't reach the beaches, as in previous dumping sites and the dispersion allowed the recovery of the area when left undisturbed. Quality assurance of analytical data and information integration can result in more efficient management and monitoring programs. Regulatory framework should clarify aspects related to the diagnosis of the dredged material and include the establishment of a dredging and monitoring plans of the dredged and disposal areas considering potential effects on human health and aquatic environment.

WP244 Arriving at a Long-term Monitoring Solution for Sediment A.H. Verwiel, M. Hillyard, E. Conti, AMEC Geomatrix, Inc. In many cases, environmentally persistent chemicals in sediment have resulted from releases that occurred decades prior, and over the ensuing time the aquatic environment has adjusted and benthic species and aquatic vegetation have returned, making sediment removal damaging to the present ecosystem. While the persistent chemicals remain, they may be inaccessible to biota, which allows for regeneration of the ecosystem. This is particularly true in depositional environments where over time the affected sediments are buried below the biologically active zone, significantly reducing potential ecological effects of the chemicals. If potential ecological risks are identified, the environmental and economic costs/benefits of proposed solutions should be evaluated. A long-term management solution may be selected as the best alternative when the potential damage to the environment by sediment removal is greater than the benefit. However, long-term management solutions are only viable if an effective plan is developed for periodic long-term monitoring, which may last for years or decades. The specific case study is at a former sawmill from which wood-surface-protection chemicals that contained dioxins/furans were released to a tidal slough connected to a large bay. Concentrations of dioxins/furans in the slough (particularly in deeper sediment) were higher than ambient concentrations in the bay sediment. Although shallow sediment concentrations did not present an ecological risk, concentrations in the deeper sediment could present a risk to ecological receptors if the deeper sediment became bioaccessible. Costs associated with focused removal in the areas of highest concentrations at depth were qualitatively

compared to the benefits. Critical to the evaluation was an understanding of the slough hydrology and the potential for sediment deposition and erosion. The cost/benefit evaluation resulted in selection of a long-term monitoring solution. The program includes annual sediment elevation monitoring as well as specific monitoring triggers for significant natural events, including earthquakes, floods, 10-year storm events, and tsunamis, and anthropogenic events, such as changes in land use. The monitoring program has been in place for almost four years, during which time earthquakes, flood events, and tsunamis have occurred, but sediment at depth in the slough has not become bioaccessible.

WP245 Concentrations and Distribution of PAHs in Sediments from Yatsushiro Sea, Western Japan, and Assessment of the Effects on Benthic Organisms K. Uehara, Y. GOTO, Kumamoto Univ; S. Shimasaki, Center for Marine Evironment Studies, Kumamoto Univ; H. Nakata, Kumamoto Univ, Graduate School of Science and Technology, Kumamoto Univ, Dept of Environmental Science. Recent studies have reported the occurrence of serious contamination by polycyclic aromatic hydrocarbons (PAHs) in the Yatsushiro Sea, western Japan. High concentrations of PAHs were detected in sediments from Tanoura bay, middle-eastern Yatsushiro Sea, at the levels of several tens mg/kg dry wt. basis. However, the number of samples analyzed in the previous study was only five, and little information is available on the comprehensive distribution of PAHs contamination in this bay. In this study we analyzed PAHs in surface sediments collected from 42 stations at inner, middle and outer Tanoura bay. PAHs were detected in all sediments analyzed in this study. The concentrations of PAHs in sediments ranged from 520 to 32,700 ng/g dry wt., at the average value of 5,240 ng/g. High concentrations of PAHs were found in sediments from two stations of southern inner bay (32,700 ng/g and 27,700 ng/g), which were approximately two orders of magnitude greater than those in sediments from reference sites. High molecular PAHs (HM-PAHs), benzo[*b*]fluoranthene, benzo[*a*]pyrene, and indeno[1,2,3-*cd*]pyrene were predominant components in sediments, suggesting the occurrence of specific sources of PAHs in this bay. HM-PAHs concentrations in sediments decreased at the stations of outer bay, implying less mobilization of these compounds in this bay. PAHs concentrations in sediments were compared with the Sediments Quality Guidelines (SQGs), which established by NOAA, in order to evaluate potential effects of PAHs on benthic organisms. Concentrations of acenaphthene, fluorene, phenanthrene, anthracene, flouranthene, pyrene, chrysene benzo[*a*]anthracene, benzo[*a*]pyrene, dibenzo[*a,h*]anthracene in sediments exceeded ERL (Effect Range Low) in 28 stations. PAHs levels in sediments from two stations were found to be greater than those of ERM (Effect Range Medium). These results imply that benthic organisms in Tanoura bay may have serious risks by chronic exposure to PAHs, and further studies are needed to evaluate biological effects in this bay.

WP246 Organochlorine Pesticides and Hydrocarbons in Sediments from the Campeche Coastal Zone, Mexico L. Alpuche Gual, Campeche Autonomous Univ/EPOMEX Center, Centro Epomex; B. Ramirez-Vargas, E. Cach-Perez, Campeche Autonomous Univ/EPOMEX Center. Coastal zone in Campeche is important for fisheries and touristic activities, and thus for the local economy. This system receives a continuous contribution of toxic compounds from domestic sewage and some industrial activities carried out mainly in the south part of the coastal area. In addition, in past years organochlorine pesticides were sprayed near to the study site for malaria control, and also close to the study site is the Sonda of Campeche, the main oil crude extraction area for Mexico. Overall goal of this study was to evaluate the levels of organic persistent pollutants in sediments (organochlorine pesticides and hydrocarbons). Sediment samples were collected with a stainless steel grab sampler in 15 stations along Campeche, Carmen and Champoton cities. Statistical analysis indicated no significant differences between samples of the three sites studied (Campeche, Champoton and Carmen), although the highest concentrations of __ hydrocarbons were detected in Carmen, which is a town near the oil platforms. We conclude that the coast zone of Campeche has had impacts of persistent pollutants that are still present together with the addition of hydrocarbons generated by oil activities and waste water residuals of cities.

WP247 Phosphate Source-sink Dynamics in Androscoggin River A. Cardamone, Bowdoin College; D. Vasudevan, Bowdoin College, Dept of Chemistry. The Androscoggin River has historically had varying levels of inorganic phosphate (o-P) input from many sources, including pulp and paper mills, agricultural runoff, and wastewater treatment plants. Since the passage of the Clean Water Act, water quality has greatly improved. As the river becomes cleaner, however, questions remain over whether the o-P currently bound to the sediment will reenter the water and adversely affect the ecosystem. To examine this dynamic, several sediment samples were collected at two locations along the river: Gulf Island Pond (GIP) and Merrymeeting Bay (MMB). Sediments from each site were used in sorption experiments from which the equilibrium phosphorus concentration (EPC) was extrapolated. The EPC value has been extensively used to establish aqueous phosphorus concentrations at which there is no net phosphorus release or uptake by the sediment. At both GIP and MMB, the EPC values indicate an equilibrium between sediment bound phosphate and current pore water and surface water phosphate concentrations. This implies that as phosphate inputs into the river continue to decrease to concentrations less than 0.5 µmol P/L (15 ppb), sediment bound phosphate could be released into the Androscoggin and potentially become a significant new source of phosphate pollution. Furthermore, GIP sediments had higher o-P sorption capacities, surface areas, and extractable iron (ex-Fe) and aluminum (ex-Al) content compared to MMB sediments, indicating the capacity to act as an o-P sink is likely determined by surface area, ex-Fe, and ex-Al content.

WP248 Potential Effects of PCDD/F, PBDE, Heavy Metals in Sediment Based Laboratory Toxicity Test with Midge and Amphipod; Case Study in Nakdong River, Korea H. Kim, Pusan National Univ, Dept of Civil and Environmental Engineering; U. Kim, Pusan Natoional Univ; N. Kemble, C. Ingersoll, USGS CERC; J. Oh, Pusan National Univ. The objective of this study is to evaluate relationships between chemically analyzed level of hazardous toxic POPs compounds (e.g., PCDD/Fs, PBDEs) and heavy metals (e.g., 20 regulated heavy metals in Korea compromising Arsenic, Chromium, Copper, Lead, Cadmium and Mercury) and their toxicity results observed from in vitro test in Nakdong river, one of major river basins in Korea, as a case study. Four major river restoration projects were started in 2009 to control flooding, improve water quality, and to restore ecosystem function, the reuse and potential toxicity of dredged sediment are an emerging issue. Sediments from six sampling sites from Nakdong river, which were suspected as contaminated areas, were selected for in vitro toxicity test and chemical analysis. The compositions of sediment samples were 39% sand, 36% silt and 30% clay in average with 35% moisture content. The toxicity tests with the amphipod *Hyalella azteca* (28-d exposures) and midge *Chironomus dilutus* (10-d exposures) were conducted and the toxicity of sediment samples were estimated based on effects on survival, growth, or biomass of test organisms following ASTM and USEPA methods. For the analysis of PBDEs, PCDD/Fs and heavy metals, modified EPA methods were used (1613, 3051). The concentration levels of PCDD/Fs in sediment ranged from 0.055 to 1.497 ng-TEQ/kg-dry and those of PBDEs were from 0.192 to 43.69 ng/kg-dry. The concentrations of most heavy metals were similar regardless of sampling sites and only Chromium and Arsenic exceeded the regulation levels of soil in Korea at all 6 points. The observed PCDD/F was below the interim sediment quality guidelines of USA (2.5 ng-TEQ/kg) but still quite high. Two points near water gate of the river (S3 and S6) was shown the significant toxicity result with *H. azteca* but the level of organic contaminants was high in order of S1>S6>S4 for PBDEs, S6>S3>S1 in case of PCDD/Fs. Additional evaluations of relationships sediment chemistry and toxicity results will be presented at the conference.

WP249 Stability and Transport of Formulated NPs Through Environmentally Relevant Porous Media M.A. Chappell, US Army Corps of Engineers, Environmental Laboratory, US Army Corps of Engineers; L.F. Miller, Us Army Engineer Research & Development Center, Environmental Laboratory; C.J. Banks, US Army Engineer Research and Development Center, CEERD-EP-R, US Army Engineer Research and Development Center, Research Biologist; M. Middleton, Badger Technical Services; C. Price, US Army Corps of Engineers. The power of nanotechnology arises from the remarkable surface energy of particles exhibited at the nanometer size range. Materials that are otherwise relatively benign often exhibit unusual reactive, mechanical, or spectroscopic activity. However, there is a great energetic cost associated with retaining particles at these small sizes, and thus, the need for special preparations to create stable nanoparticle (NP) dispersions, such as through severe ultrasonic agitation or chemical modification vial application of surface coatings. While the latter preparation provides what are deemed as "thermodynamically" stable dispersions, the trade-off is a resultant uncertainty whether the particles will exhibit

desirable properties. For this work, we investigated the long-term stability of nano silver (nAg) and carbon nanotube (CNT) suspensions by examining the simultaneous dispersion and dissolution behavior of the particles in the presence of background electrolyte, surfactants, and Aldrich humic acid over a 14-day period. Formulated NP dispersions were leached at steady state through highly porous media (e.g., sand, glass beads). Particle size and dissolved solutes were determined in the effluent and NP distribution in the column by in situ EDX mapping. Formulated NP attachment and straining coefficients were determined through analytical modeling of the transport data using colloid transport algorithms. Based on this work, we present numerical calculations of the potential mobility of these dispersions through profile of differently textured soils.

WP250 Why Be a Benthos? Application of Basic Benthic Ecology to Basic Benthic Ecological Risk Assessment and NRDA D.W. Smith, Conestoga Rovers & Associates; S.D. Cooper, Univ of California Santa Barbara, Dept of Ecology, Evolution, and Marine Biology. Benthic ecological risk assessment (ERA) and Natural Resources Damage Assessments (NRDA) generally assume that 1) the benthos dominate aquatic ecosystem structure and function AND 2) all benthic macroinvertebrates occur deep within fine sediments (i.e., they are "deep infauna" eating only buried organic matter and exposed only to pore water). Put simply, it is assumed that significant impacts to deep infauna will produce similar impacts on fish production. In reality, benthic macroinvertebrate communities and their importance to ecosystem functions vary greatly across microhabitats, within and across aquatic systems. Like all organisms, macrobenthos require food, shelter from predators and currents, and habitable physical conditions (e.g., enough dissolved oxygen, not too much ammonia). Microhabitats, which provide more of these basic requirements, will engender more benthos (i.e., higher benthic densities, biomass, and production, with higher relevance to ERAs and NRDAs.) For example, in many aquatic systems (most streams, unproductive lentic systems), food quality and quantity for the benthos are highest at the sediment-water interface. In others, food quality and quantity are highest in the water column (more productive lake systems) or on plants (marshes, weed beds). In most aquatic systems, food quantity and quality decrease with depth into the sediments, and more degradable and nutritious organic matter tends to be eaten or metabolized prior to burial. Hence, the production, biomass, and importance of the epibenthos to energy flow will potentially be higher than those of the deep infauna. Similarly, the carrying capacity of different substratum types (fine vs. coarse sediments) and sediment depths can be evaluated with respect to the other critical requirements for life. Using current theory and empirical data, we will test the following hypothesis. The importance of specific benthic communities (deep infauna, shallow infauna, epifauna, epiphyta) to an ecosystem's structure and function depends on the amount and distribution of benthic food, shelter, and habitat conditions. Thus, knowledge of basic benthic ecology has important implications for ERAs and NRDAs. Many aquatic systems are not dominated by fine sediment habitat or by deep infauna. Fish may rely on many food sources other than the deep infauna. Alternate session would be "Evaluating Human Health and Ecological Risk Assessments and Remediation Decisions: is cure .."

WP251 Altered Offspring Sex Ratios in Birds Living Along a Mercury Contaminated River A.J. Bouland, College of William and Mary, Dept of Biology; A.E. White, College of William & Mary, Dept of Biology; K.P. Lonabaugh, W.T. Northam, College of William & Mary, Dept of Biology; D.A. Cristol, College of William & Mary, Professor of Biology, College of William & Mary, Dept of Biology. Virginia's South River was contaminated by a point-source of mercury between 1929 and 1950. Mercury is a persistent toxin that is known to impact the fitness of birds inhabiting aquatic environments. Our study examined the effect of mercury exposure on nestling sex ratios in three avian species inhabiting this site and nearby reference sites. In accordance with sex allocation theory, we hypothesized that females inhabiting contaminated sites would (1) be in poor condition, and (2) would produce more female offspring, as females in poor condition are more likely to be successful in competition for mates than males of poor condition. The highly aquatic belted kingfisher (*Megaceryle alcyon*), with the highest mercury levels (~3.5 ppm wet weight), showed a bias toward female offspring (64.17% female), while no bias was found in the highly terrestrial bluebird (*Sialia sialis*), with lowest blood mercury (~1 ppm). Nestlings of both species can be assigned as male or female based on plumage coloration. A molecular PCR technique was used to determine sex of nestling tree swallows (*Tachycineta bicolor*), a species intermediate between aquatic and terrestrial environments and with intermediate mercury levels (~2.5 ppm). Preliminary analyses indicate a bias toward female offspring in this species (59.1% female), suggesting that mercury contamination weakens breeding females and causes compensatory adaptive adjustment of offspring sex ratios.

WP252 Considerations for Assessing the Status of Ecosystem Services Following the 2007 Grass Valley Wildland Fire: Thinking Historically C. Menzie, Exponent; T. Deardorff, Exponent, Senior Managing Scientist. The Grass Valley fire burned approximately 1,247 acres of land to the northwest of Lake Arrowhead in the San Bernardino National Forest in 2007. Any assessment of resource damages to the forest resource from this fire must include an assessment of pre-existing conditions. When considering the ecological service losses following the Grass Valley Fire, we determined that the services were significantly reduced prior to the fire and that the forest was at a high risk of a fire due to considerable impacts from beetles, disease, and drought. Because of the dynamic nature of forests, these pre-conditions can involve a dynamic or changing baseline that includes periodic fires. For example, immediately before the 2007 fire, the available evidence indicated that the environmental conditions and health of the forest that burned in the Grass Valley fire were substantially reduced prior to that fire and shows that most of the trees that were burned in the fire were either dead or dying prior to the fire. Thus, environmental services associated with a healthy and alive forest were also diminished. Following a wildland fire, the habitat changes deemed of value by an analysis may or may not be beneficial to all wildlife. Many of the post-fire changes are necessary for the health of a dynamic ecosystem. The values of forest services are not constant through time and the recovery process is arbitrary and contingencies, including secondary disturbances, impact the process. Distressed ecosystems do not naturally or automatically revert to the conditions observed pre-disturbance, and the extent and rate of recovery of the landscape is far too complex to put a successional and lengthy timeline on it. The integrated services supported by a natural forest are dependent on the presence of a patchwork of tree species, age/size classes, and plant communities in various successional stages. The dynamic and changing nature of forests is what provides for a healthy and functional forest condition and that the ongoing spatial and temporal changes within forests reflect the natural state and very likely the desired state with respect to net environmental services over time.

WP253 Examination of Mandibular and Maxillary Squamous Cell Proliferation in Mink (*Mustela vison*) R. Ellick, Michigan State Univ, Animal Science; S. Fitzgerald, Michigan State Univ, Diagnostic Center for Population and Animal Health; J. Newsted, Cardno Entrix; N.M. Bello, Kansas State Univ; J. Link, S. Bursian, Michigan State Univ, Animal Science. Mink (*Mustela vison*) exposed to 2,3,7,8,-tetrachlorodibenzodioxin (TCDD) and other TCDD-like compounds, such as 3,3',4,4',5-pentachlorobiphenyl (PCB 126), develop an invasive jaw lesion characterized histologically as mandibular and maxillary squamous cell proliferation. Nests and cords of squamous epithelial cells invade the adjacent alveolar bone to cause osteoporosis. Macroscopically, the lesion manifests as swollen and bleeding gums, loose teeth, and eventual tooth loss. In addition to laboratory studies, jaw lesions have been reported in wild mink residing in environments contaminated with TCDD-like chemicals and there is evidence suggesting jaw-related lesions in other wildlife species collected in environments contaminated with TCDD-like chemicals. Commercial blue iris mink have exhibited the gross clinical signs of this lesion without TCDD-like chemical exposure. To date, no studies have been published addressing the etiology of this lesion, but the arylhydrocarbon receptor (AhR) is assumed to be involved because of the lesion's induction by TCDD-like chemicals. To further examine the development of the lesion, two studies were conducted. In the first study, resveratrol, an AhR antagonist, was administered to determine if it could prevent or reduce the development of the lesion. Juvenile mink receiving a single intraperitoneal injection of 30 µg PCB 126/kg bw or a single PCB 126 injection plus 6 daily gavage doses of 50 mg resveratrol/kg bw. Mink were euthanized 9 weeks later, and the jaws were processed for histological assessment. Resveratrol had no apparent effect on the incidence or severity of the PCB 126-induced effects. A second study was conducted to determine if the periodontal disease described in the blue iris strain of mink, which is grossly identical to the PCB 126-induced jaw lesion, was in fact the same lesion. It was shown that the condition in blue iris mink is a destructive inflammatory response rather than an invasive squamous epithelial proliferation. Thus, it is recommended that wildlife species with gross signs

characteristic of the PCB 126 jaw lesion be assessed histologically to rule out other potential causes such as inflammatory disease.

WP254 Interspecific Effects of Munition Compounds in Three Avian Species: Japanese Quail, Northern Bobwhite, and Zebra Finch M. Quinn, US Army Public Health Command (prov.), & Preventive Medicine; M. Cook, Oak Ridge Institute of Science and Education; T. Hanna, US Army Public Health Command; A. Shiflett, Oak Ridge Institute of Science and Education; M. Johnson, US Army Public Health Command; K. Gust, E. Perkins, US Army Corps of Engineers. The overall objective of this study was to assess the toxicological and toxicogenomic effects of two munition compounds on three different bird species. This presentation will communicate only the results pertaining to the comparisons of the toxicological effects among the species. Two commonly used model species for avian toxicity tests (northern bobwhite and Japanese quail) and a representative passerine species (zebra finch) were exposed to 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX) and 4-amino-2,6-dinitrotoluene (4A-DNT) by oral gavage for seven days. Blood was collected following the seventh day of exposure for the following cellularity and chemistry analyses: total erythrocyte and leukocyte counts, hemoglobin, hematocrit, and plasma aspartate aminotransferase, glucose, creatine kinase, triglycerides, uric acid, phosphorus, albumin, globulin, lactate dehydrogenase, and calcium. Of the three species, the northern bobwhite appeared to be most sensitive to 4A-DNT as indicated by mortality and altered levels of red blood cells and plasma proteins, and the zebra finch was most sensitive to RDX as evidenced by mortality and seizures. Although Japanese quail were affected by both chemicals, changes in blood cellularity and chemistry were not as severe and no mortality was experienced due to either of the chemicals.

WP255 Organochlorine Compounds and Mercury in Bald Eagle Nestlings and Eggs from Coastal Maine S. Mierzykowski, US Fish & Wildlife Service, Maine Field Office/Ecological Services; L.J. Welch, US Fish and Wildlife Service, Maine Coastal Islands National Wildlife Refuge; C.S. Todd, Maine Dept of Inland Fisheries and Wildlife; B. Connery, National Park Service, Acadia National Park; C. DeSorbo, Biodiversity Research Institute. In 2009 and 2010, bald eagle nestling blood and non-viable eggs were collected along the Maine coast and analyzed for organochlorine compounds and mercury. Nestling plasma (n = 20) contained Total PCB (mean 54.7 ± 28.2 ng/g wet weight, range: 14.6 – 119.1 ng/g) and DDE (mean 7.4 ± 5.2 ng/g, range: 1.8 – 21.2 ng/g) concentrations that were below suggested toxicity threshold levels. Non-viable eagle eggs (n = 9) had substantial amounts of organochlorine compounds (means TCDD-TEQ 251 pg/g, Total PCB 12.76 µg/g, DDE 1.90 µg/g, Total PBDE 765 ng/g, fresh wet weight), but were also below suggested toxicity threshold levels. Mercury in whole blood from eagle nestlings was not elevated (n = 43, mean 0.194 ± 0.150 µg/g wet weight, range: 0.031 – 0.817 µg/g) and below background (< 0.40 µg/g). However, one bird had a mercury blood level in the range classification as moderately elevated (0.40 – 0.69 µg/g) and another had a mercury concentration that would be considered elevated (0.70 – 0.99 µg/g). Mercury in non-viable eggs (n = 9, mean 0.15 ± 0.09 µg/g fresh wet weight) was well below suggested threshold levels for reproductive effects. The results confirm previous research in Maine. Coastal birds appear to exhibit higher organochlorine levels than eagles nesting along rivers and lakes in inland Maine. In contrast, inland birds appear to exhibit higher mercury levels than coastal eagles. Differences in prey bases may be responsible for the variations in contaminant uptake by nest location. In Maine, coastal eagles principally feed on gulls, cormorants, and sea ducks; while inland eagles feed primarily on fish.

WP256 PCB Concentrations in Tree Swallow (*Tachycineta bicolor*) Eggs Collected from the Upper Hudson River Varies Within a Season and Between Zears K. Dean, Univ of Lethbridge, Neuroscience, Univ of Maryland, post-doctoral research fellow; M. Ottinger, Univ of Maryland, Dept of Animal and Avian Sciences. PCB content of tree swallow eggs collected from two uncontaminated sites (Cobleskill Reservoir, NY and Patuxent Research Refuge, MD) and the Upper Hudson River site in 2006-2008 were compared across years and within the breeding season for each year. Composite samples of two unincubated eggs were separated into chemical free jars and analyzed for PCB congener concentrations. Analyses across all three years showed total PCB concentration, dioxin-like PCB concentration, and non-dioxin-like PCB concentrations were significantly higher ($p < 0.05$) at the contaminated site. Since tree swallow breeding season begins in late April and can continue until mid-July, there is sufficient time for female tree swallow PCB body burden to translate into egg deposition. Additionally, it is likely that eggs laid later in the season would contain higher PCB concentrations as females are more likely to be exposed to higher PCB concentrations with increased insect availability during warmer months. When eggs were categorized according to time from initiation of egg laying at the Upper Hudson River, there were increases in PCB concentrations in eggs laid later in the season. These data demonstrate a dynamic uptake of PCBs by females in contaminated regions that reflect their environmental exposure on a seasonal basis, potentially impacting the development of their offspring. Acknowledgements: Supported by the US Fish and Wildlife Service and the Hudson River Natural Resource Trustees. The conclusions and opinions presented here are those of the authors, they do not represent the official position of any of the funding agencies, the Hudson River Trustees or the United States.

WP257 Recent Experiences in the Conduct of the Passerine Acute Oral Dose Study Required by the USEPA for the Registration of Conventional Pesticide Products K. Brugger, DuPont Crop Protection; M. Christ, Bayer CropScience; S. Mortensen, BASF. In 2007, Part 158 of Title 40 in the Code of Federal Regulations for the registration and reregistration of conventional pesticide products was revised to add a passerine oral dose (LD50) study to data submissions. The avian oral acute USEPA guideline (OPPTS 850.2100-draft) includes methodology for conducting studies with mallard and bobwhite quail but not song birds. Progress has been made in the last 2 years with method development in the following areas: protocol design, species selection (with a goal to develop this new database of chemical toxicity with a common set of species), bird acquisition (commercially reared vs. wild caught), gender verification, fasting period, dose administration, dose regurgitation, handling stress, determination of general husbandry requirements for each species and data interpretation. Commercially available canaries (Serinus canaria) and zebra finches (*Taeniopygia guttata*) proved to be suitable species that can be ordered in sufficient numbers to run limit tests (~20 birds) or full dose response tests (60+ birds). Small tissue or blood samples may be used for rapid and cost-effective DNA verification of gender to ensure equal allocation of individuals among treatment groups. Methods were developed to accurately dose very small birds and selectively replace birds if there is regurgitation. Studies conducted to date indicate that sensitivity of passerines to an active ingredient is generally not greater than that of mallard or bobwhite with most endpoints falling within the same hazard category of previously tested birds and a few endpoints shifting from one hazard category to the next (e.g., practically non toxic to slightly toxic). Regulatory impacts of these studies will be reviewed in light of USEPA OPP methods for risk assessments.

WP258 Results of Larval Honey Bee Inter-laboratory Validation Tests for Development of a Standardized Test Procedure M. Patnaude, Smithers Viscient, Ecotoxicology; Z. Huang, Michigan State Univ; J. Hoberg, Smithers Viscient. With no standardized test to assess sensitivity of honey bees to transgenic crops, the Agricultural Biotechnology Stewardship Technical Committee (ABSTC) recruited laboratories to participate in ring testing for this purpose. The objective was to establish a standardized GLP test. Zachary Huang (Michigan State Univ) modified an assay that other scientists developed which serves as the base method. Although originally developed for transgenic proteins, other compounds can be tested under the same design. Presented here are data from the exposures performed at Smithers Viscient, Wareham, MA. The data suggests that this assay can generate consistent results and the larval honey bee assay can provide valuable data for the assessment of honey bee sensitivity to chemicals.

WP259 Safety Profile of Furfural for Avian Exposure N. Cowen, toXcel LLC, Associate Scientist; G. Burger, J. Hensley, Agriguard Company, LLC; A. Katz, toXcel, LLC. Furfural (CAS Reg. No. 98-01-1) is registered in the US to control root infesting parasitic nematodes and to reduce fungal plant diseases such as species of Pythium, Phytophthora, Fusarium and Rhizoctonia. It acts on contact as an effective liquid crop protection agent and a substitute for soil fumigants, including methyl bromide. Furfural occurs naturally in a wide range of fruits and vegetables, as well as beverages (wine, whiskey), bread and in several essential oils of plants. It is Generally Recognized as Safe (GRAS) for use as a food flavoring agent. Furfural degrades rapidly in soil, air, water and plant surfaces following application to bare ground or foliage. Ecological characteristics of furfural such as avian

toxicity compare favorably with other nematicidal active ingredients, and range from practically nontoxic to moderately toxic. This presentation specifically explores the avian oral, dietary and inhalation routes of exposure for furfural, and gives further explanation to the results of recent studies and their relevance to actual field application exposure.

WP260 To Depurate or Not to Depurate? Using Earthworm Tissue to Estimate Doses in Ecological Risk Assessment K.B. Leigh, ENVIRON International Corporation, ENVIRON; M.H. Henning, A.L. Fogg, P. Fuchsman, E. Perruchon, ENVIRON International Corporation; N.E. Dyck, Ontario Ministry of the Environment. In ecological risk assessment, earthworms are often chosen for analysis to represent the soil-dwelling invertebrate community. Earthworms are intimately connected to the soil--by living in constant and direct contact with the soil, as well as regularly ingesting large amounts of soil. They are less mobile than other terrestrial invertebrates, allowing for a more localized assessment, and they have been shown to accumulate soil-associated chemicals into their tissue. For these reasons, earthworms often represent the highest exposure potential from chemicals in soil from a localized area. The collection of earthworm tissue samples allows for the direct measurement of chemicals in the body, thus eliminating the need to use overly conservative literature-based bioaccumulation factors. These body burden concentrations can be used to estimate a daily dose for higher trophic level species, such as the short-tailed shrew (Blarina brevicauda). It is important to determine whether or not to depurate (i.e., to allow the earthworms to eliminate their gut contents) prior to laboratory analysis and to account for this factor when estimating higher trophic level doses. Since earthworms' guts typically contain 20 to 30 percent soil, care must be taken to avoid significant overestimation of the total dose due to double-counting of the soil material contained within the earthworms. For this evaluation, earthworms were manually collected from each soil sample location and separated into two groups (one depurated and one non-depurated). Each earthworm group was weighed and analyzed for metals. Using both site-specific and literature information, the relative merits and cost-effectiveness of the depuration process was evaluated. The decision to depurate is predicated on many factors, including cost-effectiveness.

WP261 A Multigenerational Study Investigating Effects of Dietary Exposure to 17β trenbolone on the Expression of Steroid-responsive Genes in Japanese Quailty Y. Chen, Virginia Tech, Dept of Fisheries and Wildlife Sciences, USGS Patuxent Wildlife Research Center, USGS Patuxent Wildlife Research Center, Patuxent Wildlife Research Center; N. Karouna-Renier, USGS Patuxent Wildlife Research Center, Beltsville Lab ; P.F. Henry, USGS Patuxent Wildlife Research Center, Patuxent Wildlife Research Center; C. Maddox, D. Sprague, Patuxent Wildlife Research Center, USGS, Beltsville Lab. The current study investigated the effects on gonadal function of Japanese quail (*Coturnix japonica*) under continuous exposure to 17β trenbolone, a synthetic anabolic steroid, over three successive generations. Japanese quail were exposed to 5 doses of 17β trenbonlone in feed. F0 generation were exposed to treated diet from 6 weeks, F1 generation were exposed in ovo and fed the same treated diet from day 1 of hatch, and F2 exposed solely in ovo as they were provided with untreated feed. F0, F1 and F2 parents were euthanized at 16 weeks of age and expression of sex steroid responsive genes, including Vitellogenin II (VTG), Very low-density apolipoprotein II (apoVLDL II), and ZP1 in liver, and P450 aromatase in the gonads were examined by real-time quantitative PCR. Results across treatment groups within the same generation were compared to evaluate dose-related effects of trenbolone exposure. Results a cross different generations were also compared to evaluate the accumulated, cross-generational effect of long-term exposure to trenbolone. These results, combined with on going analysis on data from endocrine and physiological endpoints collected from the same population, will allow us to assess the cross-generation endocrine disrupting effects of 17β trenbolone in a model avian species.

WP262 Accumulation and Toxicity of Metals and Organic Compounds to the Oribatid Mite *Oppia nitens* O.J. Owojori, Univ of Saskatchewan, Dept of Soil Science, Obafemi Awolowo Univ, Zoology; S.D. Siciliano, Univ of Saskatchewan, Dept of Soil Science. The oribatid mite *Oppia nitens* has recently been assessed and proved suitable as a test species for ecotoxicological assessment of contaminated boreal soils. Knowledge of the ecotoxicity of pollutants of different modes of action to this species is necessary for protocol standardization. In this contribution, we assessed the toxicity of four metals (copper, zinc, cadmium and lead) and two organic chemicals (benzo[*a*]pyrene and geraniol) to *O. nitens* over a 35-day period. We monitored survival, reproduction and tissue accumulation at the end of the 35 day period. Reproduction was a more sensitive endpoint than survival. The reproduction EC50 values for Cu, Zn, Cd and Pb were 3592, 1997, 145 and 1678 mg kg-1 respectively while those for benzo[*a*]pyrene and geraniol were >1600 and 316 mg kg-1. The LC50 values for Cu, Zn, Cd and Pb were 3311, 2291, 603 and 6741 mg kg-1 respectively while those for benzo[*a*]pyrene and geraniol were >1600 and 251 mg kg-1. When using survival data to assess toxicity of metals, the mites showed the highest tolerance to Pb, but with the reproduction data, mites showed the highest tolerance to Cu. This suggests that for a correct evaluation of the toxicity of contaminants to this mite, a battery of endpoints should be used. Although none of the organic chemicals studied were accumulated by the mites, the four metals were accumulated to varying degrees showing the tendency to use body burden of *O. nitens* as an indicator of metal pollution.

WP263 Assessing the Bioaccumulation and Effects of Select Energetic Compounds on the Earthworm *Eisenia fetida* R.E. Boyd, Badger Technical Services, LLC, Environmental Laboratory; B.C. Suedel, US Army Engineer Research and Development Center, CEERD-EP-R, Environmental Laboratory, Waterways Experiment Station EP-R; N. Barker, US Army Engineer Research and Development Center; P. Gong, SpecPro Inc., Enivronmental Services; E.J. Perkins, US Army Engineer Research and Development Center, Environmental Laboratory, Environmental Processes and Effect Division. The use of munitions at military installations has resulted in the inadvertent contamination of abiotic media in these areas. While much experimentation has been performed with energetic compounds associated with these installations, questions remain as to the fate and effects of these materials in the environment and our ability to predict their environmental behavior. Among the energetic compounds most commonly found in soils at contaminated sites are RDX, TNT, and HMX. To improve our understanding of the bioavailability and effects of explosive mixtures, we performed experiments using both field-contaminated and laboratory-spiked soils containing RDX, TNT, and HMX. Field soils containing RDX, TNT, and HMX were collected from a site in the Midwestern and Northeastern US, and an uncontaminated control soil from the Southeastern US was collected for use in the spiking experiments. The experiments were conducted for 4, 14, and 28 days. Spiked soil experiments utilized radiolabeled compounds for more precise quantification. The result of the spiking experiments indicated both chemical bioavailability and physiological effects, such as retarded growth and body fragmentation. Observed physiological effects were similar between spiked soil experiments and field collected soil experiments. In most instances, there was a direct correlation between increased exposure period and soil concentration with increased body burden measurement for both the spiking and field soil experiments. In conclusion, these experiments confirmed physiological effects as well as the extent of bioavailability that some terrestrial invertebrate organisms might exhibit when exposed to the energetic compounds RDX, TNT, and HMX. This research is being used to foster the development of biological tools to help detect and discriminate these energetic compounds at military installations.

WP265 Characterization of Nanomaterial Test Solutions for Terrestrial Plant Dose-response Studies: A Comparative Study of DLS and SAXS J. Betts, M. Plocher, Dynamac Corporation; L. Tumburu, National Research Council; M.G. Johnson, USEPA, National Health and Environmental Effects Research Laboratory; G.A. King, Dynamac Corporation; P.T. Rygiewicz, C.P. Andersen, USEPA, National Health and Environmental Effects Research Laboratory. Industrial applications of nanomaterials have expanded at an increasing rate in recent years, accompanied by the need for comprehensive toxicological assessments to establish environmental health and safety standards. Relatively few studies have examined the effects of nanoparticles on terrestrial plants, and the studies that have been done often provide incomplete characterization of particle solutions, making replication and interpretation difficult. In order to fully assess the potential effects of nanoparticle exposure, it is imperative that solutions are fully characterized and exposure protocols are well documented. Preliminary results from an *Arabidopsis thaliana* Co-O seed germination trial performed with titanium dioxide (TiO_2) nanoparticles (NP) with five concentrations [0.1-1000 ppm] suggested an apparent retardation in cotyledon expansion at 10 ppm and slowest seed germination at 1000 ppm. It was difficult to interpret these results, however, because despite identical mixing protocols, concentration was not the only factor that differed among our various test solutions. To address

this problem, a comparative study of pre-exposure characterization techniques (Dynamic light scattering/Electrophoretic light scattering [DLS/ELS] & Small-angle X-Ray Scattering [SAXS]) was performed in conjunction with an *A. thaliana* plant exposure study. Nanomaterial properties including mean particle size, particle size distribution (PSD), and suspension stability at various particle abundances were compared. Initial results of TiO_2-NP suspensions using DLS/ELS suggested an increase in dispersion stability at higher concentrations, which could confound dose-response studies. Such findings highlight the need to consider the constraints associated with characterizing solutions based only on light-scattering measurements. Our results will help to quantify observable differences in physico-chemical characteristics due to variable particle abundance, leading to a better understanding of the limitations of each measurement technique in order to establish more comprehensive and accurate methods for characterizing nanomaterial test solutions for toxicological studies.

WP266 Characterization of Polychlorinated Dibenzo-*p*-dioxins and Dibenzofurans in White-tailed Deer Along the Tittabawassee and Saginaw Rivers, MI, USA J. Newsted, R. Holem, D. Kay, Cardno Entrix; A. Blankenship, Univ of Michigan; S. Roark, CH2M; J. Giesy, Univ. of Saskatchewan, Dept Biomedical Sciences and Toxicology Centre. The Tittabawassee River (TR) is located in central Michigan and flows southeast through Midland and into the Saginaw River (SR) and eventually to the Saginaw Bay of Lake Huron. Previous studies have reported elevated soil, sediment, and fish concentrations of dibenzo-*p*-dioxins (PCDD) and dibenzofurans (PCDF) downstream of Midland. Given that Michigan has a very active hunting season and concerns have been expressed over the potential risks associated with the consumption of wildgame harvested in the floodplain of both TR and SR. As part of an effort to address these concerns, a wildgame studies were conducted in 2003 and 2007 that included the collection of white-tailed deer (*Odocoileus virginianus*) from both the TR and SR floodplain. Tissues that were analyzed included muscle and liver. Statistical analyses indicated no significant differences in total 2378-tetrachlorodibenzo-*p*-dioxin equivalents (TCDD-EQ) for either liver or muscle tissues between male and females and analysis of age was inconclusive due to small sample sizes. Liver TCDD-EQ concentrations were statistically significant greater than muscle whether based on wet weight or liver normalized values. For both muscle and liver tissues, TCDD-EQ concentrations were significantly greater in deer collected downstream of Midland when compared to deer from the upstream reference location. Principle component analysis (PCA) showed that the congener patterns in deer upstream of Midland were dominated by PCDD congeners while in the downstream location the pattern was dominated by two PCDF congeners, 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF. PCA analysis of soil data from upstream and downstream locations indicated a congener pattern that was similar to that observed in deer collected from these locations. Overall, these data indicate that deer accumulate PCDD/PCDF in a manner that is reflective of the concentrations and congener profiles in found in floodplain soils.

WP267 Chronic Copper Exposure in Three Species of Amphibians: Lethal, Sublethal, and Gene Expression Effects S. Lance, Univ of Georgia, Savannah River Ecology Laboratory; K. Jones, Univ of Colorado School of Medicine; R.W. Flynn, Univ of Georgia, Savannah River Ecology Laboratory; M. Erickson, Georgia Southern Univ, Biology; T. Tuberville, D. Scott, Univ of Georgia, Savannah River Ecology Laboratory. Chronic exposure to environmental contaminants can cause effects at higher levels of biological organization such as populations and communities. However, due to inherent challenges in assessing these impacts most studies focus on individual survivorship under acute exposure. To assess the long-term effects of contaminant exposure it is critical to examine sub-lethal endpoints, and the potential for organisms to adapt to contaminated environments. We are investigating the relevance of sub-lethal endpoints in amphibians exposed to copper contamination. To date we have examined three species: southern leopard frogs (*Lithobates sphenocephalus*), southern toads (*Anaxyrus terrestris*), and eastern narrowmouth toads (*Gastrophryne carolinensis*). Overall we have found significantly different sensitivities to chronic copper exposure at the individual, population, and species levels. Leopard frogs are more tolerant to copper and successfully developed to metamorphosis in up to 150 ppb copper. However, survival is negatively impacted at 50 ppb. Southern toads and eastern narrowmouth toads are more sensitive and no larvae have reached metamorphosis at concentrations above 15 ppb. In all studies we reared eggs from clutches of multiple breeding pairs and source populations, and have found these factors to be significant sources of variation in survival. In leopard frogs we observed significant differences in egg/larval success among breeding pairs, while in southern toads there was a significant effect of source population. To further examine effects of copper on sub-lethal endpoints we are continuing treatments on post-metamorphic southern toads through reproductive maturity to assess effects on time to and size at maturity as well as survival. In addition we are using RNASeq approaches to look at the transcriptional changes that may be related to sub-lethal effects and may contribute to differences in survival and other life history endpoints. Currently we are investigating the effects of copper exposure on the transcriptome of developing southern toads from several individuals from two populations throughout egg, larval, and post-metamorphic development.

WP268 Development of Molecular Indicators to Track the Effects of Nanoparticle Toxicity in *Arabidopsis thaliana* L. Tumburu, National Research Council; C.P. Andersen, USEPA NHEERL/WED; M.G. Johnson, USEPA NHEERL/WED, NHEERL/WED; P.T. Rygiewicz, USEPA NHEERL/WED; G.A. King, Dynamac Corporation; J.N. Betts, M. Plocher, Dynamac Corporation, Environmental Protection Agency. The emergence of nanotechnology and incorporation of nanoparticles in consumer products necessitates risk assessment from an environmental and health safety standpoint. To date, very few studies have examined nanoparticle effects on terrestrial species, especially plants. Preliminary results from an *Arabidopsis thaliana* Columbia (Col-0) study performed with titanium dioxide (TiO_2) nanoparticles (P-25) using five test concentrations indicated reduced cotyledon expansion at 10 ppm and slowed germination at the highest concentration, suggesting that different mechanisms of response may be involved at the two concentrations. To examine the molecular basis for response, a study was conducted to examine how different concentrations of TiO_2 affected different life stages of *A. thaliana*. Dynamic Light Scattering/ Electrophoretic Light Scattering (DLS/ELS) technique was used to characterize TiO_2 suspensions (concentrations 5mg/L and 500 mg/L). Particle suspensions were determined to be in the < 100 nm diameter range. *A. thaliana* plants were exposed starting in the seed stage, to weekly suspensions of these mixtures. Subsequently, with the growth of plants, both root and shoot systems were exposed to the mixtures until they reached senescence. Following exposure, five different tissues (cotyledons, roots, leaves flowers, and siliques) at different developmental stages were harvested. Following the extraction of RNA from the tissues, and subsequent reverse transcription to cDNA, and conversion to cRNA, hybridization was performed with commercially available *Arabidopsis* DNA microarrays (Affymetrix) to obtain the tissue-specific transcriptome profile of *Arabidopsis*. The results varied with developmental stage, and showed that while some differences in gene up- and down-regulation were observed between the two concentrations, some differences may be related to differences in particle dispersion rather than concentration. Fully characterizing particle suspensions using DLS as well as other approaches such as Small-Angle X-Ray Scattering [SAXS], X-Ray Defraction [XRD] was important. The findings of this research will help to elucidate mechanisms of action associated with nanoparticle induced toxicity and provide primary screening information for terrestrial ecological risk assessments.

WP269 Effects of In Ovo Exposure to an Estrogenic Chemical on Development and Reproduction of Western Fence Lizards A. Delecki, Oklahoma State Univ, Natural Resource Ecology and Management; L.G. Talent, Oklahoma State Unversity, Natural Resource Ecology and Management. Many tons of pesticides and herbicides are used in the USA each year and some contain chemicals that mimic hormones, including estrogen. Some of these chemicals can persist for long periods in soil where embryonic lizards may be exposed because many lizards bury their eggs in the substrate for incubation. To evaluate the effects of in ovo exposure to estrogenic chemicals on the subsequent reproduction of adult lizards, we administered varying doses of 17α-ethinylestradiol (0, 0.000001, and 0.001 μg/egg) to western fence lizard (*Sceloporus occidentalis*) eggs by microinjection. Eggs were injected 7 days post oviposition and incubated at 26 ^{O}C. At hatching, neonates were weighed, measured, and phenotypic sex was determined by secondary sex characteristics. *In ovo* exposure of 7-day old embryos to 0.001 μg 17α-ethinylestradiol per egg caused all male embryos to develop into phenotypic females. However, as the hatchlings grew to maturity under laboratory conditions, males developed secondary sex characteristics, indicating that compete sex reversal did not occur. When lizards were six months of age, they were separated into heterosexual pairs and placed in

large aquaria to determine if reproduction was affected by estrogen exposure. Lizards exposed in ovo to 0.001 µg 17α-ethinylestradiol per egg did not produce any fertile eggs, while all other groups produced fertile eggs. The copulatory organs (hemipenes) of males that were exposed in ovo to 0.001 µg 17α-ethinylestradiol per egg were underdeveloped. Therefore, it appears that the reproductive systems of males and possibly females were permanently altered by in ovo exposure to ethinylestradiol.

WP270 Effects of Maternal Dietary Exposure to 17β trenbolone on the Growth and Development of Japanese Quail Embryo Y. Chen, Virginia Tech, Dept of Fisheries and Wildlife Sciences, USGS Patuxent Wildlife Research Center, USGS Patuxent Wildlife Research Center, Patuxent Wildlife Research Center; N. Karouna-Renier, USGS Patuxent Wildlife Research Center, Beltsville Lab ; P.F. Henry, USGS Patuxent Wildlife Research Center, Patuxent Wildlife Research Center; C. Maddox, Patuxent Wildlife Research Center, USGS, Beltsville Lab ; D.T. Sprague, Patuxent Wildlife Research Center, USGS. In ovo exposure to trenbolone, a potent anabolic and androgenic feed additive used in the cattle industry, can affect sexual development and onset of maturation in Japanese quail (*Coturnix japonica*). The current study focuses on the effects of maternal dietary exposure to 17β trenbolone on quail embryonic development. Adult Japanese quail were paired and treated with 5 doses of 17β trenbolone in feed. Upon commencement of egg laying, fertility (E8) and embryonic development and viability (E15) as well as hatching success were monitored to assess productivity. A subset of eggs were similarly artificially incubated however they were removed after 12 (E12) and 14 (E14) days of incubation. The embryos from these eggs were sacrificed, somatic indices (e.g., body/organ weight; tarsus length) were recorded to assess relative growth and development. Expression of sex steroid responsive genes (Vitellogenin II (VTG), Very low-density apolipoprotein II (apoVLDL II), and ZP1) in liver of these embryos was measured by real-time quantitative PCR. Previous studies in our group revealed trenbolone exposure can alter plasma testosterone concentration as well as the expression of VTG and ZP1 in adults. Such changes in the reproductive system in parents, in addition to the in ovo exposure of trenbolone, are expected to affect the normal pattern of sex steroid regulated gene expression in developing embryos. Findings from the current study are discussed in the context of endocrine disruption during embryonic development.

WP271 Fate and Effects of Depleted Uranium in Terrestrial Systems J.G. Coleman, US Army Engineer Reseach and Development Center, US Research and Development Center, Research Biologist; J.K. Stanley, S. Brasfield, US Army Engineer Research and Development Center, Environmental Laboratory; A.J. Bednar, US Army Engineer Reseach and Development Center; D. Meeks, US Army Research and Development Center. Depleted uranium (DU) from the military testing and use of armor-piercing "penetrators" has been shown to accumulate in both soils and sediments; however, little is known about the environmental fate and effects of DU. The purpose of the current study was to assess the environmental fate and effects of various DU geochemical species to a model terrestrial invertebrate, the earthworm, *Eisenia fetida*. To assess the impact of DU on bioaccumulation, growth, reproduction, and cellular stress we conducted a range of acute and chronic exposures. Acute soil studies consisted of a 14 day range finding exposure and soil avoidance bioassay utilizing DU contaminated and spiked soils from multiple Army locations. Additionally, a 72 hour filter paper exposure (n=10) utilizing a DU oxide solution (treatment range: 0-1,000 mg/kg) was conducted to assess dermal uptake. Dermal uptake exposures were coupled with neutral red retention time (NRRT) assays and utilized as a biomarker of cellular stress; measurements were conducted utilizing Sigma Tox4 Toxicity Assay (St. Louis, MO, USA). Chronic, 28 day soil exposures were conducted with field collected DU contaminated sand as well as clean soils from military range, spiked with DU oxide solutions (n=3, 0-3,000 mg/kg). Results to date have indicated no significant reductions in earthworm survivorship at soil concentrations of DU up to 16.7 mg DU/kg; the presence of cocoons also indicates the ability of earthworms to reproduce in low levels of DU contamination. The current work represents part of a larger Army research focus area to determine the environmental impact of DU munitions and residues in complex active range environments and to develop methods for the cost effective and environmentally protective management and/or removal of small metallic DU and DU residues from affected soils and sands.

WP272 Impact of Exposure Level and Condition on the Maternal Transfer of PDE-99 in Zebra Finches M.L. Eng, Simon Fraser Univ; T.D. Williams, Simon Fraser Univ, Biological Sciences; R.J. Letcher, Carleton Univ, Dept of Chemistry, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Science and Technology Branch, Environment Canada, Great Lakes Institute for Environment, Canadian Wildlife Service; J.E. Elliott, Environment Canada, Pacific Wildlife Research Centre, Science and Technology Branch, Environment Canada, Pacific Wildlife Research Centre, Environment Canada, Canadian Wildlife Service. Early life stages in birds are sensitive to environmental conditions, and early exposure to pollutants can have permanent effects on the resulting phenotypes at concentrations much lower than those required to affect adults. Pollutants found in the early embryonic environment (i.e., the egg) are generally accepted to be of maternal origin. Polybrominated diphenyl ethers have become ubiquitous in the environment, and BDE-99 is one of the most common congeners found in wildlife samples, including in bird eggs. The objectives for our study were to identify what effect the level of exposure and the body condition of the mother have on the rate of transfer of BDE-99 from the mother to the egg. To examine maternal transfer of BDE-99, we dosed adult female zebra finches with environmentally relevant levels (0, 25 or 250ng/g bw/day) of BDE-99 for three weeks prior to pairing. 15 females were dosed for each of the three doses. We measured blood levels of BDE-99 in the females on the day they laid their first egg and at clutch completion to estimate the reduction in body burden from egg laying. Blood was also be analyzed for lipid levels. A single egg and a single hatchling were collected per female to estimate transfer from the mother to the egg to the embryo. We collected the third egg, as its timing of formation corresponds with the timing of the first blood sample. We found a significant dose response in the concentrations of BDE-99 in all samples (first egg blood sample 0.7, 25.6, or 241.6 ng/g ww; clutch completeion blood sample 0.6, 23.0, or 114.6 ng/g ww; egg 4.0, 123.3 or 465.9 ng/g ww; first hatched chick 2.0, 112.2, or 399.4 ng/g ww for the 0, 25, and 250ng/g dose groups, resepectively). Maternal plasma BDE-99 concentration significantly decreased from the day the first egg was layed to clutch completion. Maternal lipid status was not significantly correlated with the concentration of BDE-99 found in the eggs.

WP273 Investigating the Toxicity of Ultraviolet Filter Chemicals and Their Photochemical Degradation Products S. Suhag, S. Bercovici, A. Kracunas, M. Paulick, L.A. MacManus-Spencer, Union College, Dept of Chemistry. Sunscreens are established commodities of the American lifestyle as indicated by product sales rising from 18 million dollars in 1972 to 500 million dollars in 2005. Sunscreen's ability to protect skin from the sun's harmful ultraviolet rays is credited to ultraviolet filter chemicals (UVFCs), which are organic chemicals ranging from five to twenty percent concentrations in the product. Currently, the Food and Drug Administration regulates the UVFC content in sunscreens and has "red-flagged" those exhibiting toxicity, such as the skin irritating, potentially carcinogenic para-aminobenzoic acid (PABA). Two commonly used and FDA approved UVFCs are octyl methoxycinnamate (OMC, octinoxate), and octyl dimethyl para-aminobenzoic acid (OD-PABA, padimate-O). These and other UVFCs enter the aquatic environment by direct inputs, such as swimming, and indirect inputs via wastewater treatment plants. Several UVFCs have been detected in surface waters and in the muscle and fatty tissue of fish. The increasing use of products containing these chemicals raises concerns about their negative impacts on the environment. UVFC structures are expected to withstand the absorption of sunlight and thus be photostable. However, previous research has revealed that OMC and OD-PABA are susceptible to direct photolysis, forming several degradation products. For example, the photostable products of OMC photolysis include 4-methyoxybenzaldehyde, 2-ethylhexanol and cyclodimers of OMC. Current research on OD-PABA's degradation using liquid chromatography – mass spectrometry has revealed demethylated products and some evidence of the formation of PABA. The toxicity of the parent compounds has been studied, but the toxicity and environmental impacts of the photolysis products has yet to be thoroughly investigated. PABA and other photolysis products were tested for toxicity to human skin cells using a Trypan blue assay. Understanding the environmental fate and toxicity of UV filter chemicals and their degradation products will lead to more informed decisions about their use and regulation in personal care products.

WP274 Lethal and Sub-lethal Effects of Chronic Copper Exposure on Southern Toads, *Anaxyrus terrestris* R.W. Flynn, D. Scott, Univ of Georgia, Savannah River Ecology Laboratory; K. Jones, Univ of Colorado, School of Medicine; T. Tuberville, S. Lance, Univ of Georgia, Savannah River Ecology Laboratory. Exposure to environmental contaminants is one cause of global amphibian population declines. Contamination is a widespread phenomenon, but most ecotoxicology studies have focused on endpoints based on acute exposures, which underestimate the effects of chronic exposures. For amphibians, aquatic heavy metal contamination is an increasingly common and persistent issue. We have been investigating the effects of chronic aquatic copper contamination on southern toads, *Anaxyrus* (*Bufo*) *terrestris*. We are using a combination of laboratory and outdoor mesocosm studies to examine how such contamination affects local populations. In our lab studies we have found that both copper and the source population of the parents significantly affect survival of eggs and larvae. To further this work in a more natural system, we reared toads in outdoor 1500-L experimental ponds. We set up 24 mesocosms in a replicated factorial design to examine effects of source population (N=2) and copper concentration (N=3) on metamorph traits. We placed 100 eggs (20 from 5 different *A. terrestris* breeding pairs) in each mesocosm; for all metamorphs we are determining time to and size at metamorphosis, and for a small subset we are measuring metal body burdens. Finally, we sampled subsets of toads from four different time periods during the mesocosm studies to examine the effects of copper on gene expression patterns. Because eggs came from toads from different populations (with and without previous copper exposure) we will look at differences in the transcriptomics that may account for some of the population-level differences we see in sensitivity to copper.

WP275 OECD TG223 Avian Oral Dose Test (LD50): Utilizing Passerine Species T.B. Fredricks, Monsanto, Zoology; M. Christ, Bayer CropScience. Laboratory validation of the OECD TG223 avian oral dose test was previously conducted with bobwhite quail (*Colinus virginianus*) however the utility of this study design has not been determined for passerine species. The OECD TG223 test design uses multiple sequential testing stages resulting in fewer birds (e.g., 39 birds) needed to estimate the LD50, confidence intervals, and slope. The OECD TG223 is in contrast to the USEPA guideline study (OPPTS 850.2100) that uses up to 60 birds in a classic single-stage dose-response design. The current study provides information on the usefulness of the OECD TG223 oral dose test to assess the toxicity of two pesticide products on the canary (*Serinus canaria*) and zebra finch (*Taeniopygia guttata*). The birds were dosed with MCPA Acid and Isozaphos, which were previously used for the OECD TG223 validation with bobwhite quail. The compounds are characterized as producing low toxicity values with a steep slope (MCPA Acid) and high toxicity values with a moderate slope (Isazofos). Both species were capsule dosed with each chemical at multiple stages with the aid of a Sequential Design Calculator (SEDEC) to determine the LD50, confidence intervals, and slope. Endpoints determined for each species and each test stage included: sub-lethal effects, mortality, bodyweight, and food consumption. The LD50 values for each chemical were unreliable as regurgitation occurred following the oral dose of each species. This research provides further test development and potential information supporting standardization of regulatory requirements for passerine testing in the United States combined with the conscientious vertebrate testing standards in the European Union.

WP276 Potential for Bioremediation Through Formation and Fate of Metal Rich Granules in the Terrestrial Environment M. Ansley, US Army Engineer Research and Development Center; S. Brasfield, US Army Engineer Research and Development Center, Environmental Laboratory; J.G. Coleman, US Army Engineer Reseach and Development Center, US Research and Development Center, Research Biologist; J. Seiter, US Army Corps of Engineers, Research Physical Scientist; B. Little, The Ohio State Univ, ESGP; R. Jones, US Army Engineer Research and Development Center; R. Lanno, Ohio State Univ, Dept of Evolution, Ecology, and Organismal Biology. With respect to US military instillations, lead (Pb) is the most common metal contaminant found on small-arms Army ranges. Currently, risk assessors assume 100% Pb bioavailability based on soil concentrations, although many terrestrial invertebrates are capable of rendering metals toxicologically inactive through the formation of metal rich granules (MRGs). In earthworms, metals can be sequestered through chloragosome tissue and metallothioneins (specialized proteins); once critical body burdens are reached, additional accumulation and toxic response to metals is diminished. While MRGs are thought to be trophically unavailable to invertebrates and predators, there is little known regarding the fate of MRGs once released from the exposed organism. The current research characterizes the microstructure of MRGs formed by the earthworm, *Eisenia fetida* and determining the potential for microbial degradation to remobilize Pb that has been previously bound in MRGs. If liberated by bacterial degradation, bound Pb may become newly available to invertebrates and their predators. We performed a series of soil exposures utilizing Pb spiked field soils and chronic earthworm exposures. Earthworms were exposed to soils spiked with 4000 mg/kg Pb for a six week period and fractionated utilizing differential centrifugation and digestion to separate whole-animal tissue from MRGs. Once extracted, MRG composition and concentration was analyzed utilizing synchrotron based analysis at Argonne National Laboratories (Argonne, IL). Synchrotron imaging provided multi channel analyzer plots (MCA) which revealed localized MRG hotspots within the samples confirming the presence of not only lead, but also the binding of additional metals such as zinc and iron. Additionally, synchrotron techniques were utilized on cross-sections of earthworms to determine the presence and concentration of Pb across a gradient of dermal and gut tissue. MCA plots of cross sections revealed a wide dispersion of Pb inside the gut wall, suggesting the present of un-bound Pb in addition to MRG formation.

WP277 Repeatable Among Individual Variation in Bioaccumulation of Mercury-dosed Zebra Finches K. Buck, The College of William and Mary, Biology; C. Ramos, D. Cristol, J. Swaddle, The College of William and Mary. Mercury is a ubiquitous ecotoxin with numerous detrimental effects on birds. Although mercury accumulates to different levels in different bird species, little is known about the natural variation of within-species mercury accumulation. Zebra finches (*Taeniopygia guttata*) were maintained in controlled environmental conditions on a standardized diet containing either 0.0, 0.1, 0.4, 0.5, or 1.0 mg/Kg methylmercury. Within treatments, individual zebra finches consistently differed in the amount of mercury accumulated in their blood. Among-individual variation in blood mercury greatly exceeded within-individual variation across all mercury dose treatment groups. Among-individual differences in blood mercury accumulation may reflect an underlying genetic basis for mercury mitigation, potentially allowing evolutionary adaptation to environmental mercury contamination if this variation is heritable (genetically or epigenetically). As part of an ongoing effort, the narrow-sense heritability of mercury accumulation in zebra finches maintained on diets containing 0.5 and 1.0 methylmercury was calculated using parent offspring-regressions and full sibling comparison. More research, however, is necessary to understand gene expression mechanisms underlying mercury tolerance in birds.

WP279 Selecting Experimental Endpoints to Measure Androgenic Endocrine Disruption in Avian Models P.F. Henry, USGS Patuxent Wildlife Research Center, Patuxent Wildlife Research Center; M.R. Bakst, USDA – ARS, Animal Biosciences and Biotechnology Laboratory; V.G. Akuffo, USDA, ANRI ABBL; D. Sprague, Y. Chen, N. Karouna-Renier, USGS – PWRC. Although progress has been made in assessing effects of environmental contaminants that disrupt estrogenic –related processes in wildlife, far less is known about measuring disruption when the chemical is androgenic or anti-estrogenic. Along with the increase in release of emerging chemicals, personal care products, pharmaceuticals, and agricultural feed conversion synthetic hormone mixtures, is the increased detection of anti-estrogenic and androgenic chemicals. A rational basis is needed for the development and selection of appropriate endpoints for testing and assessing androgenic exposure and/or effect. Starting with the avian endocrine system and focusing on receptors, tissues, and organ changes related to native testosterone or its metabolites, we are evaluating the efficacy of potential endpoints. Using findings obtained from a study in which Japanese quail were fed an an anabolic androgen disrupting synthetic steroid, 17β trenbolone, we discuss the use of markers such as onset of foam production, plasma testosterone, sperm activity relative to the developing blatodisc, and the viability of sperm storage tubules – markers that may reflect alterations in fertility of birds caused specifically by androgenic endocrine disrupting chemicals.

WP280 Studies on the Phyto-toxicicity and Accumulation of Heavy Metals Using *Capsicum annum* L. M. Kim, Korea Univ; J. Son, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences; H. Mo, Korea Univ, Division of

Environmental Science and Ecological Engineering; Y. Kim, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences; Y. Lee, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences; K. Cho, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences. Heavy metal contamination of soils may deleterious effect on human and environmental health through a food chain. In this respect, plants have been considered a route that transfers the heavy metals from soil to herbivorous insects. As a preliminary study of the metal accumulation from soil to invertebrate, phyto-toxicity test about each metal using *Capsicum annum* L. was implemented in this experiment. A pot experiment was carried out to evaluate the effects of arsenic, cadmium, lead and zinc on biomass, shoot and root length, chlorophyll, and heavy metal content of *Capsicum annum* L. grown in artificial substrates for three weeks. Artificial substrates consist of potting mix and OECD artificial soil which make up with sand, silt and clay with 75, 20, 5% respectively. Using the measured metal concentrations in soils and plant part of the pepper, bio-concentration factors and translocation factors (from root to shoot) were calculated. In the majority of cases, application of metal increased both total and bio-available forms of metals in the soils and plant growth parameters were decreased. Our results showed that pepper plant could store a high concentration of heavy metals in the root rather than shoot.

WP281 The Effects of Glyphosate and Aminopyralid on Artificial Plant Communities T. Pfleeger, M. Blakeley-Smith, USEPA WED; G. King, Dynamic, Inc; H. Lee, D. Olszyk, USEPA WED; M. Plocher, Dynamic, Inc. The USEPA has responsibility for registration of pesticides under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). The potential adverse effects of pesticides to nontarget terrestrial plant communities are a concern that must be addressed in the pesticide registration process. The protection of nontarget terrestrial plants requires a tiered approach using two single species greenhouse tests with an increasing level of test sophistication being required if a compound fails at the preceding tier. This can culminate in field testing which currently is not well-defined. Our objective was to develop a simple, economical, and geographically flexible field test with ecologically significant endpoints. Three plant species native to Oregon: *Clarkia amoena* (Farewell to spring), *Prunella vulgaris* (Self-heal), *Festuca roemeri* (Roemer's fescue) were grown together along with a fourth introduced species, *Cynosurus echinatus* (Bristly dogtail grass). The experiment was replicated at two research farms within the Willamette Valley, Oregon. Round up Original (41% glyphosate) was applied at 0, 0.01, 0.1, and 0.2 x FAR (Field Application Rate) (32 fluid oz/acre (2.34 l/ha) roundup). Milestone (40.6% aminopyralid) was applied at 0, 0.037, 0.136, and 0.5 x FAR (7 fluid oz/acre (.51 l/ha) milestone). One third of the plots received a single application, 1/3 received two applications and 1/3 received three applications at the above listed rates. The control was a no spray treatment. Herbicide applications were two weeks apart. Plant height and width, in two perpendicular directions, were measured every two weeks during the growing season. Periodically, buds and flowers were counted and seeds were collected. Differences between sites were minor. Increasing the number of applications had less than an additive effect. Plant volume decreased with increasing glyphosate concentration. *Clarkia* died at all concentrations of aminopyralid while *Festuca* and *Prunella* increased in volume. *Cynosauruas* increased in volume at the lowest concentration of aminopyralid while decreasing at the highest concentrations. Flowering was delayed in *Clarkia* when exposed to glyphosate. The results indicate that simple field tests can be successfully performed to investigate the ecological effects of herbicides on nontarget plant interactions. We found that simple physiologically based greenhouse toxicity testing is not a reliable predictor of ecological outcomes in the field.

WP282 The Effects of Perfluoroundecanoic Acid (PFUnA) Injections on Developing Japanese Quail (*Coturnix japonica*) A.N. Iwaniuk, Univ of Lethbridge, Neuroscience; K. Dean, Univ of Lethbridge, Neuroscience, Univ of Maryland, post-doctoral research fellow. Perfluorinated chemicals are virtually ubiquitous in the environment and are found in a wide range of wildlife species. The potentially harmful effects of chronic exposure to low levels of these chemicals is, however, poorly understood. Furthermore, most laboratory studies focus on relatively high doses of perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) and very little is known about the effects of environmentally relevant levels of exposure to other perfluorinated chemicals. Here, we focus specifically on perfluoroundecanoic acid (PFUnA), the second most abundant perfluorinated chemical found in the eggs of wild birds. PFUnA was injected at low, environmentally relevant doses (0.05-3.0 µg/g) into Japanese quail (*Coturnix japonica*) eggs. The eggs were then incubated and necropsies conducted on day of hatching. We observed a significant increase in mortality rate across all of our PFUnA doses relative to both controls and PFOS injected eggs. PFUnA exposed hatchlings had significantly more developmental abnormalities than control eggs, but did not differ in hatchling body weight or other measures of body size. Lung, brain and adrenal weights did not differ between PFUnA treated eggs and controls. In contrast, testis, ovary+shell gland and bursa weights were lower and yolk and gastrointestinal tract weights were higher in PFUnA treated eggs than in controls. Thyroid, heart and liver weights were lower only in some PFUnA treatment groups. In addition, to organ weights, we also conducted thyroxine (T4) assays and examined brain morphology across treatment groups. Overall, we conclude that exposure to environmentally relevant levels of PFUnA affects egg survival and multiple organ systems of hatchlings and could therefore have deleterious effects on wild populations.

WP283 The Influence of Environmental Dynamics on Mercury Concentrations in the Florida Panther (*Puma concolor coryi*) A. Brandon, Florida Gulf Coast Univ; M. Cunningham, D. Onorato, Florida Fish and Wildlife Conservation Commission; D. Jansen, National Park Service; D. Rumbold, Florida Gulf Coast Univ. The Florida panther (*Puma concolor coryi*) is a federally listed endangered sub-species of puma located in the Everglades and Big Cypress ecosystems of southern Florida. Environmental stressors, including environmental contaminants, low genetic variability and habitat loss may have contributed to the decline of this sub-species. Hair and blood were collected for analysis through live capture and liver, brain, muscle and kidney were collected during necropsies of salvaged dead cats. Concurrently, other metrics including body condition, presence of congenital defects, blood chemistry analysis and reproductive success were also assessed as part of a larger investigation on health and fecundity of the population. Evaluated here were the spatial and temporal patterns in hair-Hg and blood-Hg over the period of record (1978-2007) and the potential influence of hydroperiod as an explanatory variable as it relates to methylation potential and habitat quality for prey species. All collected hair (n=478) and blood samples (n=338) had measureable concentrations of mercury, ranging from 0.086 mg/kg to 100 mg/kg and 0.009 mg/kg to 5.3 mg/kg, respectively. These data demonstrated that while average Hg levels have decreased in panthers in most areas, some individuals continued to attain high mercury burdens. As an endangered species suffering from numerous stressors, these maximum exposure concentrations remain a concern. These changes in tissue-Hg concentrations were well correlated with variations in hydroperiod indentified among the study regions. Regions experiencing repeated wetting and drying cycles and long hydroperiods were home to individuals with elevated tissue-Hg concentrations. Hydroperiod appears to be a significant factor in prey species availability for cats as well as an influence on methylation rates in these areas. Habitat management to support large populations of ungulate species as prey items for Florida panthers is an important part of decreasing their reliance on aquatic food web items and lowers their risk of adverse health effects as a result of exposure to Hg.

WP284 Toxic Effect of Insect Growth Regulators (IGRs) on Biological Trait of *Paranura rosea* (Collembola) Y. Lee, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences, Korea Univ, Environmental Science and Ecological Engineering; J. Son, Y. Kim, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences; M. Kim, Korea Univ; K. Cho, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences, Korea Univ, # 407, Division of Environmental. It is known that insect growth regulators (IGRs) have lower toxicity than conventional insecticides against vertebrates. Although IGRs have a selective effect on target organisms, they may exert a more selective effect on non-target organisms. In this study, the toxic effects of three IGRs (teflubenzuron, fenoxycarb, tebufenozide) on biological traits of *P. rosea*, Collembola, were assessed in the OECD artificial soil under two different exposure conditions, one was exposed in the bulk soil and the other was exposed in the compacted soil which unidirectional force was applied to the soil surface. Several biological traits, such as survived adults, egg production, hatched juvenile and molting, were examined after 28 days exposure to three IGRs. The toxicity of all the IGRs on the survival and juvenile production of *P. rosea* in the bulk system

was more toxic than that of the compact system. Among them, the chitin synthesis inhibitor, teflubenzuron, was most toxic chemical and it is toxic for *P. rosea* at concentration that are probably close to environmental levels. Juvenile hormone agonist, fenoxycarb, was more toxic for juveniles and egg relatively than others. Moreover, the hatching rate and molting frequency of *P. roseas* was decreased in a concentration dependent manner. These results suggest that the IGRs exhibit significant impacts on the biological traits of non-target organism *P. rosea* and its toxic effects are differently assessed depending on the exposure conditions.

WP285 Toxic Sulfur Compounds from the Plant *Chorispora tenella*
O.R. Arnold, Colorado State Univ, Center for Environmental Medicine, Colorado State Univ, Environmental and Radiological Sciences; H.S. Ramsdell, Colorado State Univ, Center for Environmental Medicine
Chorispora tenella is an introduced species in North America and has been described in at least 31 states including all of those west of the Mississippi and 3 Canadian provinces. It is known by several common names, including blue mustard, crossflower and purple mustard. It is among the *Brassicaceae* species that have been blamed for causing toxic effects in animals. Toxicity of plants in the mustard family is generally attributed to the products of enzymatic hydrolysis of glucosinolates. Additionally, digestible sulfur can be toxic to ruminants when converted to hydrogen sulfide in the rumen. As little phytochemical information is available for *C. tenella*, we have investigated potentially toxic constituents of the plant. Samples were collected in the spring in the vicinity of Fort Collins, Colorado. Plant material was homogenized in pH 7.5 citrate/phosphate buffer and incubated at room temperature. This autolysis process would be akin to what would happen should a grazing animal eat the plant. The volatile products were collected in an overlying layer of pentane in the sealed flask. The pentane extracts were analyzed by gas chromatography and were found to contain allyl isothiocyanate, propyl isothiocyanate and butyl isothiocyanate. Liver, kidney and thyroid toxicity have been associated with allyl isothiocyanate exposure. The other isothiocyanate products of *C. tenella* autolysis may also contribute to adverse effects if the plant is consumed by animals. The aqueous slurry was divided for dry weight and total sulfur content determination. Total sulfur was measured by a standard AOAC digestion modified to measure the resulting sulfate by a turbidimetric method. The sulfur content of the *C. tenella* samples was found to exceed 0.3% of plant dry weight. This level is sufficient to be of concern for cattle also consuming water with elevated sulfate concentrations, as is commonly found in ground water in eastern Colorado and the northern Great Plains.

WP286 Toxicity of Mosquito Control Insecticides to Florida Native Caterpillars via Ingestion
T.C. Hoang, Florida International Univ, Southeast Environmental Research Center, Dept of Environ Study, Loyola Univ Chicago, Center for Urban Environmental Research and Policy; G. Rand, Florida International Univ, Ecotoxicology & Risk Assessment; R. Frakes, US Fish and Wildlife Service.
Mosquito control insecticides have been applied frequently in the Florida Keys. Non-target organisms such as butterflies are at risk of being exposed to mosquito control insecticides. Toxicological research indicates that larval stages of butterflies (i.e., caterpillars) are sensitive to mosquito control insecticides via topical dermal contact. However, during mosquito control insecticide application, caterpillars can and will be exposed to chemicals via ingestion of contaminated food (host plant). This study characterized the effects of permethrin, dibrom (naled), and the naled metabolite (dichlorvos) to three Florida native caterpillars (4th instar stage *Junonia coenia* (common buckeye), white peacock (*Anartia jatrophae*), atala hairstreak (*Eumaeus atala*)) using an ingestion method. Host plants were dipped in either permethrin, naled or dichlorvos solutions for approximately 1 minute and then air-dried for approximately 1 minute before feeding caterpillars. Survival was determined 24 h post exposure. After 24 hour exposure, contaminated host plants was removed (if left) and surviving caterpillars were fed fresh untreated host plants daily up to pupation occurred (5 days). The studies were conducted for more than two weeks until caterpillars pupated to butterflies. Time needed for caterpillars to pupate to butterflies and pupation hatching efficiency were characterized. Results of this study indicated that dietary exposure of mosquito insecticides produced toxicity to caterpillars. White peacock caterpillars were most sensitive to permethrin. The 24-h LD 50s for white peacock caterpillars were 0.41, 0.62, and 1.80 µg insecticide/g body for permethrin, naled, and dichorvos, respectively. Buckeye caterpillars appeared to be more sensitive to naled than dichlorvos and permethrin. The 24-h LD50s for Buckeye caterpillars were 0.24, 0.33, and 0.76 µg insecticide/g body for permethrin, naled, and dichorvos, respectively. In general, time needed for caterpillars to become butterflies appeared to be longer for permethrin exposure than for control. Based on observation of insecticide residues in the field after application, caterpillars are at risk of being exposed to pemethrin and naled via the dietary route. Results of this study suggest that protection of non-target butterfly species should be taken into consideration when applying mosquito control insecticides in the Florida Keys and in other areas of the US.

RP001 An In Situ Thermal Extraction and Detection System for Rapid, Accurate, Quantitative Analysis of Environmental Pollutants in the Subsurface P. Antle, Tufts Univ; A. Robbat, Tufts Univ, Chemistry. The characterization of environmental pollutants is highly important for not only understanding their fate and behavior, but also predicting the potential long-term impact and taking necessary clean-up measures. With evaporation, dissolution, and sorption partitioning some pollutants and pollutant components and microbial degradation transforming others, distinguishing the role each process plays is important from an assessment and cleanup perspective. Previous research has led to the determination of those mass spectral patterns needed to target PAH, PASH, and their alkylated homologs (important biomarkers for petroleum hydrocarbons) lost to evaporation, dissolution, and degradation. This powerful characterization method loses a level of utility, however, if hampered by traditional sampling and analysis procedures, which are slow, expensive, and inefficient. In contrast, real-time chemical analyses better capture the extent and nature of the contamination because areas that are contaminated are highly sampled whereas areas shown to be clean are less sampled. To this end, we at the Tufts Univ Center for Field Analytic Studies and Technology have developed an in situ sample collection system that provides on-line, real-time detection of environmental pollutants, including fossil fuels and their byproducts, chlorinated solvents, biphenyls (PCBs), and pesticides without bringing sample to the surface. During real-time analysis, the system's heated membrane inlet probe (MIP) is driven into the subsurface, extracting and desorbing organics from groundwater and soil, respectively, and a high temperature transfer line (HTTL) transports said organics to a photoionization detector (PID) for continuous depth profiling. When the PID signal spikes, probe advancement is halted, and flow is diverted to cryotrap for preconcentration, followed by thermal desorption and analysis by a portable gas chromatograph/mass spectrometer (GC/MS). As the system is integrated with VOC and SVOC calibration units, this GC/MS analysis allows for not only detection, but also identification and semi-quantification of all subsurface organics. This is the only technology that can completely, unambiguously profile the subsurface as the probe is advanced from the surface to bedrock.

RP002 Regional and National Ambient Background Investigations for PAHs and Metals S. Emsbo-Mattingly, New Fields Environmental, Forensics Practices, LLC; W. Swanson, CDM. Ambient background generally refers to the presence of anthropogenic contaminants in various environmental media cumulatively generated by point and non-point sources and distributed by global, regional, and local processes. The understanding of ambient background in soils, in particular historic fill soil/brownfields, has received a great deal of attention since 2000. Research consortia including USGS, EPRI, Civic Agencies, and affiliated consultants are producing valuable reference data sets for demonstrating the influence of soil type and land use on contaminant analyte concentrations. This presentation provides 1) an update on regional and national efforts to better quantify ambient background and 2) technical strategies to differentiate ambient background from point sources, such as former MGPs. Studies of urban background in Illinois and Massachusetts provide concentration benchmarks for comparison to surface soils based on land use (i.e., rural, suburban, or urban) and soil type (i.e., fill present or absent). The presence or absence of fill is particularly important in residential, commercial, and industrial areas around MGPs as demonstrated by a comparison of the Illinois (fill absent) and Massachusetts (fill present) datasets. This presentation will also discuss recent efforts on the part of the USGS to conduct a comprehensive national background study that includes a greatly expanded list of metals, PAHs, hydrocarbons, and other constituents. Preliminary results from the New England phases of this project will be presented.

RP003 Distinguishing the Source of a BTEX Groundwater Plume Using Multiple Lines of Evidence C.B. Tuit, Gradient, Associate; E. Butler, Gradient. In 2005, a Benzene, Toluene, Ethylbenzene, and Xylene (BTEX), chlorinated solvent, and Freon groundwater plume was discovered adjacent to a former refinery site. The contamination, including the chlorinated compounds, was initially attributed to the former refinery laboratory; however, further investigation suggested that an aerosol packaging company operating on the site of the former refinery laboratory may have contributed. Spatial analysis of the chlorinated solvent and Freon plumes showed two distinct sources originating from the site of the former refinery laboratory. Hydrocarbon fingerprinting and compound specific isotope analysis of benzene proved that the hydrocarbons associated with the chlorinated solvent and Freon plumes had a different source than the hydrocarbons under the adjacent refinery property. Historical groundwater plume maps were developed that distinguished the refinery and non-refinery contaminant plumes. Temporal analysis of the first detections of the chlorinated compounds, and travel time analysis of the plumes indicated that the chlorinated solvent and associated hydrocarbon plume post-dated refinery operations at the former refinery laboratory site. These multiple lines of evidence were able to identify the aerosol packaging company as the source of both the chlorinated solvents and the BTEX contamination.

RP004 Fingerprint and Weathering Characteristics of Stranded Oils After the *Hebei Spirit* Oil Spill U. Yim, Korea Ocean Research and Development Institute, Oil and POPs Research Group; S. Ha, J. An, S. Ha, S. Hong, M. Kim, J. Jung, W. Shim, Korea Ocean Research and Development Institute. After the *Hebei Spirit* oil spill in December 2007, mixtures of three kinds of Middle East crude oil were stranded along the 375 km coastlines of West Coast of Korea. Stranded oils from 19 stations covering three oiled Provinces were monitored for their identity and weathering status. Weathering model results right after the spill indicated evaporation as dominant process and were in line with sequential changes of chemical composition. In the early stages of weathering, half-life of spilled oil was calculated as 2.6 months. Tiered fingerprint approaches revealed that two samples did not match but the other samples had same fingerprint with spilled sources. Even double ratio using alkylated phenanthrenes and dibenzothiophenes showed the effects of weathering 8 months after the spill. However biomarker compounds provided defensible fingerprint and source allocation information. Weathering status of stranded oil was evaluated using composition profiles of saturated hydrocarbons, polycyclic aromatic hydrocarbons and various weathering indices. Most of samples collected 8 months after the spill were categorized as advanced or extreme weathering stages. Gradual changes of hydrocarbon compositions in the residual oils according to the weathering emphasized the adapted ecotoxicological approaches.

RP006 14C-labeling of Functionalized Multi-walled Carbon Nanotubes (MWCNTs) and Distribution in Fish Tissues Y.D. Soubaneh, Univ of Quebec, Rimouski, ISMER; E. Pelletier, Institut des Sciences de la Mer de Rimouski, Université du Québec À Rimouski, Univ of Quebec, Rimouski, ISMER/UQAR, Univ of Quebec, Rimouski, ISMER; C. Rouleau, Institut Maurice-Lamontagne; I. Desbiens, Univ of Quebec, Rimouski, ISMER. The lack of solubility of carbon nanotubes (CNTs) in all organic solvents and in water severely limited the use of CNTs in monodisperse solutions and emulsions, but chemical techniques to modify CNTs are progressing rapidly toward surface functionalization of nanotubes and extend their applications to engineering n and biomedical applications. Commercial applications of functionalized carbon nanotubes (fCNTs) are expanding rapidly, although the potential risk of this new class of nano-compounds to exposed aquatic organisms is yet little known. Radio-labelling techniques to investigate the distribution and kinetics of toxic metals and organic compounds have been used intensively in biomedical world as well as in environmental organisms. We report in this work a wet chemistry method to functionalize and 14C-label water-dispersible multi-walled carbon nanotubes (MWNTs). An amidation step allows the labeling of these fCNTs by grafting on 14C-labeled ethanolamine. The fCNTs were fully characterized by elemental analysis, electron dispersive X-ray, transmission electron microscopy, thermogravimetric analysis, and Raman and FTIR spectroscopy. An uptake experiment was carried out with Arctic char (Salvelinus alpinus) using water dispersed 14C- fCNTs to assess biodistribution in fish tissues using whole body autoradiography. Radio-labeled fCNTs were mainly observed in the fish head and apparently clogging head canals and gills with possible consequences on fish disability.

RP007 CdSe QD-induced Morphological and Functional Impairments to Liver in Mice W. Liu, Univ of Pennsylvania Medical School, Dept of Microbiology; Q. Chen, S. Zhang, L. Wang, C. Zhang, S. Liu, G. Jiang, State Key Laboratory of Environmental Chemistry and Ecotoxicology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences. Quantum dots (QDs), as unique nanoparticle probes, have been used in in vivo fluorescence imaging such as cancers. Due to the novel characteristics in fluorescence, QDs represent a family of promising substances to be used in experimental and clinical imaging. Thus far, the toxicity and adverse health effects from exposure to QDs are not recognized and are publicly

concerned. To assess the biological effects of QDs, we performed a variety of in vivo and in vitro toxicological assays. Results from the present study demonstrated that QD particles could readily spread into various organs, and liver was the major organ for QD accumulation upon in vivo exposure. QDs caused significant hepatoxicity as reflected by morphological alternation to the hepatic lobules and increased oxidative stress. QDs induced dramatic hepatic toxicity in vivo and in vitro, much greater than that induced by cadmium ions at a similar or even a higher dose. The mechanism underlying QD-mediated biological influences might derive from the toxicity from QD particles themselves and from free cadmium ions liberated from QDs as well.

RP008 Influence of Meteorological Factors on Submicron Particles in the Urban Atmosphere in Hangzhou L. Jian, Y. Zhao, Curtin Univ, Curtin Health Innovation Research Institute ; Y. Zhu, Hangzhou Traffic Administration and Control Centre. With rapid economic development, the size of road vehicle fleet has increased dramatically in China. In order to characterise the impact of meteorological factors on the emission of submicron particles from vehicles in the urban atmosphere, a model study was conducted in Hangzhou, a fast-developing contemporary city located along the Southeast coast of China. An autoregressive integrated moving average model was used to explore the effects of the meteorological factors on the ultrafine particle (UFP) and particulate matter 1.0 ($PM_{1.0}$) concentrations. Results showed that the average UFP concentration was 45,805 (10,428~147,350) particles cm^{-3} and the average concentration of $PM_{1.0}$ was 217 (30 ~506) $\mu g\ m^{-3}$ during the survey period. While relative humidity ($p=0.011$) was positively correlated with the UFP concentration, barometric pressure ($p< 0.001$) and wind velocity ($p=0.003$) were inversely correlated with the UPF concentration. Relative humidity ($p=0.022$) and wind speed ($p=0.023$) were also significant predictors of the $PM_{1.0}$ concentration. Results from this study suggest that meteorological factors should be taken into consideration in interpretation of air monitoring results for submicron particles as unfavourable meteorological factors may play a role in the formation of new air pollutants and change the ability of the atmosphere to scatter/disperse air pollutants. This study provides first hand information on UFP and $PM_{1.0}$ emission levels and a model that can be used in future with large scale time series data to predict the impact of meteorological factors on submicron particle concentrations in the urban atmosphere.

RP009 Tracking Radiolabeled Silver Nanoparticles in Fish Organs and Tissues E. Pelletier, Institut des Sciences de la Mer de Rimouski, Université du Québec À Rimouski, Univ of Quebec, Rimouski, ISMER/UQAR, Univ of Quebec, Rimouski, ISMER; I. Desbiens, Univ of Quebec, Rimouski, ISMER; C. Rouleau, Institut Maurice-Lamontagne; D. Bussolaro, Universidade Federal de Parana, Departemento de Biologia Celular. Manufacturers started to introduce nano-sized silver materials into consumer and medical products in early 2000 and over 250 consumer products are claimed to contain silver nanomaterials. Recent progress in our laboratory includes the synthesis of 110mAg labeled nanocomposites (size = 15-60 nm) highly dispersible in natural waters, and the use of a homogeneous dispersion of these nanoparticles to study the uptake and distribution of silver nanomaterials in tissues of bivalves (scallop and mussel) and fish. Results of the exposure of salmonid, Salvinus alpinus, to radio-labeled silver nanoparticles (AgNp) using whole body autoradiography are reported. Fish exposed to AgNp from water showed a migration of nanoparticles from gills (6 h after exposure) to liver and intestine (5 days later). Autoradiograms taken 11 days after exposure indicated the presence of radio-labeled silver in head lateral canals and blood system. Fish exposed to food contaminated with AgNp showed a migration of AgNp from stomach (24h after force feeding) toward intestine, spleen and liver 8 days after ingestion. Aggregated AgNp were observed in liver tissues by transmission electron microscopy confirming observations done by autoradiography. Results highlight a slow depuration de labeled AgNp taken from water and food with a tissue distribution different from ionic silver taken also from water and food. Results also indicate a probable oxidation of AgNp to ionic Ag and a distribution in blood system with possible incorporation in bones.

RP010 Use of the Plant Bioindicator *L. multiflorum* for Ecological Risk Analysis of Air Emissions R.d. Magali, Federal Institute of Education, Science and Technology of Rio Grande do Sul, Porto Alegre Campus, Environmental; K. Tallini, Federal Institute of Education, Science and Technology of Rio Grande do Sul, Porto Alegre Campus, Biotecnology; M.T. Raya-Rodriguez, Federal Univ of Rio Grande do Sul, Ecology Center. Ecological Risk Analysis (ERA) is a tool used to assess the sustainability of ecosystems, allowing for a more accurate assessment of actual risk to ecological receptors affected by contaminants (Junger, et al., 2005, Sousa, 2005; Nakagome, et al., 2006; Arias, et al., 2007; Niemeyer, 2007, Froehmer & Martins, 2008, Parkhurst, 1996). It is a scientific methodology for quantifying or perceiving the adverse effect risks of a pollutant on the environment (Mines & Lackey, 2009). The study was conducted in the vicinity of an oil refinery (January 2005 to March 2008) in Esteio (29_49´16″ S 51_08´09″ O), Rio Grande do Sul, Brazil. The aim was to develop and implement an ERA model in order to classify the risks associated with air emissions on the basis of using the bioindicator *Lolium multiflorum*. The latter associated the information from the effect of the stressors, derived from the atmospheric emissions of sulfur compounds, in the receptors, that is, in the tissue of the bioindicator. The percentage of accumulated sulfur was evaluated in the bioindicators, classified, in this study, as a response variable. This was integrated with the data of the SO_2 concentration in the atmosphere, which gave rise to the explanatory variables, toxic potential unit (TPU) and toxic exposure unit (TEU). TPU was defined as the quotient between the average concentration of SO_2 that exceeded the primary air quality standard and secondary air quality standard (CONAMA 03/90), indicating environmental concentrations of SO_2 that can affect the growth of the bioindicators through chronic effect. TEU was defined as the product of TPU and the exposure period of the bioindicators to a higher concentration than the primary air quality standard, indicating SO_2 concentrations that can affect bioindicators through acute effect. The classification TPU _ 1 unlikely ecological risk and TPU _ 1 potential adverse effects were considered as evidence of risk. On the basis of the environmental quality data (Crittenden & Read, 1979; CONAMA 03/90; USEPA, 1989, Tarazona, 2000, Klumpp, 2001) the classes of ecological risk were established (low, medium and high). The integration between the explanatory and response variables on the basis of multivariate statistical correlation analysis with the use of SPSS software, version 13.0 for Windows, showed evidence of risk to vegetation surrounding the refinery when exposed to TPU greater than the unit.

RP011 Evaluating the Potential for Endocrine Disruption in Urbanized Aquatic Environments: A Multi-dimensional Assessment H. Schoenfuss, St. Cloud State Univ, Aquatic Toxicology Laboratory, St. Cloud State Univ, Dept of Biological Sciences MS-273; T. Minarik, Metropolitan Water Reclamation District of Greater Chicago; D. Martinovic-Weigelt, Univ of St. Thomas; M.M. Schultz, College of Wooster, Dept of Chemistry. Urban aquatic ecosystems are often overlooked in toxicological studies even though they serve many functions and often sustain fish populations despite large-scale habitat alterations. However, urban fish populations are likely exposed to a broad range of stressors, including endocrine active compounds that have been found to affect anatomy and reproduction of fish in other studies. Over a two-year study period we have collected and assessed quarterly water samples from 45 locations in the Greater Metropolitan Area of Chicago, IL, for total estrogenicity and a selected subset of samples for analytical chemistry. This effort was coupled with wild- and caged fish studies assessing indicators of endocrine disruption such as vitellogenin induction in male fish and histopathological changes in over 3,000 fish. Our findings indicate that treated effluent from municipal wastewater treatment plants contributes a locally predictable amount of estrogenic activity to its receiving waterways. However, total estrogenicity, measured in vitro, and resultant biological effects are often driven by other, highly-variable urban sources of contamination including runoff and combined sewer overflows that require additional study. The comprehensive assessment used in this study is well suited to understand how endocrine active compounds enter the urban environment and may affect resident fish populations. Results from this study are providing the first system-wide assessment of the potential for endocrine active compounds to interfere with sustainable fish populations in an urban environment. Funding by the Metropolitan Water Reclamation District of Greater Chicago.

RP012 Tracing the Exposure and Effects of Urban Pollutants to an Aquatic Songbird in UK Rivers C. Morrissey, Univ of Saskatchewan, Biology; D. Stanton, Cardiff Univ, School of Biosciences; C. Tyler, Univ of Exeter, School of Biosciences; J. Newton, Scottish Universities Environmental Research Centre (SUERC), NERC Life Science Mass Spectrometry Facility; G. Pereira, Centre for Ecology and Hydrology, Lancaster Univ; S. Ormerod, Cardiff Univ, School of Biosciences. Rivers in urban locations

across south Wales in the United Kingdom now show widespread recovery from gross pollution associated with wide-scale industrial development during the 20th century. Substantial improvements in regulation of discharges over the last 2 to 3 decades have permitted recolonization of river organisms that can now persist in these environments but little is known about the stability or viability of their breeding populations. Organisms that recolonize recovering locations are exposed to complex mixtures including endocrine disrupting chemicals frequently found in treated sewage effluent and urban runoff. This project aimed to identify the movement of such compounds through riverine food webs to top avian predators, Dippers (*Cinclus cinclus*), using stable isotope tracers and vitellogenin biomarkers in combination with egg contaminant levels, measures of reproduction, nestling thyroid hormones, and primary sex ratios . We observed significant enrichment in $\delta^{15}N$ but not $\delta^{34}S$ in aquatic invertebrates and dipper eggs associated with increased urbanization. Although reproductive impairment and poorer condition in nestling dippers was detected on urban impacted rivers, prey availability on impacted streams was higher than in reference areas. Nestling broods were male-dominated and plasma thyroid hormones T_4 and T_3 were lower in the more urbanized sites after controlling for age and size of the brood. The study revealed that observed changes in nestling dippers along urban streams impacted by sewage and stormwater runoff do not reflect the indirect effects of altered freshwater invertebrate prey but evidence suggests that direct chemical toxicity is the basis.

RP013 Effects and Occurrence of Organic Microcontaminants in Coastal Stormwater Retention Ponds Impacted by Runoff from a Wastewater-irrigated Golf Course L. Ferguson, Duke Univ, Dept of Civil and Environmental Engineering, Duke Univ, Nicholas School of the Environment , Pratt School of Engineering, Dept of Civil & Envionmental Engineering; T. Sabo-Attwood, Univ of Florida, Dept of Environmental & Global Health; A.S. Kolok, Univ of Nebraska Medical Center, Environmental, Agricultural and Occupational Health; K. Ralston-Hooper, Visiting Dupont Research Scientist at Duke Univ, Nicholas School of the Environment ; G.J. Getzinger, Duke Univ, Nicholas School of the Environment ; G.A. Dominguez, Univ of Florida, Center for Environmental and Human Toxicology; L.J. Macaulay, A.J. Bone, Duke Univ, Nicholas School of the Environment. We have examined the in vivo and in vitro effects and occurrence of wastewater-derived and turf grass management organic contaminants in stormwater retention ponds impacted by sewage-derived irrigation water and located on a coastal golf course community at Kiawah Island, SC. Synthetic xenoestrogens (4-nonylphenol, bisphenol A) were detected in wastewater and retention pond water up to ~350 $ng \cdot L^{-1}$, while biogenic estrogens (17β-estradiol, estrone, and estriol) were present in these samples at lower concentrations (below 10 $ng \cdot L^{-1}$). Turf management chemicals such as fipronil and propiconazole were measured at concentrations > 1,000 ng/L in stormwater retention ponds adjacent to fairway turf. In vivo estrogenic activity of stormwater and wastewater was tested by exposing male fathead minnows (*Pimephales promelus*, FHM) for 14 days to treated wastewater in an effluent holding pond as well as 3 stormwater retention ponds receiving irrigation runoff from land-application of wastewater effluent. The fish were exposed to pond water and wastewater using a novel, field-deployable, flow-through chamber system. Following the exposure, vitellogenin mRNA was quantified by qRT-PCR in livers. Additionally, to determine other biomarkers of exposure to complex mixtures containing xenoestrogens, we performed microarray and proteomic analyses on liver, gonad and brain tissues from the fish. We have also employed an in vitro largemouth bass (*Micropterus salmoides*, LMB) estrogen receptor based reporter gene assay to assess the estrogenicity of the compounds that were isolated from wastewater and stormwater ponds by solid-phase extraction and passive sampling (POCIS). For this assay, HepG2 cells were transfected with LMB estrogen receptor alpha and a luciferase reporter gene driven by 2X classical EREs. Results indicate that the effluent holding pond and one of the stormwater retention ponds induced significant estrogenicity in FHM (by qRT-PCR and microarray response) and in reporter assays. Gene expression responses were diverse among stormwater retention ponds, illustrating the complexity inherent in assessing effects of contaminant mixtures (such as stormwater) on aquatic organisms.

RP014 Health of Fish Inhabiting an Urban Embayment M. Gagnon, Curtin Univ, Dept of Environment and Agriculture, Curtin Univ (Bentley Campus), Dept of Environment and Agriculture, Curtin Univ, Environment and Agriculture; C. Rawson, Curtin Univ, Dept of Environment and Agriculture; H. Nice, Dept of Water, Government of Western Australia. This study presents the results of an investigation on the health of an Australian native fish species, black bream, collected from Claisebrook Cove (Swan River, Perth, Western Australia). The sediments of this urban embayment were shown to contain the highest concentrations of polycyclic aromatic hydrocarbons (PAHs), all OC pesticides (except one) and among the highest concentrations of metals of 20 sites along the Swan River (an urban estuary in Western Australia). Physiological indices, and biomarkers of fish health were measured in black bream collected in Claisebrook Cove, and in a reference site, Burswood Lake. Black bream from Claisebrook Cove had a lower gonadosomatic index relative to those from the reference site. In addition, 15% of the males collected in Claisebrook Cove exhibited intersex, with well developed male and female gonads. Black bream captured in Claisebrook Cove had higher hepatic EROD levels indicating increased exposure to organic contaminants. This was paralleled by elevated biliary PAH metabolites. Fish captured in Claisebrook Cove had higher serum sorbitol dehydrogenase concentrations than those collected in Burswood Lake, but these were within the expected range in healthy individuals of this species. There was no difference in the oxidative DNA damage occurring in fish captured at the two sites. The results indicate that fish captured in Claisebrook Cove were exposed to a source of organic contaminants and were assimilating these contaminants (potentially via the consumption of mussels). Physiological indices indicate that the general health of fish collected in Claisebrook Cove may be compromised below that of fish in Burswood Lake.

RP015 Effect of Urban Effluents on Fathead Minnow (*Pimephales promelas*) Gene Expression: Linkages Between Pollutants and Physiological Processes I.A. Rodriguez, Univ of Florida, Soil and Water Science; K.J. Kroll, Univ of Florida, Physiological Sciences; G.S. Toor, Univ of Florida, Gulf Coast Research & Education Center, Gulf Coast Research & Education Center, Univ of Florida, Soil & Water Science Dept; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology. In spite of all the regulatory efforts to maintain and protect habitats for wildlife, water effluents often trespass borders of wildlife refuges, potentially carrying toxic compounds. Here, we show the gene expression profiles of male fathead minnow liver, exposed to three common effluents that enter wildlife refuges in Gainesville, Florida: Surface water downstream of waste water treatment plant (streamwater), a waste water treatment plant effluent used for landscaping irrigation (wastewater), and a lake (stormwater). These waters were collected in barrels and used as whole effluents in a 48 hour exposure study under laboratory conditions. Microarray analysis was used to assess changes in gene expression for exposed male fathead minnows. After LOESS normalization and ANOVA, there were several statistically significant differences in gene expression ($p \leq 0.05$) compared to controls. In the liver, 172 genes were altered for the streamwater, 349 genes for the stormwater and 327 genes for the wastewater. Enrichment analysis showed six biological processes were affected for streamwater including immune response and liver development, six for stormwater including cell cycle and transport and eight processes for wastewater including carbohydrate metabolic process and phosphate transport. Fish exposed to both streamwater and stormwater showed lipid metabolism process altered. These effluents are complex and contain many chemicals including some that behave as endocrine disruptors, for example bisphenol A and perflourinated chemicals, among others. The microarray results suggest that these chemicals may influence normal physiological responses in exposed aquatic wildlife.

RP016 Storm-water Treatment at Mammoth Cave National Park, Kentucky L. Spear, Tennessee State Univ. Mammoth Cave in Central Kentucky is home to unique biological communities that have adapted to cave habitat. These organisms depend on clean water and could be harmed by contaminants carried into the cave system during storm events. Potential threats to the quality of water include vehicle petroleum leaks, improperly discarded batteries, the shoe-disinfection stations, road salts in the winter, and general parking lot runoff. This project was conducted to determine if leaf-pack filter-systems, in different stages of service, attenuated storm runoff at parking lots in Mammoth Cave National Park. The service timing of the filter systems ranged from less than 1 year, 2 years and 8 years. Grab samples were collected at the inlet and outlet of the filter systems, and analyzed for oil and grease, sediments, turbidity, gasoline compounds, nitrate, ammonia, fecal bacteria, dissolved iron, and chemical oxygen demand (COD). For the

first sampling round, the filters had not been serviced for 8 years and did very little to remove contaminants. The contaminant concentrations at the outlet were similar to those at the inlet, with the exception of removing 20-70 % of the oil and grease. Two-year old filters removed approximately 70% of the nitrate, 90% of the sulfate, 50% of the sediment and iron, but did not reduce zinc. Re-conditioned filters removed up-to 99% of the benzene, toluene, ethyl-benzene and xylene, and, up to 90% of the turbidity, *E. coli*, COD and iron from the storm runoff. Additional work is being done to determine if the filters reduce quaternary ammonia compounds; a more recent addition to the list of potential contaminants due to the installation of white-nose syndrome disinfection stations.

RP017 Characterizing the Contaminant History of an Urban Impaired Watershed Using Lake Sediments T.V. Willis, K.A. Wilson, Univ of Southern Maine, Dept of Environmental Science; L.A. Benedict, Univ of Southern Maine, Chemistry; J. Staples, Univ of Southern Maine, Dept of Environmental Science. The Long Creek watershed is a 9.1 km^2 watershed that drains one of the most densely populated areas in the state of Maine. In the last 50 years, the watershed has undergone dramatic changes in land use and impervious cover. In the 1950s the watershed was primarily forested farmland (impervious cover < 1%) and the stream still had remnants of a historic brook trout fishery. By the 1970s, commercial development included a mall structure, small airport and interstate highway. By 2004, 38% of the watershed was in medium to high intensity development. The most heavily developed area, at the confluence of Long Creek's seven subwatersheds, is 59% impervious cover, and, as a result, Long Creek fails to meet state water quality standards. In 2009, land owners were required to take significant steps in addressing stormwater impacts based on a landmark voluntarily agreement between those landowners, MeDEP and the EPA. In this study we focus on Clarks Pond, a small impoundment located at the base of the watershed that receives runoff from all branches of the creek, and, historically, had waters sufficiently clean to supply an ice export business. We will present preliminary results characterizing metal and aromatic hydrocarbon change over time as reflected in the sediments of Clarks Pond. In winter 2011 we sampled cores from throughout the basin and sectioned the cores into 2 cm segments. Cores extended to marine clays marking the parent material underlying the impoundment sediments. Samples were dried at 50 ºC and ground. Samples are currently being analyzed for metals using combustion gold amalgamation atomic absorption spectrometry (C_GA_AAS) via DMA_80 Direct Mercury Analyzer. Aromatic hydrocarbons will be assessed using a flame ionization detector (FID) after preparation of samples using microwave digestion and solid phase extraction. This study was designed to engage Univ students in meaningful environmental research and will provide a contextual framework for student-driven research and research-based curriculum that will focus on urban contaminants in the Long Creek watershed.

RP018 Growth and Survival of Pacific Coho Salmon Smolts Exposed to Pesticides Within Urban Streams in Western Washington K.A. King, Washington Cooperative Fish and Wildlife Research Unit, Univ of Washington; C. Grue, Washington Cooperative Fish and Wildlife Research Unit, Univ of Washington, School of Aquatic and Fishery Sciences, Univ of Washington, School of Aquatic & Fishery Sciences; J.M. Grassley, Washington Cooperative Fish and Wildlife Research Unit, Univ of Washington; R.J. Fisk, Washington Cooperative Fish and Wildlife Research Unit, Univ of Washington, SAFS; L.L. Conquest, Univ of Washington, School of Aquatic and Fishery Sciences. We studied the growth, survival, and return rates of coho salmon (*Oncorhynchus kisutch*) smolts that had been exposed to a pesticide mixture ("cocktail") representative of that most frequently reported in urban streams in western Washington State, USA, coded-nose wire tagged, and released in spring of 2008 and 2009. Smolts were either continuously exposed from fertilization through swim-up (2007-08) or fertilization through smoltification (2007-08 and 2008-09) to pulses of the cocktail simulating that in urban streams in fall through early spring. Nominal concentrations of eight herbicides (2,4-D, dicamba, dichlobenil, MCPA, MCPP, prometon, simazine, and triclopyr), two insecticides (carbaryl and diazinon), a fungicide (pentachlorophenol), and a breakdown product (4- nitrophenol) were the either the maximum reported during fall-early spring (duration = 48 h), 20% of the maximum (72 h), or a transition between the two (48 h). With the exception of the fungicide and breakdown product, formulated products (single AI) were used, and if possible were selected from those available at retail outlets. Growth (condition factor), survival, gender, brain AChE activity, and gonado- and hepatosomatic indices were not affected by pesticide exposure. However, return rates did differ among treatment groups and years, but overall were low (0.15-0.90%). The number of returning adults exposed to the cocktail to swim-up (0.90%, n=42) was close to twice that of unexposed controls (0.38%, n=26) in 2008, whereas in 2009, adults exposed through smoltification returned in lower numbers (0.15%, n=18) than controls (0.37%, n=30). Reasons for the apparent differences in return rates among treatments are not known, but may include differential harvest, timing of returns relative to that of hatchery operations, and effects on olfaction and immune competency. Additional studies incorporating releases of larger numbers of smolts are necessary to adequately quantify differences in return rates between pesticide-exposed and control smolts.

RP019 Storm-water Treatment at Mammoth Cave National Park, Kentucky A. Barzanji, Tennessee State Univ; R. Toomey, Western Kentucky Univ & Mammoth Cave National Park; A.C. West, Tennessee State Univ, Civil & Environmental Engineering; L. Spear, Tennessee State Univ; T. Byl, US Geological Survey, Dept of Interior, Tennessee State Univ., College of Engineering. Mammoth Cave in Central Kentucky is home to unique biological communities that have adapted to cave habitat. These organisms depend on clean water and could be harmed by contaminants carried into the cave system during storm events. Potential threats to the quality of water include vehicle petroleum leaks, improperly discarded batteries, the shoe-disinfection stations, road salts in the winter, and general parking lot runoff. This project was conducted to determine if leaf-pack filter-systems, in different stages of service, attenuated storm runoff at parking lots in Mammoth Cave National Park. The service timing of the filter systems ranged from less than 1 year, 2 years and 8 years. Grab samples were collected at the inlet and outlet of the filter systems, and analyzed for oil and grease, sediments, turbidity, gasoline compounds, nitrate, ammonia, fecal bacteria, dissolved iron, and chemical oxygen demand (COD). For the first sampling round, the filters had not been serviced for 8 years and did very little to remove contaminants. The contaminant concentrations at the outlet were similar to those at the inlet, with the exception of removing 20-70 % of the oil and grease. Two-year old filters removed approximately 70% of the nitrate, 90% of the sulfate, 50% of the sediment and iron, but did not reduce zinc. Re-conditioned filters removed up-to 99% of the benzene, toluene, ethyl-benzene and xylene, and, up to 90% of the turbidity, *E. coli*, COD and iron from the storm runoff. Additional work is being done to determine if the filters reduce quaternary ammonia compounds; a more recent addition to the list of potential contaminants due to the installation of white-nose syndrome disinfection stations.

RP020 Chloride from Roadsalt: Impacts Microbial Community Structure and the Implications for Regional Nitrogen Budgets N. Horrell, Univ of Connecticut, Center for Environmental Science and Engineering; J. Bushey, J. Chau, Univ of Connecticut, Dept of Environmental Engineering. Current studies indicate that shifts in microbial community structure impact their function however; this has not been extensively studied in freshwater ecosystems. As urban watersheds are impacted by increasing nitrogen and chloride loading, it is important to determine what the consequences will be for water quality and regional nitrogen budgets. Chloride levels have been shown to reach concentrations above 2 g/L during winter months due to road salt in areas with high roadway density. In urban areas nitrogen loading is usually quite high and water quality managers are under increased pressure to reduce nitrogen exports from the urban environment. In healthy streams, only 10-25% of the nitrogen from the terrestrial landscape is exported to the coastal ecosystem which is a testament to the value of the ecosystem service provided by these streams. The microbial community is a key player in the nitrogen cycle and if the health of this community is degraded, water quality will also be degraded. This summer I will be collecting sediment samples to analyze microbial community structure and function. First I will collect sediment samples and incubate them with varying concentrations of chloride. Terminal Restriction Fragment Length Polymorphism (TRFLP) analysis will be conducted prior to and after the incubations to get an approximation of the shift in microbial community structure. After we confirm that there is a shift in microbial community structure in the sediments that are collected, we will perform similar incubations with the addition of nitrogen as nitrate and determine denitrification rates. Additionally water samples will measured at the end of the incubation to verify the amount of nitrate that utilized for denitrification. The end result will be data that shows the shift in microbial community structure as a function of chloride and how

this impacts nitrogen utilization in the sediments. Our hypothesis is that the diversity of microbial population will decrease as we increase the chloride concentration and that this will also decrease the rates at which nitrogen is removed from the water column through denitrification. This will provide water quality managers important insight into how increasing chloride concentrations will impact regional nitrogen budgets.

RP021 Estimating Impacts on Coho Salmon Populations from Land Use-related Spawner Mortality in Urban Streams J. Spromberg, NOAA Fisheries, Northwest Fisheries Science Center, NOAA Fisheries, Environmental Conservation Dep; D. Baldwin, B. Feist, E. Buhle, N. Scholz, NOAA Fisheries. Since the late 1990s, monitoring efforts evaluating the effectiveness of urban stream restoration projects in the greater metropolitan area of Seattle, Washington, have detected high rates of premature mortality among adult coho salmon (*Oncorhynchus kisutch*) in restored spawning habitats. Affected animals display a consistent suite of symptoms (e.g., disorientation, lethargy, loss of equilibrium, gaping, fin splaying) that ultimately progresses to death on a timescale of a few hours. Annual rates of pre-spawn mortality (PSM) observed over multiple years across several drainages have ranged from ~20% to 90% of the total fall run within a given watershed. The current understanding of coho PSM is that it occurs when pollutants accumulate on impervious surfaces during summer and early fall dry periods are then washed into coho-bearing streams by fall storm events. The phenomenon seems to require both specific land uses and precipitation patterns to occur. To evaluate the relationships between PSM, land use and precipitation patterns, we ran a series of spatial analyses to detect correlations between land cover (roadways, impervious surfaces, forests, etc.) patterns, seasonal rainfall patterns and PSM rates in 6 watersheds. The relative proportion of local roads, impervious surfaces, and commercial property in the catchment was most strongly correlated with coho PSM rates. Further, our analyses suggest that as urban expansion continues, areas that once supported coho salmon may experience PSM rates that could jeopardize the coho salmon population viability. So, to evaluate the potential consequences of current and future urbanization on wild coho salmon, we constructed life-history models to estimate the impacts of pre-spawn mortality on coho populations and metapopulations. At the low (20%) and high (90%) ends of the range of observed mortality, model results indicated the mean time to extinction of localized coho populations in 115 and eight years, respectively. The presence of productive source populations (i.e., unaffected by pre-spawn mortality) within a metapopulation reduced local extinction risk. However, as more populations within a metapopulation become affected by spawner die-offs, the source population's productivity declined. These simple models demonstrate the potential for rapid losses from coho populations in urbanizing watersheds.

RP022 Effects of Road Salt on Hydraulic Conductivity in Stormwater Retention Ponds, Owings Mills, MD R. Casey, Towson Univ, Urban Environmental Biogeochemistry Laboratory, Towson Univ, Dept of Chemistry; M. Gallagher, Lawrence Univ, Dept of Geology; K. Linford, J. New, S.M. Lev, Towson Univ, Urban Environmental Biogeochemistry Laboratory. The abundance of impervious cover in urban areas impacts stream geomorphology and in turn local hydrology by directing stormwater runoff into streams. In Maryland, mitigation of these impacts has led to the installation of stormwater retention ponds. In colder climates, these ponds also receive deicing salts which are applied during winter storm events. Sodium chloride (NaCl) is the most commonly used salt for this purpose. It is possible for this salt to impact the structure of pond soils if present in high enough concentrations. Soil structure collapse can occur as sodium replaces other cations bound to the surface of soil clay particles. An automated mini-disk infiltrometer (AMDI) array was used to measure infiltration rate at two sites within seven different ponds in the Red Run watershed, Owings Mills, MD. The hydraulic conductivities (max. = 4) at each location were then averaged to determine a composite hydraulic conductivity for the test site. In order to calculate an accurate hydraulic conductivity the test soil needed to be classified according to the USDA soil classification scheme. Composite soil samples from each site were sieved using 5 mm, 2 mm, 63µm dry sieves and a 5 µm wet sieve. The mass percentage of each fraction smaller than 5 mm was used to determine the USDA soil classification. Each soil sample was also analyzed using ion chromatography to determine the concentration of major cations present. Soils from stormwater retention ponds in the Red Run watershed exhibited a large range in sodium concentrations due to the application of road salt and there was a significant negative relationship between sodium concentration and hydraulic conductivity. The areas within these ponds that are regularly inundated tended to have higher soil sodium concentrations and significantly lower hydraulic conductivities resulting in a retarded infiltration rate. Because infiltration is being retarded, these ponds may not be adequately performing the functions for which they were designed, potentially resulting in increased loading of stormwater and associated contaminants into adjacent surface receiving waters.

RP023 Assessment of Urban Road Dust in Tokyo Using Whole Sediment Toxicity Identification Evaluation Procedures H. Watanabe, National Institute for Environmental Studies, Center for Environmental Risk Research; F. Nakajima, The Univ of Tokyo, Environmental Science Center; N. Tatarazako, National Institute for Environmental Studies, Center for Environmental Risk Research, National Institute for Environmental Studies, Endocrine Disrupter Research Laboratory; I. Kasuga, The Univ of Tokyo, Dept of Urban Engineering; H. Furumai, The Univ of Tokyo, Research Center for Water Environment Technology. Road dust is considered as an important source of sediment contamination; however, there are few studies on the toxicity of road dust on benthic organisms. This study evaluated the toxicity of road dust to the benthic ostracod, *Heterocypris incongruens*, through a 6-day direct exposure test. Moreover, in order to identify the main groups of toxicants in road dust, we applied the whole sediment toxicity identification evaluation (TIE) methods to road dust in Tokyo. Six road dust samples (St.1-6) collected using a vacuum cleaner from street gutter in heavy traffic areas and from highway parking area caused high mortality of the ostracod, whereas the road dust collected in a residential area (St.7) did not show toxicity to the ostracod. Road dust collected using a street sweeper truck from a highway (St.8) also did not show lethal toxicity. Three out of six toxic samples (St.1-3) were subjected to the TIE experiment. The addition of Ambersorb and XAD completely eliminated the toxicity in all the samples. It is suspected that hydrophobic compounds were main toxicants in the road dust samples. In addition, Chelex treatment also resulted in a considerable reduction of the mortality to 3-10% in two samples (St.2, 3). However, the measured concentrations of dissolved Cd, Cu, Ni, Pb and Zn in the overlying water of the toxicity tests did not exceed the LC50 values in literature. To test a hypothesis that the toxicity reduction by XAD and Chelex in St.3 sample was due to the removal of hydrophobic compounds, not heavy metals, a toxicity test was conducted on the fractions eluted with organic solvents from XAD and Chelex which were recovered from the TIE experiment. Methanol-extracted fractions of both the recovered adsorbents, XAD and Chelex, showed 100% mortality of the ostracod, indicating that the hydrophobic organic compounds removed by XAD and Chelex were the principal toxicants in the road dust from St.3.

RP024 Decision-making Framework for Identifying and Communicating Benefits and Risks of Disinfecting Wet-weather Flows P.E. Goodrum, Environmental Resource Management; J. LaGorga, Stearns & Wheeler GHD; S.E. Boehme, ERM, Sediments and Watershed Management. Most wet weather flows contain high levels of bacteria that may pose health risks to recreational users and aquatic organisms in receiving waters. Water quality impacts of combined sewer overflows, sanitary overflows, and stormwater discharges are highly site-specific, temporally variable, and sporadic in occurrence. Chlorine has long been the most common disinfectant for drinking water, wastewater, and wet weather flows. Literature suggests that treatment technologies can decrease concentrations in effluent of some compounds, including pharmaceuticals, but may have little treatment impact on others. In addition, disinfectants added to wet weather flows can result in residuals and react with organic matter in the water to form disinfection byproducts (DBPs). The types and quantity of DBPs is a function of the disinfection type and dose, the length of contact time, and the water quality characteristics inherent to the wet weather flow. Concerns regarding chlorine disinfection are mainly in two areas: (1) safety in handling and use, and (2) potential impacts of residuals and DBPs on human health and the aquatic ecosystem. Viable alternatives to chlorination/dechlorination treatment technologies include chlorine dioxide, ozonation, and ultraviolet (UV) irradiation. A decision-making approach was developed and implemented in a demonstration project in Onondaga County to select the most sustainable wet weather flow disinfection technology that balances benefits and risks, including social and economic impacts. This framework was then considered for application to full-scale facilities to determine the key site-specific factors that have the greatest influence on the selection of an appropriate treatment technology. Results from the pilot study may be used to guide future studies

to evaluate byproducts associated with treatment alternatives applied to a broader class of chemicals, including pharmaceuticals.

RP025 Effects of Salinity Derived from Road Salt and Total Suspended Solids on Yellow Perch Eggs and Larvae from Two Chesapeake Bay Tributaries G. Ziegler, Univ of Maryland, Wye Research & Education Center; A. Pinkney, US Fish and Wildlife Service, Chesapeake Bay Field Office; D. Ownby, Towson Univ, Urban Environmental Biogeochemistry Laboratory; D.J. Fisher, Univ of Maryland, Wye Research & Education Center; R. Casey, Towson Univ, Urban Environmental Biogeochemistry Laboratory, Towson Univ, Dept of Chemistry. Yellow perch (*Perca flavescens*) have historically been a major commercial and recreational fishery in the Chesapeake Bay watershed. A semi-anadromous species, it lives in fresh to brackish waters of many Chesapeake Bay tributaries, and migrates to upstream freshwater habitats to spawn. The primary movements are the upstream spawning migration of adults and the downstream dispersal of juveniles. Although Bay tributaries like the Choptank have healthy populations of yellow perch, with no indication of egg/larval viability problems, Severn River populations are doing poorly with evidence of depressed egg and larval viability. Two of the potential causes are elevated salinity and total suspended solids (TSS). The goal of this study is to analyze the impacts of salinity (ambient estuarine and road salt adjusted well water) and exposure to suspended sediments on the survival of yellow perch eggs and larvae from two rivers, the Severn and the Choptank. Adult yellow perch were collected and spawned in a hatchery and fertilized eggs were transported to the test facility. Year one of this study looked at the effect of salinity, while year two studied the combined effect of salinity and TSS, since little is known about the potential for synergistic effects. Eggs and larvae from the Severn and Choptank Rivers were maintained at three salinities (1.5, 3 and 6‰ derived from diluted estuarine water or road salt in well water), Severn River water, or well water as a control. Eggs were tested till hatch out (approximately 2 weeks) while larvae were tested for 5-7 days. Water samples were analyzed for dissolved metals, cations, and anions. Percent hatch, time to hatch, survival and abnormality data was collected from eggs, while survival and abnormality data was analyzed for larvae. No effects were observed for either Choptank or Severn larvae when exposed to elevated salinities. Although total hatch out of eggs was unaffected, the time to hatch and number of malformations increased in eggs from both rivers in 6‰ road salt; and for Severn River eggs only in 6‰ estuarine water. Interestingly, time to hatch was also increased for both egg types exposed to Severn River water samples at 1‰. Results from year one salinity tests and year two, combined effects of TSS and elevated salinity, will be presented.

RP026 Runoff of Fipronil from Concrete Surfaces Following Simulated and Natural Rainfalls W. Jiang, Univ of California, Riverisde, Dept of Environmental Sciences, Univ of California, Riverisde, graduate student; D. Haver, Univ of California South Coast Research and Extension Center; A. Soeprono, M. Rust, Univ of California, Riverside, Dept of Entomology; J. Gan, Univ of California, Riverside, Dept of Environmental Sciences. Increasing fipronil use for urban pest control has resulted in their occurrence in urban runoff and contamination of urban streams and estuaries. In this study, we investigated the runoff behaviors of fipronil following simulated and natural rainfalls from concrete surfaces, and evaluated influences of precipitation intensities and concrete surface conditions on fipronil runoff transferability. High levels of fipronil were found in the runoff 1 d after pesticide treatment, and the concentrations of fipronil in the runoff water rapidly decreased as the pesticide residence time on concrete increased. Fipronil exhibited long persistence on the concrete and prolonged runoff transferability. After 3 months under summer conditions and four wash-offs, fipronil residues were still detected in the runoff water at 0.18 ± 0.06 ppb. Fipronil residues were detected in the runoff from natural rainfalls even 7 months after the initial pesticide application, implying that fipronil applied early in the year may still be available to contaminate winter storm runoff. Precipitation intensities and modifications to concrete surfaces did not significantly influence fipronil runoff behaviors. A surface wiping method was developed to measure fipronil residues on the concrete and the results showed good correlations between the wiping-extractable residues and fipronil concentrations in the runoff water.

RP027 Occurrence of Fipronil Degradates in the Runoff from Concrete Surfaces W. Jiang, Univ of California, Riverisde, Dept of Environmental Sciences, Univ of California, Riverisde, graduate student; D. Haver, Univ of California South Coast Research and Extension Center; M. Rust, Univ of California, Riverside, Dept of Entomology; K. Goh, California Dept of Pesticide Regulation; J. Gan, Univ of California, Riverside, Dept of Environmental Sciences. Due to the increasing use of fipronil in urban areas for termite and ant controls, fipronil degradates have been widely detected in urban streams throughout the United States. Fipronil metabolites exhibit similar or even higher toxicity to non-target aquatic organisms than fipronil itself, but the causes and pathways for fipronil and its metabolites to contaminate urban surface waters are not well understood. In this study, concrete surfaces were treated with a commercial formulation of fipronil, and the occurrence of three major fipronil degradates, i.e., desulfinyl fipronil, fipronil sulfide, fipronil sulfone, in the runoff water from the treated concrete surfaces were evaluated following simulated and natural rainfalls. High concentrations of fipronil degradates were found in the runoff water 1 d after the treatment, and these degradates were also detected in runoff water after 3-month exposure under outdoor summer conditions. The fipronil degradates were further found in the runoff from the first two natural winter rainfalls after 7 months from the fipronil treatment. Over 80% of fipronil degradates in the runoff water were in the dissolved aqueous phase. The results indicate that use of fipronil around residential homes may serve as an important source for sustained contamination of fipronil metabolites to urban surface streams.

RP028 Assessment Priorities for Emerging Contaminants in the Delaware Estuary R. MacGillivray, Delaware River Basin Commission, Dept of Modeling, Monitoring and Assessment. Emerging contaminants are unregulated substances that have entered the environment through human activities. Current regulatory approaches are inadequate to address these contaminants and the increasing public concern over their environmental and human health implications. Six sites in the tidal Delaware River were sampled in 2007, 2008 and 2009 for emerging contaminants. Water samples collected during these surveys were analyzed for 119 pharmaceuticals and personal care products, 13 perfluorinated compounds, 17 hormones, 3 nonylphenols and bis-phenol A. Concentrations of emerging contaminants in the Delaware Estuary were compared to concentrations found in surface water at other locations and to benchmarks developed for environmental health and safety by other regulatory agencies. Assessment priorities in the estuary are identified including further characterization of persistent and bioaccumulative perfluorinated compounds and a more comprehensive evaluation of potential ecological effects from pharmaceuticals.

RP029 Prioritizing Chemicals Used in PCPs in China for Environmental Risk Assessment: Application of the RAIDAR Model T. Gouin, Unilever, Safety and Environmental Assurance Centre; R. van Egmond, O. Price, Unilever; J. Mortimer, Unilever, Unilever, SEAC. Brazil, Russia, India, and China (BRIC) are expected to be the four biggest economies by 2050. Of these four countries, China is commonly recognized as the biggest potential market for home and personal care products. It is thus important that infrastructure and regulatory instruments are sufficient to reduce environmental impacts related to economic growth and use of such products. Chemicals used in personal care products (PCPs) represent a significant fraction of chemicals used in commerce in China. The environmental fate and effect datasets of many cosmetic ingredients, however, are limited. Recently, there has been emerging concern regarding the use of a number of substances classified under this category, including the nitro- and polycyclic musks, UV blockers such as methylbenzylidene camphor, and preservatives such as the parabens. Given the continuous emission of chemicals used in PCPs to wastewater and the aquatic environment after regular use during showering or bathing, methods for prioritising the environmental risk assessment are needed. In an effort to address this knowledge gap we have identified the chemical ingredients used in 2500 PCPs across China, and estimated the annual emission of these chemicals. The physical-chemical property data for these substances have been estimated and used as model inputs in the Risk IDentification And Ranking (RAIDAR) model. A sensitivity analysis relating to model input parameters and environmental release scenarios is performed as a method for assessing the influence of input parameters with respect to chemical ranking and prioritisation.

RP030 Probabilistic Evaluation of Mammalian Pharmacology Data to Target Human Pharmaceuticals for Environmental Hazard Assessment J. Berninger, Baylor Univ, Institute of Biomedical Studies; B.W. Brooks, Baylor Univ, Environmental Science and Biomedical Studies, Baylor Univ,

Dept of Environmental Science. It is well established that human pharmaceuticals are present in the water, sediment, bio-solids, and biota of aquatic systems. Which drugs are present and what effects they may have on aquatic organisms is less well understood. Because hundreds of drugs enter aquatic systems, the need for prioritization of research efforts is evident. To this end, several different prioritization schemes have been postulated, though each has limitations. For example, our previous research has focused on leveraging mammalian pharmacological potency data to potentially identify chemicals for future study, but there are many other potentially useful pharmacokinetic and pharmacodynamic parameters. The objective of this study is to evaluate an extensive series of mammalian pharmacological parameters for 600 drugs using a probabilistic model, which is similar to approaches used in development of species sensitivity and chemical toxicity distributions. Using this approach we identify the probability of encountering therapeutic parameters in general and within specific classes in particular for margin of safety, Cmax, acute toxicity (LD50), volume of distribution, clearance rate, half life, log P, log D, pKa, and BCF. For example, with Cmax there is a 10% probability of encountering a value below 0.002 µg/mL; while for volume of distribution there is a 10% probability the value will be greater than 10 L/kg. We demonstrate how various centiles of important parameters may be used for ranking compounds for future study. Further, the potential relevance for integration of this approach within various prioritization frameworks is discussed.

RP031 Use of QICARs to Predict the Speciation of Data-poor Metals and Their Toxicity Towards Aquatic Organisms S. Le Faucheur, INRS – Eau, Terre et Environnement; C. Fortin, INRS – Eau, Terre et Environnement, Universite du Quebec; P.G. Campbell, INRS-Eau, Terre et Environnement, INRS-ETE, , INRS, Centre Eau Terre Environnement. To deal with less common metal-containing compounds, governmental agencies will require information about the speciation and inherent toxicity of many "data-poor" elements. In this context, we explored the possible use of quantitative ion character-relationships (QICARs) to estimate the speciation and the relative toxicity of some rarely studied elements in model natural waters. The studied elements were bismuth, the Platinum Group Elements (PGE) and the lanthanides. The prediction of the speciation of the studied elements in natural freshwaters was initiated with a screening of the available geochemical databases, gathering complexation constants between metals and dominant inorganic ligands. Chemical equilibrium models (here VMINTEQ) were then used to calculate the inorganic speciation of the elements in two typical Canadian surface waters in the presence and absence of natural organic matter. Stability constants for Bi and PGE are scarce relative to those for the lanthanides. The simulations showed that the contribution of the free lanthanide ions to the solution speciation should be low in the presence of natural organic matter, suggesting that their bioavailability should also be low under these conditions. Among predictive models for metal toxicity found in the environmental toxicology literature, we selected two promising models to predict the toxicity of our data-poor elements. The first model was published by Wolterbeek and Verburg (Sci. Tot. Environ. 279: 87-115 (2001)). This model successfully relates the electrochemical and ionization potentials, electronegativity, atomic radius and atomic weight of a given metal to its toxicity towards a variety of aquatic organisms. The second model was published by Kinraide (Environ. Toxicol. Chem. 28: 525-33 (2009)) and uses a "consensus scale of softness" and a "consensus scale of toxicity" to predict the toxicity of 92 ions. Both models predict that the elements of the PGE as well as Bi should be more toxic than the elements of the lanthanide group. Moreover, Bi, Ir, Pt and Pd are predicted to have comparable or higher toxicities than the more "common" metals (e.g., Cd, Hg and Pb). Information provided by the present study should be useful for designing new toxicity tests for the little-studied elements and also for determining priorities based on which metals are likely to be the most problematic.

RP032 Occurrence of Pharmaceuticals and Steroids in Sewage Effluent and Surface Waters of the Rio de la Plata Estuary and Pampa's Shallow Lakes, Argentina Y. Elorriaga, D.J. Marino, Centro de Investigaciones del Medio Ambiente – UNLP, CONICET, Dto. Química, Facultad de Ciencias Exactas; P. Carriquiriborde, Conicet, Centro de Investigaciones del Medio Ambiente, Facultad de Ciencias Exactas, Universidad Nacionala de la Plata, Quimica, Centro de Investigaciones del Medio Ambiente – UNLP, CONICET, Facultad de Ciencias Exactas, UNLP; A.E. Ronco, Centro de Investigaciones del Medio Ambiente – UNLP, CONICET, Dto. Química, Facultad de Ciencias Exactas. Over the last years emerging pollutants have gained the attention of the public and scientific community. However, the occurrence of this group of contaminants in some parts of the world is still almost unknown. In the present study, a group of pharmaceuticals together with synthetic and natural steroids were analyzed in sewage effluent and surface water samples collected from urbanized sites on southern coast of the Rio de la Plata Estuary and Pampa's Region shallow lakes. A total of 14 pharmaceutical and four steroids were analyzed. They were selected on the bases of a survey of use. Sampling sites were selected according with the sewage effluent outfall location, collecting the water samples at increasing distances from the discharge. Samples were filtered through 0.45 µm, extracted by SPE, and then analyzed using a HPLC system (Agilent1100) with either a C18 (steroids) or a PFP (pharmaceuticals) column and attached to a MS (G1956A MSD VL) equipped with both ESI (pharmaceuticals) and APCI (steroids) sources. In the effluent samples the following pharmaceuticals were detected: caffeine, paracetamol, atenolol, carbamazepine, ciprofloxacin, ibuprofen, diclofenac, loperamide, clonazepam. The same group of compounds, but at lower concentrations, was detected in the surface waters samples near the discharge. At 1 km downstream the discharge caffeine, carbamazepine, ibuprofen and diclofenac were still detected. Mayor identified steroid in the sewage and surface water samples were estrone, ethynilestradiol, and estradiol, presenting concentrations concentration between 300-100 ng/L in the effluents and 25-4 ng/L in the surface waters collected next to the discharges. The study confirmed previous concentrations of steroids found in sewage and surface waters of the Rio de la Plata Estuary and Pampa's shallow lakes, and reported for the first time the occurrence of pharmaceuticals for this region of Argentina.

RP033 Evaluating the Impact of Dispersed Oil from the MC252 Deepwater Horizon Incident Based on Laboratory Studies of Field-collected Water and Sediment M. BenKinney, Exponent; W. Bryant, US Geological Survey; M. Edwards, Exponent; J. Biedenbach, US Geological Survey; J.S. Brown, Exponent. As part of the sub-sea and sub-surface sampling program to determine the location, fate, transport and threat of oil and dispersant from the MC252 Deepwater Horizon incident, an investigation of the coastal nearshore water and sediment was initiated on behalf of the Unified Area Command (UAC) in the Gulf of Mexico by multiple parties, including the US Environmental Protection Agency (EPA), BP, and the US Geological Survey (USGS). Samples were collected along the coastline using water column fluorometry profiles, water quality measurements, and collection of sediment and water for chemical analyses and toxicity studies to assess the environmental fate of the dispersed Macondo oil. Fluorometry casts were used as an operational field tool in deeper coastal water to measure fluorescence as an indicator of polycylic aromatic hydrocarbons (PAH) in the water column at each station. Water quality measurements of particle size, conductivity, temperature, pH, and dissolved oxygen were measured at depth intervals at each station. Chemical analysis and toxicity testing were performed on water samples collected at depth and on sediment grabs (top 2 cm of the grab sample) collected by hand or using a grab sampler (e.g., Ponar, modified double VanVeen). Samples were analyzed for hydrocarbons (benzene, toluene, ethylbenzene, xylenes [BTEX]; total petroleum hydrocarbons [TPH] and saturated hydrocarbons; PAHs; petroleum biomarkers in sediment (dipropylene glycol n-butyl ether [DPnB], propylene glycol, and dioctylsulfosuccinate [DOSS]), and sediment physicochemical characteristics (total organic carbon [TOC] and grain size). Toxicity tests were conducted in the laboratory with representative fish, marine shrimp, sea urchins, amphipods, worms, molluscs, diatoms, and algae. Limited effects outside the range of acceptable natural variability were seen in all species, with the amphipod showing greater sensitivity than the in-water species.

RP034 *Hebei Spirit* Oil Spill in Korea: Temporal Trends of Petroleum Hydrocarbons in Oyster (*Crassostrea gigas*) S. Ha, U. Yim, M. Kim, G. Han, J. An, S. Hong, Korea Ocean Research and Development Institute, Oil and POPs research group; J. Jung, Korea Ocean Research and Development Institute; W. Shim, Korea Ocean Research and Development Institute, Oil and POPs research group. An oil tanker named *Hebei Spirit*, spilled an estimated 12,547 kL of crude oil of three kinds, at the entrance of Taean coast, Korea on December 7, 2007. Temporal variation in petroleum-derived hydrocarbons in oyster (*Crassostrea gigas*) was investigated at Taean coastal region after the *Hebei Spirit* oil spill (HSOS). Oil contamination in oyster, in the survey area, during December 2007, rose to 10-1000 times over its pre-spill level. The PAHs concentration increased significantly after the

spill and decreased 7-8 months later close to the background level. Among the PAH homologues, alkyl-substituted dibenzothiophenes were highest in the relative proportion, except naphthalenes, and followed by alkylated phenanthrenes. This compositional signature in oyster is consistent with those of spilled oil. PAHs composition profile and chemical fingerprints in oyster revealed that the impact of spilled oil continued until the next spawning season. PAHs concentrations in oyster showed seasonal variations at all stations thereafter. Since oyster does not metabolize petroleum hydrocarbons significantly, the compositional profile in oyster can be effectively used to trace the source of oil pollution in the marine environment.

RP035 Use of Principal Component Ananlysis and Source Apportionment for PCBs in Sediment: An Urban Bay Example E.L. Butler, Gradient; C.B. Tuit, Gradient, Associate; E. Wannamaker, Gradient. Polychlorinated Biphenyls (PCBs) are persistent organic pollutants that become associated with particles upon discharge, and are often a major concern in urban waterways because of their concentrations in sediments relative to their toxicity. PCBs had many uses in commerce and there were frequently many sources of PCBs in urban sedimentary environments. This talk will describe the use of various lines of evidence to identify a distinct source of PCBs to an urban bay. A number of different data sets pertaining to bay sediments were evaluated and combined for analysis. These data provided PCB congener and PCB homolog results, but not Aroclor results. A spatial analysis of the data revealed the likely presence of a distinct source of PCBs. Principal Component Analysis (PCA) was performed on the PCB homolog data to elucidate relationships among the samples and the similarity of their PCB distributions to various Aroclors. The PCA corroborated the spatial analysis and identified the Aroclors that were involved. This step was important because consumers purchased and used Aroclors, not PCB homologs or PCB congeners *per se*. Subsequently, an Alternating Least Squares (ALS) apportionment method was used to estimate the amount of each Aroclor that comprised the PCBs in each sediment sample. Mapping of the results, along with aerial photography showing the location of a large industrial discharge leading into the bay, provided strong evidence of a previously unidentified contributor of PCBs to sediments in the bay.

RP036 Toxicity Tests as Primary Tool for Assessing Sediment Quality W. Ahlf, TU Hamburg-Harburg, Environmental Science and Technology Dept, TU Hamburg-Harburg, Environmental Technology and Energy Economics. Toxicity tests are recommended in concepts for the assessment of contaminated sediments. Due to the heterogeneity of the matrix (sediment) and the genetic variability of test organisms, toxicity tests are often undervalued in relation to their statistical power. In most cases standardized tests are performed with the same requirements for quality control as chemical analyses have. Consequently, toxicity testing can only be done with a limited number of species, tested under controlled laboratory conditions, thus limiting their ecological relevance. Quality Assurance/Quality Control (QA/QC) requirements for the biological tests are highly specific, because a calibration using reference material does not cover all aspects of biological variability. Another crucial point is the quantitative comparison of toxic effects. Sensitivity of toxicity tests is not only species and contaminant-specific; it also varies depending on the endpoint measured. The variation and standard deviation of each bioassay has to be known in order to categorize toxicity reliable. Information on the responsiveness of a test system is hence of high importance for the interpretation. In this lecture we suggest an approach on how to set up a site-independent classification system for sediment toxicity tests, emphasizing the following steps: the assessment of test-specific response spans for each applied biotest and the subsequent interpretation of inhibition values in terms of toxicity, estimation of accuracy and uncertainty of different test systems. A brief overview will be given how control procedures ensure the quality of ecotoxicological tests. Finally a bioavailability concept will be presented to reduce uncertainty for the derivation of sediment quality standards and enhance ecological relevance, as requested for the European regulation.

RP037 The Application of Systems-based Analysis and RNA-Seq Technologies in Ecotoxicology F. Brinkman, Simon Fraser Univ, Dept of Molecular Biology and Biochemistry; L.L. Brown, Univ of Simon Fraser, Molecular Biology and Biochemistry, Environment Canada, Environmental Toxicogenomics. In the last decade, there has been a surge of transcriptomic data generated in the field of ecotoxicogenomics due to the availability and rising popularity of tools such as microarrays, qPCR and most recently, RNA-Seq. Analyses often result in large gene lists of up/down regulated genes that, alone, may not be very insightful. Microarrays, in particular, are fraught with noise that can hide more subtle, but still significant, gene expression changes. Using a systems-based approach, one can examine transcriptomic profiles in a more pathway-based context, or larger molecular interaction network-based framework – essentially treating the organism as the whole system that it is. This approach becomes even more powerful when coupled with RNA-seq, which has better signal-to-noise and higher dynamic range than microarrays. We present analyses of transcriptomic data in this context, data generated by ourselves and re-analyses of others, illustrating both the potential and challenges of this approach.

RP038 The Importance of Normalization on Large and Heterogeneous Microarray Datasets E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Environmental Processes and Effect Division; T. Habib, Badger Technical Services; L. Burgoon, US Environmental Protection Agency, National Center for Environmental Assessment; S. Edwards, US Environmental Protection Agency, National Health and Environmental Effects Research Laboratory; F. Falciani, School of Biosciences, Univ of Birmingham; A. Loguinov, Univ of California at Berkeley; D. Villenueve, USEPA National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; C. Vulpe, Univ of California at Berkeley; R. Taylor, Pacific Northwest National Laboratory, US Deptartment of Energy,; N. Garcia-Reyero, Jackson State Univ. DNA microarray technology is a powerful functional genomics tool increasingly used for investigating global gene expression in environmental studies. Microarrays can also be used in identifying biological networks, as they give insight on the complex gene-to-gene interactions, networks and pathways, thereby enabling the exploration and examination of how chemicals cause toxicity. Gene expression analysis is a multi-step process and there are many sources contribute to systematic variations that can affect the measured gene expression levels. Normalization is one step to minimize the systematic variations in the measured gene expression levels. Appropriate normalization procedures must be implemented so that the expression levels can be effectively compared across biological samples within an experiment and between different experiments. In this study we used the dataset composed of 1,472 single color 15k Agilent arrays from different experiments. All experiments were performed in the same laboratory, on the same tissue (fathead minnow ovary), and with a range of treatments for which we can hypothesize the original assumptions to be correct. Non-linear normalization methods: quantile normalization and a slightly modified cyclic loess normalization, fastlo normalization. We applied two network inference algorithms, based on mutual information, Accurate Cellular Networks (ARACNE) and Context Likelihood of Relatedness (CLR) to infer the network model from combining the datasets. Results indicated that fastlo was found to be best normalization as the correlations between interacting genes were enhanced and models obtained from combined datasets revealed that the networks were associated with specific biological processes or potential relevance for ovary biology.

RP039 The Sampling Protocol and Measurement of Trace Organics: Recent Learnings K.V. Ohman, Associated Engineering Alberta Limited; M. Chen, City of Calgary, UEP – Water Resources; D. Smith, Univ of Alberta, Civil Engineering; S. Smyth, Environment Canada. Over the last fifteen to twenty years in Europe, North America, and elsewhere, there has been growing interest and concern about the potential impact of trace organics on the health of the local and regional environment A number of jurisdictions in North America and Europe have undertaken studies to determine the concentrations, and quantity of these constituents, and the ability of water and wastewater systems to remove these compounds, as well as their impact on human health and the local ecosystem. What is often overlooked and poorly understood, is the sampling and analytical tools used to measure these parameters and the subsequent level of uncertainty that must be applied to the results used by water and wastewater facility design and operations personnel. As with many analytical parameters the location, type, and timing of sample collection is critical to the value derived from the sample analysisThere are concerns related to the type of sample container used which impact sample integrity, degradation, adsorption, volatilization, photo-degradation, as well as other physical actions that may impact each trace organic differently. Sample handling, storage temperature (i.e., freezing) and holding time exceedances can have a significant impact on transformation mechanisms that may occur. The container material and surface to volume

ratio can influence concentration levels in the final result. Furthermore,the analytical methods matrix effect, the holding time, uncertainty level and recovery rate associated with the particular instrument and method, and analyst will have a significant impact on the final result. Furthermore, the level of data validation and proficiency testing (both of which seldom apply to analytical tests undertaken for these compounds) need to be considered when using the published laboratory data. The practitioner needs to factor in these aspects when evaluating the analytical results. Mistaken conclusions can ultimately cost utility owners and operators millions of dollars which in turn can undermine the credibility of their staff and the associated customers or clients. This paper addresses the stewardship of trace organic compounds from the collection source to the production of the analytical results. It also addresses the level of diligence required to ensure a result that in spite of the best of intentions and a high level of technical ability, may still carry with it, a very high degree of uncertainty.

RP040 The Use of a New Class of Sewage Tracers to Characterize the Sources and Fate of Di-ethylhexyl Phthalate in a Large Sewage Affected Coastal Lagoon A.C. Doherty, Stony Brook Univ, School of Marine and Atmospheric Sciences, Stony Brook Univ, graduate student; B.J. Brownawell, Stony Brook Univ, School of Marine and Atmospheric Sciences. There are generally multiple point and non-point sources of chemical contaminants to urban or highly developed estuarine and coastal environments. Recent research indicates that a group of hydrophobic organic cations, quaternary ammonium compounds (QACs), can serve as stable, particle reactive sewage tracers to separate the sources and differential fate of other strongly sorbed contaminants, yet application in environments with a single sewage source have been lacking. Hempstead Bay is located on the southwest shore of Long Island, NY and receives 70 million gallons per day of sewage into a restricted area. A study has been undertaken to distinguish sources of the particle reactive di-ethylhexyl phthalate (DEHP), a known marine contaminant and suspected endocrine disrupting compound, within the Bay. DEHP sediment concentrations varied from an average value of 2.6 µg/g close to the sewage source and decreased steadily with distance away (over 20 km). QAC sediment concentrations were as high as 104 µg/g and were linearly related to DEHP (r^2=0.94) with a zero intercept, suggesting sewage as a dominant source of DEHP in this environment. Results also suggest that particle-bound DEHP is persistent in Hempstead Bay. Additional work will be presented that examines the relationship between QACs, DEHP and trace metals in areas where other sources may be more important. While sewage is known to be a potentially important input of phthalate esters, this is the first work that suggests that it can be the dominant source of DEHP in coastal marine waters.

RP041 Short-term Weathering Profile of Oil Released from the Deepwater Horizon Blowout from Surface and Shallow Subsurface Samples A. Revill, D. Fuentes, S. Armand, A. Ross, X. Qi, E. Crooke, C. Stalvies, A. Talukder, CSIRO. The Deepwater Horizon incident began on April 20th 2010 and oil was released into the Gulf of Mexico until July 15th 2010. Although there is evidence for some entrainment of oil at depth, significant quantities of the oil reached the surface. Different components of crude oils are known to be subjected to evaporation, dissolution, photo-oxidation and biodegradation at different rates. Analysis of specific components provides the potential to assess the degree to which individual samples have undergone each of these processes. Between June 5th and 15th September 2010, 440 surface seawater and slick samples were collected in the Northern Gulf of Mexico. A reference sample of oil recovered from the Macondo well was available for calibration purposes in the field. The samples were subjected to liquid-liquid extraction followed by gas chromatography mass spectroscopy onboard the vessel. This work was in support of the calibration efforts of the CSIRO hydrocarbon sensor survey which collected 8,998 linear nautical miles (~16,664 line kilometers) of flourimeter sensor data, gathering over 4.5 million real time data points. Technical details of the fluorimeter survey are presented in an accompanying poster. The analyses of the seawater samples show the concentration of dissolved hydrocarbon, and oil droplets in the surface waters directly beneath the slick. The surface slicks collected from the spill site towards the Alabama, Florida coastline show, through molecular ratios, varying degrees of weathering. In this paper we will present the detailed geochemical findings from both the seawater and surface slicks and compare them with other published data. Particular emphasis will be placed on the interpretation of the weathering and geographical and temporal distribution of these samples.

RP042 Coagulation/Flocculation Treatment of the Oil Sands Process Affected Water P. Pourrezaei, Univ of Alberta, Civil and Environmental Engineering. Coagulation-flocculation (CF) is one of the most commonly used processes to remove suspended solids and colloidal particles with the ability to decrease natural organic matter (NOM) in water and wastewaters. Due to their small size and surface charge, suspended particles cannot be removed by sedimentation or filtration. Thus, they should be destabilized and aggregated into larger particles to be efficiently removed by subsequent treatments. CF can be applied as a pretreatment for the oil sands process affected water (OSPW) generated from the oil sands operations in northern Alberta, Canada. The main constituents of the OSPW include suspended and dissolved solids, metals and organic acids such as naphthenic acids (NAs). NAs are a group of organic compounds with the general formula of $C_nH_{2n+Z}O_2$, in which n represents the number of carbons and Z is the number of rings in their structure. In this work, CF was used as a pre-treatment for OSPW. The main objectives were to remove the suspended particles and organic compounds. Aluminum sulfate and ferric sulfate were selected as the main coagulants. In addition, cationic polymer was used as the flocculant. Numerous jar test experiments were performed at various conditions to optimize the process to achieve the highest possible total organic carbon (TOC) removal and turbidity reduction. TOC removal and turbidity reduction were in the range of 7-19% and 90-99% for both aluminum and ferric sulfate. Results for the mixing intensities and times showed that 120 rpm for 30 second and 30 rpm for 10 min were the optimum for rapid and slow mixing periods, respectively. Aluminum sulfate at 250 mg/L was chosen as the optimum concentration to achieve the satisfactory TOC and turbidity removal. Addition of the cationic polymer did not enhance the removal efficiency. The obtained results indicated that coagulation/flocculation using alum was effective treatment for complete turbidity removal which might be beneficial for the advanced oxidation processes. Additionally, satisfactory TOC removal was also achieved which could decrease the load of the organic compounds for the subsequent treatment processes.

RP043 Aerosol-mediated Transport and Deposition of Brominated Diphenyl Ethers to Antarctica R.M. Dickhut, Virginia Institute of Marine Science; A. Cincinelli, Università degli Studi di Firenze, Dipartimento di Chimica; M. Cochran, Virginia Institute of Marine Science; H. Kylin, Linköping Univ, Dept of Thematic Studies – Water and Environmental Studies. Brominated diphenyl ethers (BDEs – 47, 99, 100, and 209) were measured in air, snow and sea ice throughout western Antarctica between 2001 and 2007. BDEs in Antarctic air were predominantly associated with aerosols and were low compared to remote regions of the northern hemisphere, except in Marguerite Bay following the fire at Rothera research station in Sept. 2001, indicating that this event was a local source of BDE209 to the Antarctic environment. Aerosol BDE47/100 reflects a mixture of commercial pentaBDE products; however, BDE99/100 is suggestive of photodegradation of BDE99 during long range atmospheric transport (LRAT) in the austral summer. BDEs in snow were lower than predicted based on snow scavenging of aerosols indicating that atmospheric deposition events may be episodic. BDE47, -99, and -100 significantly declined in Antarctic sea ice between 2001 and 2007; however, BDE209 did not decline in Antarctic sea ice over the same time period. Significant losses of BDE99 and -100 from sea ice were recorded over a 19 day period in spring 2001 demonstrating that seasonal ice processes result in the preferential loss of some BDEs. BDE47/100 and BDE99/100 in sea ice samples reflect commercial pentaBDE products, suggesting that photodegradation of BDE99 is minimal during LRAT in the austral winter.

RP044 Seasonal Variations of Pharmaceuticals in a River/Lake System in Eastern Finland A. Meierjohann, Abo Akademi Univ, Laboratory of Organic chemistry; J. Brozinski, Abo Akademi Univ, Laboratory of Organic chemistry, ?bo Akademi Univ, Laboratory of Organic chemistry; L. Kronberg, Abo Akademi Univ, Laboratory of Organic chemistry. The river Rakkolanjoki in eastern Finland receives water from the wastewater treatment plant (WWTP) of the city of Lappeenranta (72000 inhabitants). The river is approximately 3 – 10 m wide and consists essentially entirely of treated wastewater from the WWTP. About 15 km downstream from the WWTP, the river enters a small eutrophic lake. At the opposite side of the lake the water enters a small river that reaches the Russian border within a distance of 6 km. The river/lake system was sampled at 9 points and the concentration of 17 different pharmaceuticals including the four antidepressants, were determined by LC – MS/MS analysis following solid phase

extraction. The measured concentrations were normalized against the concentration of the stable wastewater marker compounds carbamazepine and acesulfame. In most cases, the concentrations of the pharmaceuticals in the river were higher than those reported in previous studies and ranged from around 10 ng/l for the antidepressives citalopram sertraline and venlafaxine to close to two µg/l for the antiepileptic drug carbamazepine. For most compounds the transformation rate during the sampling periods in May and June was faster than in February, even though some compounds such as the beta blockers sotalol and bisoprolol did not follow this trend. Normalization of the results against carbamazepine and acesulfame did not provide the expected data on dilution and transformation rates or mechanisms. This may be due to the long residence time in the river/lake system combined with fluctuation in the input of pharmaceuticals.

RP045 Antimicrobials in Streams/Rivers Subject to Both Agricultural and Urban Influence A.J. Cessna, National Water Research Institute, Environment Canada, Environmental Health National Program, Agriculture and Agri-Food Canada; C. Yost, Univ of Regina. Frequently, irrigation water is derived from rivers impacted by manure and, when enteric pathogens are present in fecal material, human infections can result. Up to 75% or more of veterinary antimicrobials can be excreted in the feces and/or urine so that manure-treated land also becomes a source of these chemicals to surface water via runoff. Their simultaneous detection in irrigation water may not only help to determine sources of fecal contamination in agricultural watersheds, but may also serve as a possible indicator of the presence of enteric pathogens. The study site was situated in southern Saskatchewan, Canada and included a portion of the Qu'Appelle River watershed of which > 95% consists of agricultural fields and pasture. Within the study site, the Qu'Appelle River runs through the towns of Lumsden and Craven. The Qu'Appelle River is influenced by its tributary Wascana Creek which receives effluent from the Regina City municipal wastewater treatment plant. Downstream of the confluence with Wascana Creek, water is drawn from the River for irrigation of vegetable crops. Sites along Wascana Creek and the Qu'Appelle River were sampled from May to August/September of 2008 and 2009 using automated water samplers programmed to collect weekly composite samples consisting of subsamples collected every 3 h. In 2010, weekly grab samples were collected above and below the treatment plant. After solid-phase extraction, sample extracts were analyzed by LC-MS-MS to determine concentrations of erythromycin (ERY), monensin (MON), lincomycin, tylosin, sulfamethazine and chlortetracycline. Only ERY (30 – 317 ng L-1) and MON (4 – 47 ng L-1) were consistently detected in the water samples. In Wascana Creek water, concentrations of ERY, which is used in human and veterinary medicine, were significantly higher downstream of the wastewater treatment plant whereas concentrations of MON, which is used only in veterinary medicine, were relatively unchanged. There was a strong correlation (R2 = 0.81) between ERY concentrations just downstream of the treatment plant and those just upstream of the confluence with the Qu'Appelle River suggesting that concentrations in Wascana Creek were dominated by ERY inputs from the treatment plant. In both years, at sampling sites on the Qu'Appelle River where the water is used for irrigation of vegetable crops, concentrations of ERY and MON were lower, most likely because of dilution of Wascana Creek water with Qu'Appelle River water.

RP046 Chemical Hydrolysis Is a Significant Degradation Pathway for Beta-lactam Antibiotics Compared to Sulfonamide, Amphenicol and Macrolide Antibiotics S.M. Mitchell, Washington State Univ, Civil and Environmental Engineering; J.L. Ullman, Univ of Florida, Agricultural and Biological Engineering; R.J. Watts, Washington State Univ, Civil and Environmental Engineernig. Anthropogenic antibiotic contamination in natural systems presents a human health concern because of the increasing cases of antibiotic-resistance observed over the past few decades. Antibiotics are biologically active at trace levels, and environmental health concerns exist because of the continued biological activity of non-metabolized, excreted compounds released to soil and aquatic ecosystems. About 5-75% of an antibiotic dose is excreted unchanged for the target antibiotics in this study. Therefore, there is a need to elucidate specific antibiotic dissipation mechanisms in natural systems exposed to municipal or agricultural waste effluents. This project focused on hydrolysis reactions, which are fundamental degradation or dissociation reactions caused by water molecules. Two primary factors that affect hydrolysis degradation rates are pH and temperature. In this study, 14 antibiotics (ampicillin, cefalothin, cefoxitin, ceftiofur, chloramphenicol, florfenicol, spiramycin, tylosin, sulfachloropyridazine, sulfadiazine, sulfadimethoxine, sulfamethoxazole, sulfamethazine and trimethoprim) were separately placed in water at different pH (4-9) and temperature (25°C, 50°C). Degradation was monitored, and first-order rate constants and half-lives were calculated for the compounds that hydrolyzed. This research found that trimethoprim and the selected amphenicol, macrolide and sulfonamide antibiotics did not hydrolyze at neutral pH and 50°C. Notable acid- and/or base-catalyzed hydrolysis was observed for the amphenicol and macrolide antibiotics. However, the four β-lactam antibiotics displayed accelerated hydrolysis at all pH units, with the highest degradation rates at basic pH. Cefalothin and cefoxitin hydrolyzed the quickest with half-lives of less than 10 days at neutral pH and 25°C. Ampicillin and ceftiofur half-lives were about 26 and 53 days at neutral pH and 25°C, respectively. In addition, for the β-lactam antibiotics, second-order rate constants for the acid- and base-catalyzed reactions were computed which can be used to estimate hydrolysis rates at any pH between 4 and 9. Arrhenius coefficients were also calculated which can be used to extrapolate theoretical hydrolysis rates at any temperature. In conclusion, this research suggests that because the β-lactam antibiotics hydrolyzed on the order of days to months at ambient temperatures and neutral pH, they might be less persistent in the environment.

RP047 Degradation of Octamethylcyclotetrasiloxane (D4) and Decamethylcyclopentasiloxane (D5) in Aquatic Sediments S. Xu, Dow Corning Corporation, Health and Environmental Sciences; J. Miller, Dow Corning Corporation; R. Gerhards, Evonik Goldschmidt GmbH. As the major ingredients in personal care products, cyclic volatile methylsiloxanes (cVMS) such as D4 and D5 may be released to aquatic environment through waste water treatment discharge and may partition into freshwater sediment. Acurate determination of degradation rates of those compounds in aquatic sediment systems is very challenging due to their high volatility and the difficulty to keep the test material in the aquatic system. In order to overcome the challenge, a new test method was developed for those volatile compounds based on several modifications of the testing guideline (OECD 308 TG by OECD, 2002) to maximize the recovery of the spiked radioactivity of the test material. Using the new methodology, the degradation rates of 14C-D4 and D5 in aquatic sediment systems were determined under both aerobic and anaerobic conditions. The overall average recovery ranged from 88.8% to 105.1% for D4 under various conditions with incubation times ranging from 28 days to 200 days. Generally, D4 undergo hydrolytic degradation in aquatic sediment systems under both aerobic and anaerobic conditions. The degradation rates varied greatly with sediment types, cVMS types and aerobic and anaerobic conditions. Under aerobic conditions, the hydrolysis of D4 was biocatalyzed with half-lives of D4 at 24 oC varied from 47 days in low OC sediment to 242 days for high OC sediment. The sterilization significantly slowed the degradation under this condition. Under anaerobic conditions, the degradation was mostly abiotic with the half-life of D4 in Lake Pepin sediment about one year with no significant difference in measured rates between sterilized and non-sterilized samples. Similar results were found for D5 except that the degradation rates of D5 were slower with an aerobic half-life about 5 years and anaerobic half-life greater than 5 years in Lake Pepin sediment at 24 oC.

RP048 Organic Carbon Parameterization in Fate and Transport Models of Contaminated Sediment Sites U. Kipka, P. Israelsson, P. Oates, J. Connolly, D. Chiavelli, C. Forrest, J. Benaman, Anchor QEA, LLC. The fraction organic carbon (foc) in sediment is generally expected to vary by grain size, with finer particles (e.g., clays, silts, fine sands) typically exhibiting greater organic content. The need to represent this variation in foc among particle sizes within contaminant fate and transport models has grown over the past decade as sediment transport calculations involving multiple size classes have become more common. In constructing a coupled hydrodynamic, sediment transport, and polychlorinated biphenyl (PCB) fate and transport model of the Upper Hudson River (UHR) PCB Superfund Site, we have noted the influence of foc parameterization in several contexts, including the prediction of downstream PCB load following flow-driven sediment resuspension during storm events. In these cases, accurately defining foc values for each size class is important primarily because it controls partitioning behavior within the sediment bed, and thus the concentration distribution among the different size classes of eroding particles. Sediment cores from the extensive UHR 2003 Sediment Sampling and Analysis Program database were analyzed using several approaches to estimate a representative relationship between foc and particle size. Class-specific foc values

were determined for each of the four modeled sediment size classes for incorporation into the UHR PCB fate and transport model. In this work, foc analysis and parameterization approaches will be presented along with illustrations of model response. Although the UHR application has the benefit of a large dataset to constrain site specific foc values, the considerations reviewed in this talk have general relevance to the simulation of chemical fate and transport at contaminated sediment sites.

RP049 Investigating the Environmental Fate, Dose-Response and Toxicokinetics of Triclosan in *Daphnia* spp. K. Albanese, The Ohio State Univ Environmental Science Graduate Program; R. Lanno, The Ohio State Univ Dept of Evolution, Ecology and Organismal Biology; Y. Chin, The Ohio State Univ School of Earth Sciences; C. Hadad, The Ohio State Univ Dept of Chemistry. Pharmaceuticals and personal care products (PPCPs) have recently become an increasing environmental concern as their usage has escalated dramatically and more is discovered about their potential toxic and estrogenic effects. One common PPCP, triclosan (2,4,4'-trichloro-2'-hydroxydiphenyl ether), is an antimicrobial compound that has recently been included in commercial toothpaste, hand soap, and deodorant formulations and has been classified as an "emerging organic pollutant". With a relatively high log K_{ow} (4.8), triclosan may bioaccumulate in organisms. In vitro assays have also shown triclosan to impair mitochondrial function, activate pregnane X receptors, and inhibit estrogen and thyroid hormone sulfotransferases in humans and has demonstrated toxicity to algae. A more detailed understanding of the environmental fate of triclosan is needed since, in addition to concerns associated with toxicity of the parent compound, triclosan has been shown to transform to various forms of dioxin in aquatic systems. Little is known about how this process occurs or the rate and the extent to which it occurs under varying aquatic conditions, i.e., DOC concentration. This study will examine possible reaction intermediates and transition states of triclosan in water by both laboratory experiments and computational chemistry, determining the bioavailability of triclosan to *Daphnia spp*. via bioaccumulation tests and reproduction bioassays, and determining the toxicokinetics of triclosan. The effects of DOC concentration on these processes will also be examined.

RP050 Contaminants in Fish and Sediment of the Charles River Near Boston, USA, 2005 K. Echols, T. May, US Geological Survey, Columbia Environmental Research Center; P. Peterman, US Geological Survey; J. Meadows, K. Feltz, W. Brumbaugh, C. Orazio, US Geological Survey, Columbia Environmental Research Center. The Charles River watershed drains 300 square miles including 24 cities and towns. Common carp, largemouth bass, white suckers, and sediments from the Watertown Dam to New Charles River Dam reach in the Boston area were collected as part of USGS study evaluating effects of contaminants on fish populations. Individual whole fish and sediment samples were extracted, purified and fractionated for polycyclic aromatic hydrocarbon (PAH), polychlorinated biphenyl (PCB), organochlorine pesticide, and polybrominated diphenylether (PBDE) residue analyses by dual column GC-ECD or GC/MS. The fish and sediments were also analyzed for Ni, Cu, Zn, Cd, Pb, Hg, As, Se, and ICP-MS elements scan. Sediment analyses included acid volatile sulfide (AVS) and simultaneously extractable metals. Complex mixtures of organic contaminants were found in the fish at the following concentration ranges (ng/g wet weight): total-PCBs (960-3600), total-PBDE (50-400), total-toxaphene (< 19 -100); dieldrin (6-210) and p,p'-DDE (100-500). PBDE congeners 47, 100, and 28 were predominant in the fish, with PBDE-47 comprising 40-70% of the total-PBDE. Total-PCBs in the three sediment samples were 110, 3400, and 5000 ng/g dry weight; sediment levels of chlordane and DDT related components were higher than the other pesticides. Total-PBDE concentrations in all sediment samples were < 6 ng/g. Sediment had high levels of PAHs, ranging up to 20,000 ng/g dry weight for some individual PAHs. PAH concentration ratios indicated both pyrogenic and petrogenic sources. Tetra-octa congeners of polychlorinated terphenyls (PCT) were also present in the sediments. Sediment concentrations Ni, Cu, Zn, Cd, Pb, Se, and As were unremarkable. Fish fillets had mercury levels ranging from 2.48 to 4.43 µg/g dry weight, exceeding the USEPA consumption advisory for edible fish portions of 1.5 µg/g dry weight (0.3 µg/g wet weight). In summary, the mixture of contaminants in Charles River fish and sediments are indicative of multiple sources: storm water runoff, municipal waste water discharge, urban and agricultural pesticides, and industrial effluents.

RP051 High Resolution Observations of Near-surface Properties in Boston Harbor: Implications for Transport from Land to Ocean B. Gardner, R. Chen, UMASS Boston, EEOS. Multiple observations in Boston Harbor and its tributaries have demonstrated the importance of carefully examining the very near surface layer (top 1 m) within the Harbor, and by extension, other comparable waters. In the early 1990's we conducted "tow-yo" surveys of Boston Inner Harbor using a Seabird 9/11 CTD system. We found a very thin (< 1m) low salinity layer which would be missed by standard sampling techniques. In 2000, Gordon Wallace asked one of us (Bernie Gardner) to survey the Weymouth Fore River to examine nutrient concentrations along a horizontal salinity gradient. The plan was to slowly tow the Seabird CTD at the surface and take samples approximately every 2 PSU salinity value. That turned out to be impossible because the surface salinity was essentially constant (and low) well into the harbor, and then at the edge of the "plume" suddenly increased over a scale of a few meters. More recently, we have found that under common river flows there is essentially a salt wedge in the upper stretch of the Neponset River with the bulk of the upper mixed layer found between 0.5 and 1.0 meters. Colored dissolved organic matter (CDOM) can provide a good tracer of the transport of land-derived dissolved compounds through the Harbor into the coastal ocean. Generally, the largest source of CDOM comes from land drainage associated with decaying plant material, though we have found significant contributions from salt marshes. We will present results of our studies using towed vehicles and moored instruments to provide high temporal and spatial measurements of the near surface environment and demonstrate the importance of a thin surface layer to the flux of dissolved material from the land to the coastal ocean.

RP052 Seasonal Land Use and Land Cover Effects on Nutrient Levels of the Neponset River Watershed N. Henderson, A.D. Christian, Univ Of Massachusetts Boston, Biology Dept; R. Hannigan, Univ Of Massachusetts Boston, Environmental, Earth, and Ocean Sciences. The Neponset River Watershed is a 337 km^2 urban watershed located in Boston, MA and flows into the recently restored Boston Harbor. While Boston Harbor has undergone extreme restoration, the streams flowing into the harbor largely have been ignored. The goal of this research was to compare physical and chemical parameters of at 5 different land cover/use treatments (forested, golf course, industrial, residential, and wetland) in the watershed. Water samples were collected monthly from September 2009 to September 2010 from 33 sites. Each sample was measured for temperature, DO, conductivity, pH, TSS, AFDM, nitrate, ammonium, orthophosphate, TDN, TDP, and particulate C, N, and P. Using MANOVA analysis, we found that conductivity, DO, pH, temperature, and TSS were statistically different among land use treatments. We conclude that both seasons and land uses appear to influence water quality in the Neponset River Watershed and that implementation of best management practices could increase water quality in the watershed.

RP053 Towards Rational Design of Safer Chemicals: Property Guidelines for Reduced Acute Aquatic Toxicity A. Voutchkova, Yale Univ, Center for Green Chemistry and Green Engineering, Yale Univ; J. Zimmerman, Yale Univ, Center for Green Chemistry and Green Engineering; P. Anastas, Yale, Center for Green Chemistry and Green Engineering; B.W. Brooks, Baylor Univ, Environmental Science and Biomedical Studies, Baylor Univ, Dept of Environmental Science. One of the most elusive yet significant goals of green chemistry is for chemists to routinely design commercially useful chemicals with reduced toxicological hazard. The main objective of this study was to derive property guidelines for the design of chemicals with reduced acute aquatic toxicity. The properties explored included chemical solubilities, size, shape and molecular orbital energies. Physicochemical properties were predicted using Schrodinger's QikProp, while frontier orbital energies (HOMO, LUMO and HOMO-LUMO) were determined based on AM1 and DFT calculations using Gaussian03. Experimental toxicity data included acute toxicity thresholds (LC_{50}) for the fathead minnow (*Pimephales promelas*; 570 compounds), the Japanese medaka (*Oryzias latipes*; 285 compounds), a cladoceran (*Daphnia magna*; 363 compounds) and green algae (*Pseudokirchneriella subcapitata*, 300 compounds). Mechanistically-driven qualitative and quantitative analyses between the in-silico predicted molecular properties and in-vivo toxicity data were explored in order to propose property limits associated with higher probabilities acutely safe chemicals. The analysis indicates that 70-80% of the compounds that have low or no acute aquatic toxicity concern to the four species have a defined range of values for octanol-water partition

coefficient ($logP_{o/w}$) and ΔE (LUMO-HOMO energy). Compounds with $logP_{o/w}$ values less than 2 and ΔE greater than 9 eV are significantly more likely to have low acute aquatic toxicity compared to compounds that do not meet these criteria. These results are mechanistically rationalized. Our work proposes design guidelines that can be used to significantly increase the probability that a chemical will have low acute toxicity to the four species studied, and potentially other aquatic species.

RP054 A Novel, Safer Treatment of Liver Cancer Based on Carbon Nanotubes Functionalized with Bovin Serum Albumin L. Mocan, T. Mocan, Univ of Medicine and Pharmacy, Cluj-Napoca, Romania, Nanomedicine Dept; D. Bartos, Univ of Medicine and Pharmacy, Cluj-Napoca, Romania; F. Zaharie, R. Stiufiuc, A. Stir, C. Iancu, Univ of Medicine and Pharmacy, Cluj-Napoca, Romania, Nanomedicine Dept. We previously presented a method of Carbon nanotube-enhanced laser thermal ablation of HepG2 cells (Human hepatocellular liver carcinomacell line), based on a simple multi-walled carbon nanotube (MWCNT) carrier system, such as human serum albumin (HSA), and demonstrate its selective therapeutic efficacy. Transmission electron, contrast phase and confocal microscopy combined immunochemical staining were used to demonstrate the selective internalization of HSA-MWCNTs via Gp60 receptors and the caveolin-mediated endocytosis inside HepG2 cells. We examined the ability of laser activated carbon nanotubes to induce Hsp70 expression using confocal microscopy. Hep G2 cells heat-shocked (laser activated HSA-MWCNTs) to 42°C demonstrated an up-regulation of Hsp70 compared with control cells (HSA-MWCNTs treated cells whithout laser), which showed no detectable constitutive expression of Hsp70. We observed a time-dependent induction in Hsp70 expression in Hep G2 treated with HSA-MWCNTs and LASER iradiated. The post-irradiation apoptotic rate of HepG2 cells treated with HSA-MWCNTs ranged from 88.24% (for 50 mg/L) at 60 seconds, while at 30 minute the rate increased to 92.34% (50 mg/L). These unique results may represent a major step in liver cancer treatment using nanolocalized thermal ablation by laser heating.

RP055 Biodegradable Solvents for the Pharmaceutical Industry: A Study of Toxicity, Ecotoxicity and Stereochemistry of (a) Chiral Ionic Liquids N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences; D. Coleman, Dublin City Univ, School of Chemical Sciences and National Institute for Cellular Biotechnology. The search for more environmentally friendly alternatives to Volatile Organic Compounds (VOCs) has become an important issue in recent years. Ionic Liquids (ILs) have been studied as possible replacements for these solvent types. ILs are highly polar solvents with negligible vapour pressure and low flammability that offer a potentially "green" alternative to VOCs. However in order to confidently label this class of solvents as "green", their behaviour in the environment must be thoroughly examined. As a result various toxicity, ecotoxicity and biodegradation studies have been carried out on ionic liquids. A number of (a)chiral ILs have been designed and synthesized where functional groups to improve biodegradation are incorporated into the cation side chain. Toxicity and biodegradation studies have been carried out on the ILs, to investigate their potential as green solvents. In the toxicity screening, the ILs were tested against several strains of bacteria using a Minimum Inhibitory Concentration (MIC) assay. An activated sludge assay was also employed to investigate the biodegradability of the ionic liquids. HPLC-MS analysis was used to determine the primary biodegradation and subsequently determine the possible metabolites formed during biodegradation. The results obtained from these tests have proved promising and are in accordance with literature.

RP056 Formation and Structure Elucidation of Stable Transformation Products of Pharmaceuticals in the Water Cycle M. Lamoree, Institute for Environmental Studies, VU Univ, Chemistry & Biology, Institute for Environmental Studies, Chemistry & Biology; E. Baginska, T. Haddad, C. Leder, Leuphana Universität; P. Roche, V. Boireau, A. Hebert, Veolia Environnement Recherche et Innovation SNC; B. Roig, S. Mompelat, Ecole des Hautes Etudes en Santé Publique; K. Kuemmerer, Leuphana Universität. Pharmaceutically active substances can undergo transformations starting from human metabolism to degradation in advanced effluent treatment, in environmental processes and finally during drinking water treatment. Often degradation in sewage and water treatment and the environment is incomplete, resulting in the formation of stable transformation products. In only a few cases, full mineralization of the parent compounds is achieved. This is even more important as advanced oxidation techniques employing e.g., ozone, hydrogen peroxide, light or electro-coagulation are subject of discussion for the removal of pharmaceuticals in effluent treatment and drinking water treatment. Treatments using these techniques may even lead to the formation of transformation products that are more toxic than the parent compound. In the past years, comprehensive information on the degree of contamination of our environment with pharmaceuticals has been collected, but there are still some important knowledge gaps regarding the ecological and human health impact of two groups of pharmaceuticals, which will be addressed in the Pharmas project (EU grant agreement no. 265346). On the one hand, for anti-cancer drugs only little information is available on environmental concentrations, while for the antibiotics, concern is raised regarding their occurrence and the potential role of these compounds in spreading resistance against these valuable pharmaceuticals. For a selection of pharmaceuticals of both classes, the formation of stable transformation products in various stages of the water cycle (both drinking and sewage) will be investigated in laboratory and pilot scale studies. Treatment processes include mainly chlorination, ozonation and UV-disinfection for drinking water treatment and advanced oxidation, photolysis/photocatalysis/photo-fenton for sewage treatment. For structure elucidation of the transformation products formed, different LC-MS/MS approaches as well as high resolution MS techniques will be implemented. Characterization of the stable transformation products in terms of (eco)toxicological behavior will be done using a battery of in vitro and in silico bioassays. The knowledge on specific transformation product formation pathways, the molecular identity and (eco)toxicological behavior is expected to ultimately lead to recommendations for the targeted design of pharmaceuticals with improved degradation and elimination properties, whilst maintaining their therapeutic value.

RP057 Highly Recyclable, Low Antimicrobial and Antifungal Toxicty Ionic Liquids: A New Strategy for Brønsted Acid Catalysed Reaction N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences; R. Gore, Dublin City Univ, School of Chemical Sciences and National Institute for Cellular Biotechnology. The research project combines two fields of green chemistry, ionic liquids and catalysis. Our study is directed towards ionic liquids which can also catalyse reactions. This overlap between organocatalysis and ionic liquid research enables us to design low toxicity and potentially biodegradable catalysts based on the extensive biological screening data of ionic liquids. Assessment of the performance of a new catalyst, in tandem with the (eco) toxicity screening, allows the chemist to develop green synthetic methods. We have designed a library of aprotic ionic liquids which can act as Brønsted acid catalysts with low antibacterial and antifungal activity. Preliminary studies of the toxicity of all the ionic liquids were performed to establish the influence of the ester or amide group in the cation. Antifungal and antibacterial toxicity studies demonstrated that the ionic liquids did not inhibit the growth of any organism screened at concentrations of 2.0 mM. Acetalisation and thioacetalisation reactions of a variety of aldehydes have been studied at room temperature and low catalyst loadings. The study demonstrated the activity of these aprotic molecules as active Brønsted acids in the presence of protic media, as well as the importance of the choice of counter-ion in catalytic activity. The most active catalyst has been recycled 15 times without any loss of catalytic activity.

RP058 Selective Hydrogenation of Trans-cinnamaldehyde and Hydrogenolysis-free Hydrogenation of Benzyl Cinnamate in Imidazolium ILs N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences; M. Gurbisz, Dublin City Univ, School of Chemical Sciences and National Institute for Cellular Biotechnology. Applications of ionic liquids as solvents in clean hydrogenation reactions under very mild conditions were studied. Reductions of olefins in the presence of other functional groups with metal catalysts were performed, at various catalyst loadings and study of catalyst recycling. Remarkable results were recorded for selective hydrogenation of trans-cinnamaldehyde to the saturated aldehyde and reduction of benzyl cinnamate without hydrogenolysis of the benzyl ester both at 100% conversion. Asymmetric reduction of methyl α-acetamidocinnamate in the presence of chiral catalysts was also studied.

RP058.5 Designing Molecular Guidelines for Reducing the Acute Toxicity of Pesticides on Birds Using Support Vector Regression B. Husowitz, Center for Green Chemistry and Green Engineering at Yale. There

is a definite need to develop QSAR methods to help with the rational design of chemicals that have reduced toxicological hazard. In this regard, support vector regression SVR methods were used to derive molecular guidelines that will reduce the acute toxicity of pesticides on birds. The chemical descriptors used in the QSAR study were predicted using Schrodinger's QikProp and Epik programs along with various Density Functional Theory (DFT) based descriptors. SVR methods enabled us to identify ranges and bounds for various chemical properties. These bounds and ranges define the necessary chemical properties that a pesticide should posses to be considered nontoxic for a wide range of bird species. These species include, but are not limited to, Mallard Duck, Canada p Goose, Japanese Quail, Domestic Chicken, Ring-Necked Pheasant.

RP059 Ecotoxicological Evaluation for Metal Contaminated Abandoned Mine Soil in Korea J. Son, Y. Kim, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences; Y. Lee, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences, Korea Univ, Environmental Science and Ecological Engineering; M. Kim, Korea Univ; S. Hyun, Korea Univ, Environmental Science & Ecological Engineering; K. Cho, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences, Korea Univ, # 407, Division of Environmental. Mining activities may be one of significant sources of metal contamination of soil as well as sediment. From the regulatory perspectives, ecotoxicological tests coupled with analytical techniques have been gaining popularity as supplementary tools to assess ecotoxicological risk caused by chemicals to human and environmental health. In this study, soil toxicity tests using microbe (microbial enzyme activities) and invertebrate (collembola reproduction) as well as sediment toxicity tests using bacteria (*Vibrio fischeri*) and crustacean (daphnid/ostracod survival) were carried out to assess ecotoxicity of metal contaminated mine soil. The reproduction toxicity test was conducted with collembola, *Paronychiurus kimi* using soil as test medium. The Microtox solid-phase test was performed with *V. fischeri*, and sediment toxicity tests with *Daphnia magna* and *Heterocypris incongruens* were conducted in accordance to the ASTM guideline. From the results of this study, all the toxic responses were closely related to the metal concentration in the mine soil, regardless of test species. These results clearly demonstrate that the use of ecotoxicity test coupled with chemical analysis is promising way to assess ecological risk and should be incorporated in the context of ecological risk assessment process.

RP060 Mass Balance Assessment of Dioxins in Kaolin Ball Clay Used in Ceramic Industry Y. Horii, N. Ohtsuka, K. Minomo, K. Nojiri, Center for Environmental Science in Saitama. Elevated concentrations and unique congener profiles of dioxins in American ball clay were attributed to arise from the natural formation processes. Several studies have been conducted to elucidate the sources and mechanisms of formation of high concentrations of dioxins, particularly polychlorinated dibenzo-*p*-dioxins (PCDDs; >450 ng/g dry wt and 1500 pg WHO-TEQ/g dry wt) in ball clays. An estimated 1.1 million metric tons of American ball clay was mined in 2007, for use in the ceramic industry. Our recent study has reported that inventory of dioxins from kaolin clay production worldwide was estimated to be 650 kg/yr on a mass basis and 2400 g-TEQ/yr on a toxic equivalents. In the production of ceramics, dioxins present in kaolin can be destroyed or volatilized at high temperature (typically exceed 1000 °C in kilns). In this study, we investigated the mass balance assessment of dioxins in ceramic industry based on laboratory experiment. Two gram each of American ball clay was baked at the constant temperatures from 200 °C to 1000 °C for 1h with continuous nitrogen flow (400 mL/min) in a quartz tube installed in a muffle furnace. Flue gas from baked ball clay was collected using a gas sampling unit (water and diethylene glycol absorption bottles, and XAD-2 adsorbent); this connected to the outlet of quartz tube. Concentrations of dioxins were determined both in the flue gas and residue of ball clay using a gas chromatography-high resolution mass spectrometry, and rates of destroyed and volatilized dioxins during kiln were estimated. In preliminary results, on a mass basis, 20% of dioxins reduced in the residue of ball clay whereas negligible level of dioxins was observed in the flue gas after kiln at 200 °C. After kiln at 600 °C, non-detectable dioxin was found in the residue of ball clay, and 5% of dioxins was observed in the flue gas, indicating that most of dioxins in ball clay was destroyed at high temperature. We are currently investigating the volatilization rate of dioxins from baked ball clay at the temperature gradually increase from 100 °C to 1000 °C, which is more reliable to the actual conditions of firing clay in ceramic industry, and estimating the emission of dioxins from ceramic industry.

RP061 Assessment of Natural Background Levels and Composition of Dioxins in Mississippi River Sediment A. Pawlisz, Conestoga-Rovers&Associates. There is mounting evidence documenting the natural formation and deposition of polychlorinated dibenzo-*p*-dioxins (PCDDs) dating back to middle Eocene (40 to 45 million years ago) in the Mississippi River (River) watershed. The initial discovery of elevated levels of non-anthropogenic dioxins in soils along the River came as part of a nationwide survey of food conducted by the United States Food and Drug Administration (FDA). The agency detected high levels of dioxins in chickens fed soybean meal containing fine-grained hydrated aluminum silicate (ball clay). The clay was used as an anticaking additive, which was determined to originate from a quarry in Crenshaw, MS. A second dioxin-affected clay was discovered by the US Dept of Agriculture (USDA) and the US Environmental Protection Agency (USEPA) in Sledge, MS. Both mines were found in an area associated with a geologic formation called Mississippi Embayment (ME), which spans over 45,000 square miles along the River. Subsequent investigations by the USEPA demonstrated conclusively that the ball clay from these mines was the source of dioxins found in animal stock and feed. This determination was based on the strong correlation between the clay and feed/animal tissue concentrations, isomer ratios, and dioxin patterns. The presentation discusses the results of key dioxin studies and provides a synopsis of recent evidence documenting the natural formation and deposition of PCDDs in the vicinity of the River. The significance of the findings is discussed in context of fingerprinting methods and characteristics of natural vs. anthropogenic dioxins as applicable to assessing background levels of dioxins in the River sediments.

RP062 Dioxin-like Toxicity in Sediments and Floodplain Soils from the Saginaw River Watershed: Polychlorinated-dibenzo-*p*-dioxins, Dibenzofurans, Biphenyls S. Yun, Wadsworth Center, Student, New York State Dept of Health; K. Kannan, Wadsworth Center, New York State Dept of Health; J.M. McCabe, A. Ostaszewski, A.B. Taylor, D.M. Taylor, Waste and Hazardous Materials Division, Michigan Dept of Environmental Quality. Concentrations of PCBs including non-ortho coplanar congeners, PCDDs, and PCDFs were measured in more than 120 sediment and floodplain soil samples collected from the Shiawassee River (a tributary of the Saginaw River), the Saginaw River, and Saginaw Bay, to determine the sources and magnitude of contamination, and to elucidate the contributions from individual contaminant groups to the overall 2,3,7,8-tetrachlorodibezo-p-dioxin equivalents (TEQs). Sediment and soil extracts were also analyzed for total dioxin-like activity by means of the H4IIE-luc cell bioassay. Elevated concentrations of PCBs (>1000 ng/g, dry weight) were found in the Shiawassee River near Chase Lake, from Middleground Island in the Saginaw River, and from subsurface sediments in Saginaw Bay. Concentrations of PCDD/Fs from the Saginaw River and Saginaw Bay were 2-3 orders of magnitude higher than concentrations in the samples from the Shiawassee River. The highest PCDD/F concentration (55200 pg/g, dry weight in a subsurface layer) was found in sediment collected at the mouth of the Saginaw River. Concentrations of PCDFs were greater than the concentrations of PCDDs in sediment from the Saginaw River. 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, and 2,3,4,7,8-PeCDF were the major PCDF congeners found in sediments from the Saginaw River. The elevated concentrations of PCDFs, and the predominance of the less highly chlorinated PCDF congeners, in sediments from the Saginaw River were similar to previously determined characteristics of the PCDF contamination of the Tittabawassee River. These results suggest the existence of a major source of PCDFs within the watershed. A few localized areas of high PCDD/F and PCB concentrations, with unique congener compositions, in the Saginaw River indicated the presence of other minor sources, such as wastewater treatment plants. PCDFs were the major contributors to TEQs from the Saginaw River and Saginaw Bay. Approximately 30% of the samples analyzed in this study had values exceeding the screening level of 50 pg TEQ/g, dry wt, suggested for soils by the Agency for Toxic Substances and Disease Registry.

RP063 Sources and Distribution of Polychlorinated-dibenzo-*p*-dioxins and Dibenzofurans in Soil and Sediment from the Yellow Sea Region of China and Korea J.E. Naile, Univ of Saskatchewan, Dept of Veterinary Biomedical Sciences and Toxicology Centre; J. Khim, Korea Univ, Division of Environmental Science and Ecological Engineering, ; T. Wang, Chinese

Academy of Science, Research Center for Eco-environmental Sciences; Y. Wan, Peking Univ; S. Hong, Korea Univ, Division of Environmental Science and Ecological Engineering, ; P. Jones, Univ of Saskatchewan, School of Environment and Sustainability, ; Y. Lu, Chinese Academy of Science, Research Center for Eco-environmental Sciences; J. Giesy, Univ of Saskatchewan, Dept of Veterinary Biomedical Sciences and Toxicology. Polychlorinated-dibenzo-*p*-dioxins and -dibenzofurans (PCDD/Fs) were measured in soils and sediments from the Yellow Sea region. Korean soils and sediments mostly contained detectable PCDD/Fs and showed a widespread distribution among locations. Soil and sedimentary PCDD/Fs from China were comparable to or less than those in Korea. The patterns of relative concentrations of individual congeners in soils were different between the two countries, but similar in sediments. Sources of PCDD/Fs in China and Korea were found to be independent of each other and their distributions reflected matrix-dependent accumulation. Spatial distribution indicated some point sources in Korea while Chinese sources were more widespread and diffuse. PCDD/Fs measured in the coastal areas of the Yellow Sea were comparable to or less than those previously reported in for eastern Asia. When compared to Canadian guidelines, which are one of the more stringent guidelines, 51% of Korean soils (n = 49) and 79% of Chinese soils (n = 48) did not exceed corresponding guidelines, but all Japanese soils (n = 20) exceeded the guidelines.

RP064 Analysis of Perfluorochemicals and Pharmaceuticals in Fish Using ACQUITY Liquid Chromatography-Xevo G2 QToF Mass Spectrometry T.M. Holsen, B. Crimmins, X. Xia, Clarkson Univ. The Great Lakes Fish Monitoring Program (GLFMP), administered by the USEPA Great Lakes National Program Office (GLNPO), aims to monitor temporal trends of emerging contaminants in the Great Lakes using top predator fish as biomonitors. Recent work has focused on quantifying the concentrations of perfluoroalkyl compounds (PFCs) and pharmaceuticals in lake trout due to their environmental persistence, toxicity and potential chronic effects on the aquatic environment. In this study, an ultra-high pressure liquid chromatography-mass spectrometry (UPLC-MS) method was developed. PFCs and pharmaceuticals in fish tissue were quantified using a Waters Xevo G2 QToF UPLC-MS. Reversed-phase separation of target compounds was achieved using an ACQUITY UPLC®HSS T3 column for both classes of compounds using aqueous 0.1% (V/V) formic acid and methanol mobile phases. The mass spec was configured to continuously monitor precursor and product ions to selectively quantify compounds of interest and identify potential interferences respectively, utilizing Waters MSe technology allowing providing precursor/product identification for the entire chromatogram. Sample preparation procedures and analysis methods will be discussed with results of different target compound classes.

RP065 Mass Spectrometric Identification of Naturally Produced Brominated Compounds in Fish and Fish Oil A. Covaci, Univ of Antwerp, Toxicological Centre; A.C. DIRTU, Toxicological Centre, Univ of Antwerp, Dept of Pharmaceutical Sciences. While fish products of marine origin are essential for the human diet, their consumption may result in increased exposure to anthropogenic organohalogen contaminants (OHCs), e.g., polybrominated diphenyl ethers (PBDEs). Recently, the presence of naturally-produced organobrominated compounds (NOCs), such as methoxylated PBDEs (MeO-PBDEs) has been reported in the marine environment. Here we present the identification of different classes of NOCs in fish oils dietary supplements and in fish of commercial value (e.g., bluefin tuna). Tetrabrominated MeO-PBDEs (2'-MeO-BDE 68 and 6-MeO-BDE 47) were identified based on their retention times and confirmed by EI-MS spectra and comparison with authentic standards. The molecular ion cluster showed an abundant ion at *m/z* 516, followed by an ion cluster centered at *m/z* 420, corresponding to $[M\text{-}Br\text{-}CH_3]+$, specific for an *ortho* substitution of the MeO group. These two compounds were detected in 90 % of FODS and in 100% of fish samples and their concentrations were, in most cases, higher than those of PBDEs. Levels of other tri- to pentabrominated MeO-PBDEs were minor. In many samples, the retention times of two peaks eluting after the tetrabrominated MeO-PBDEs did not match the retention times of available MeO-PBDE standards. For the 1st peak, the molecular ion at *m/z* 468 $[M]^-$ in the ECNI-MS spectra had a low abundance, while the weak fragment at *m/z* 387 $[M\text{-}Br]^-$ contained 2 Br atoms. In the EI-MS spectra, the isotope pattern for the fragment at *m/z* 464 $[M]^+$ corresponded to three Br atoms. In contrast, the 2nd peak showed an abundant molecular ion in ECNI-MS at *m/z* 542 $[M]^-$, while fragment ions were found at *m/z* 466 $[M\text{-}Br]^-$. Likewise, its molecular ion (*m/z* 546 $[M]^+$) containing 4 Br atoms was detected in EI-MS mode, while other important fragment ions were detected at *m/z* 385 $[M\text{-}Br]^+$ (3 Br atoms) and *m/z* 264 $[M\text{-}HBr_2]^+$ (2 Br atoms). Both compounds presented the base ion at *m/z* 121 $[C_9H_{13}]^+$ originating from a non-brominated fragment. By comparing retention times and mass spectra (ECNI and EI) with reference standards (courtesy of W. Vetter, Germany), the peaks were identified as tri- and tetrabrominated hexahydroxanthenes (PBHDs). PBHDs had a high detection frequency in fish oil (>50%) and fish samples (>95%). Both classes of NOCs have been measured in concentrations higher than OHCs usually targeted in monitoring schemes, but more has to be learned about their occurrence and their potential toxicological effects.

RP066 Screening for High Molecular Weight Phthalates in Sediments Using Atmospheric Pressure Chemical Ionization GC/MS S. Lai, K. Rosnack, Waters Corporation; D. Stevens, Waters Corp., GC/MS Marketing Manager; P. Hancock, Waters Corp.; F. David, P. Sandra, Research Institute for Chromatography. Measuring phthalates in environmental samples is an important application due to their potential endocrine-disrupting properties. Most classical methods for this application are based on gas chromatography mass spectrometry (GC/MS). Attention has recently turned to the analysis of di-isononylphthalate (DiNP) and di-isodecylphthalate (DiDP) but their analysis by traditional GC/MS results in an unresolved cluster of peaks that all fragment to the phthalic anhydride ion at m/z = 149. The difficulty in chromatographically resolving the separate isomeric forms along with the poor selectivity of the abundant fragment at 149Da makes detection and quantitation of individual forms challenging. Consequently, quantification of DiNP and DiDP is impossible at the same sensitivity levels possible for the single isomer phthalates when using conventional GC/MS with electron ionization (EI). Atmospheric pressure ionization has primarily been used to interface MS with LC but it can now also be applied to GC/MS. Atmospheric pressure gas chromatography (APGC) is a novel atmospheric pressure ion source for MS instruments that allows well established chemical ionization (CI) types including protonation, charge exchange and electron capture to be applied to gas phase analytes eluting from a GC column. Due to the source region being at atmospheric pressure during operation and its capability of handling very high gas flow it is possible to employ a wider range of CI reagents including some, such as water, not practical for routine use with vacuum source CI instruments. Furthermore, GC separations can be optimized as the carrier gas flow and column dimensions are not limited by the pumping capacity as is the case for ionization sources that run under a vacuum. In this work, APGC coupled to a quadrupole time-of-flight mass spectrometer was used to analyze high-molecular-weight phthalates. DiNP and DiDP were successfully ionized in protonation mode yielding spectra that contained the molecular ion as the base peak. The method was also applied to measure DiNP and DiDP in a sediment extract at relevant levels for environment samples.

RP067 Temporal Trends in Human Exposure to Fluorosurfactants and Their Metabolites L.W. Yeung, S. Robinson, Univ of Toronto, Dept of Chemistry; S.A. Mabury, Univ of Toronto. Fluorinated chemicals have been used in various industrial and daily applications for over 5 decades. Their unique oil-repellence and high surface activity make them excellent surface-protectors and surfactants. Perfluorooctanesulfonte (PFOS) and perfluorooctanoate (PFOA) are two well-known fluorinated chemicals which, due to their persistency and bioaccumulation potential, have been banned in several countries. Another group of fluorinated chemicals having a phosphate head group, polyfluoroalkyl phosphoric acid diester surfactants (diPAPs), has received growing attention. Unlike PFOS and PFOA, diPAPs are direct consumer products, used in food contact paper, while PFOS and PFOA were mainly used in industry. Through consumption of diPAP contaminated food, humans may have direct exposure to these chemicals. Recent studies found diPAPs in North American human blood serum at low part-per-billion (ppb) levels. Such low concentrations make quantification difficult for archived samples of limited size. In the present study, human blood serum samples from the German Environmental Specimen Bank (1981-2009) were analyzed for this new class of fluorinated chemicals using an Agilent 1100 HPLC and AB Sciex API 4000 MS-MS in ESI(negative mode). Preliminary results indicated diPAPs at low ppb levels, and many of them were not quantifiable (lowest point of the calibration curve: 0.5 ng/mL). A new Acquity UPLC and Waters Xevo-TQ S MS-MS system has been used for further analysis. Preliminary results suggest the limit of

quantification is 0.05ng/mL with an injection of 6 uL of sample on-column. Results for 300 samples from the German Environmental Specimen Bank will be presented, and challenges towards diPAP analysis will be discussed.

RP068 Untargeted Sreening of San Francisco Bay Harbor Seals for New Organohalogen Pollutants J.R. Kucklick, National Institute of Standards and Technology (NIST), Analytical Chemistry Division, National Institute of Standards & Technology, Hollings Marine Laboratory; S. Klosterhaus, San Francisco Estuary Institute; N. Dodder, Southern California Coastal Water Research Project; E. Hoh, San Diego State Univ, Graduate School of Public Health; J. Murray, National Institute of Standards and Technology, Analytical Chemistry Division; D.J. Greig, The Marine Mammal Center; K. Maruya, Southern California Coastal Water Research Project. Contaminant measurements are generally made based on target compound lists and calibration standard availability. Many compounds produced by society are not routinely monitored even though several of these compounds have physical properties similar to well known bioaccumulative pollutants. The goal of this study was to use a relatively new analytical tool, two dimensional gas chromatography with time of flight mass spectrometry (GCxGC TOF/MS), to screen harbor seal (*Phoca vitulina*) samples from San Francisco Bay, California for new contaminants. The GCxGC technique allows for separation of several thousand individual compounds in a single run while the TOF/MS portion allows for full electron impact ionization spectra to be acquired. Samples (blubber, liver and blood) were collected from six dead stranded or euthanized harbor seals from locations around San Francisco Bay. In addition, liver and blubber samples were obtained from an archived harbor seal collected from Alaska to serve as a "non-urban" control. Blubber samples were extracted, processed through size exclusion chromatography, and then fractionated by silica gel/alumina chromatography. Serum samples were extracted to yield a neutral and a phenolic fraction. Samples were analyzed by GCxGC TOF/MS. To date, blubber samples have been analyzed. Legacy pollutants tended to dominate with several unusual compounds tentatively identified as DDT-related, current use pesticides, chlorinated polycyclic aromatic hydrocarbons and other halogenated compounds. Results from this work will help to inform water managers in the San Francisco Bay region about the scope of contamination in the bay as reflected in higher organisms.

RP069 Review of Tissue Effect Concentrations for Mercury in Benthic Invertebrates M. McMeechan, J. Conder, ENVIRON International Corporation. The tissue residue approach seeks to use the concentration of a contaminant in tissue as a dose metric for evaluating toxicity and can be used in ecological risk assessment to evaluate whether contaminated sediment has the potential to cause harm to benthic invertebrates. Although concentrations of mercury in benthic invertebrate tissue associated with toxic effects from such sources as the United States Army Corps of Engineers (USACOE) Environmental Residue Effects Database (ERED), reported values should be evaluated carefully to ensure relevance and applicability in environmental decision making. Publicly available information on tissue effect concentrations for total mercury (inorganic plus methylmercury) in both freshwater and saltwater benthic invertebrates were reviewed to establish a compilation of values useful as benchmarks of population-level effects in benthic invertebrates exposed to sediment containing mercury. Multiple lethal and sublethal (growth, development, behavior, and physiology) effects were considered. Tissue effect concentrations were selected with a preference for controlled, single-contaminant exposure studies with a dose-response relationship with a range well defined between No Observed Effect Doses (NOEDs) and Lowest Observed Effect Doses (LOEDs). Of the nineteen total mercury effects tissue effect concentration values reported, nine total mercury effects tissue effect concentration values ranging from 0.19 mg/kg, ww to 40 mg/kg, ww were found to be most relevant for characterizing mercury effects on a tissue concentration basis. The most common issues leading to exclusion of tissue effect concentrations from this compilation include: presence of multiple stressors during exposure, lack of a definitive demonstration of ecologically-relevant effects, and averaging values for multiple species. A study-by-study evaluation will be presented. Although tissue effect concentration data can be tabulated in a matter of seconds (e.g., via ERED), this review reinforces the need to carefully evaluate available tissue effect data for relevance in regards to the desired decision-making application.

RP070 Assessing the Effects of Dietary Selenium on Survival and Reproduction of *Ceriodaphnia dubia* M. Jatar, Univ of Ottawa; C. Rickwood, Natural Resources Canada, CANMET MMSL, Univ of Saskatchewan, Dept of Toxicology; M. Pawlak, CANMET MMSL. Water Quality guidelines for selenium are not adequate in predicting toxicity to aquatic organisms, as the primary route of exposure is dietary. Revision of guidelines to encompass a fish tissue-based criteria are currently under way in both the US and Canada. While the primary focus of research examining dietary-Se exposures has been conducted with fish, very little information exists on dietary-Se exposures on invertebrates. In response to this knowledge gap, our objective was to elucidate the effects of dietary-Se on aquatic invertebrates. Specifically, the effects of water and food-borne selenium exposure on survival and reproduction of *Ceriodaphnia dubia* were compared. The recommended Environment Canada protocol (EPS 1/RM/21) was modified to incorporate selenium contaminated algae as an alternative food source. Exposures were conducted with both selenate and selenite over a 7-day period; survival and reproductive endpoints were measured. Exposure concentrations ranged from 1.25 to 40 µg selenium/g algae. Results allow us to address the significance of dietary-Se on invertebrates and assess the protectiveness of current water quality guidelines. In addition, the modification of a standard sub-lethal toxicity test provided a simple method to assess dietary-exposure of contaminants to a commonly used invertebrate species.

RP071 Assessing the Effects of Dietary Selenium on Survival and Reproduction of *Ceriodaphnia dubia* M. Jatar, First Institute of Oeanography, State Oceanic Administration, Univ of Ottawa; C. Rickwood, Natural Resources Canada, CANMET MMSL, Univ of Saskatchewan, Dept of Toxicology; M. Pawlack, CANMET-MMSL. Water Quality guidelines for selenium are not adequate in predicting toxicity to aquatic organisms, as the primary route of exposure is dietary. Revision of guidelines to encompass a fish tissue-based criteria are currently under way in both the US and Canada. While the primary focus of research examining dietary-Se exposures has been conducted with fish, very little information exists on dietary-Se exposures on invertebrates. In response to this knowledge gap, our objective was to elucidate the effects of dietary-Se on aquatic invertebrates. Specifically, the effects of water and food-borne selenium exposure on survival and reproduction of *Ceriodaphnia dubia* were compared. The recommended Environment Canada protocol (EPS 1/RM/21) was modified to incorporate selenium contaminated algae as an alternative food source. Exposures were conducted with both selenate and selenite over a 7-day period; survival and reproductive endpoints were measured. Exposure concentrations ranged from 1.25 to 40 µg selenium/g algae. Results allow us to address the significance of dietary-Se on invertebrates and assess the protectiveness of current water quality guidelines. In addition, the modification of a standard sub-lethal toxicity test provided a simple method to assess dietary-exposure of contaminants to a commonly used invertebrate species.

RP072 A Study of Mercury, Methylmercury and Selenium Concentrations and Nitrogen Stable Isotopes in a Marine Tropical Food Chain H.A. Kehrig, Universidade Federal do Rio de Janeiro, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho; T.G. Seixas, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho; A.M. Di Beneditto, C.M. Souza, C.E. Rezende, Universidade Estadual do Norte Fluminense, Laboratorio de Ciencias Ambientais; O. Malm, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho. Trophic transfer of trace elements along marine food chains has been recognized as an important process influencing metal and metalloid bioaccumulation. Mercury (Hg), methylmercury (MeHg) and selenium (Se) concentrations and nitrogen ($\delta^{15}N$) stable isotope were assessed in two size classes of plankton, two top-predators, *Sotalia guianensis* (cetacean) and *Trichiurus lepturus* (fish), and their representative prey species (fish, cephalopod and crustacean species), which are distributed in different habitats along the water column of the northern Rio de Janeiro coast. This area in southern Brazilian coast belongs to a faunistic transition zone. The stable isotope was used to assess the modes of MeHg and Se bioaccumulation and biomagnification along the food chain. Hg and MeHg in the cetacean muscle were 2.5 times higher than those found in its preferential prey, *T. lepturus*. *T. lepturus* presented higher muscular Se concentrations than those found in cetacean (mean: 1.0 and 0.6 $\mu g.g^{-1}$, respectively). Cetacean presented the highest Hg and MeHg concentrations, followed by the benthic-feeder and planktivorous fishes, whereas the benthic-feeder fish showed the highest Se concentrations. The lowest Hg, MeHg and Se concentrations were found in planktonic organisms. This fact suggests that MeHg was transferred among the trophic levels from the lower trophic level to the top-level predators. Se showed

some evidence of trophic transfer between lower trophic levels. *S. guianensis* presented lighter $\delta^{15}N$ (12.2‰) than their prey species (mean: 13.3‰), and this fact indicates that in our study the trophic position of this top-predator was not clearly related to muscular $\delta^{15}N$. The concentrations of Hg, MeHg, Se and $\delta^{15}N$ increased successively with increasing trophic levels. The log HgX$\delta^{15}N$ and log MeHgX$\delta^{15}N$ regression slopes (0.26 and 0.31, respectively) indicated that this food chain presented elevated biomagnification rates that can be related to the environmental water quality. However, the log SeX$\delta^{15}N$ regression slope (0.12) indicated that this food chain presented a low biomagnification power for selenium. Hg and MeHg are biomagnified through the food chain while selenium does not present the same behavior. Se is biomagnified mainly in the lower and intermediate trophic levels.

RP073 Mercury and Selenium in a Voracious Predator Fish, *Trichiurus lepturus* (Linnaeus, 1758), from Two Tropical Brazilian Areas T.G. Seixas, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho; I. Moreira, Pontifícia Universidade Católica do Rio de Janeiro (PUC-Rio), Chemistry; O. Malm, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho; H.A. Kehrig, Universidade Federal do Rio de Janeiro, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho. Mercury (Hg) and selenium (Se) were determined in the muscle tissue of cutlassfish (*Trichiurus lepturus*) caught by trawl nets or in gillnet fisheries in two different areas along the Rio de Janeiro coast, Brazil: Ilha Grande Bay (IGB) and Buzios coast (BC). IGB presents an oligotrophic environment and BC is an upwelling area. These areas presented different degrees of trace elements inputs and are subject to different environmental impacts. The diet of *T. lepturus* can be changed during the ontogeny, in which the specimens can be grouped by size (total length – TL). The specimens from BC were taken with three different ontogenic stages: large adults (> 100 cm – feed on pelagic and demersal fishes, including co-specifics), small adults (> 70-100 cm – feed on pelagic macrozooplankton, mainly juveniles fishes) and sub-adult (30 to 70 cm – feed on pelagic macrozooplankton, mainly eufasids and juveniles fishes). The specimens from IGB were taken with two ontogenic stages: large and small adults. No significant difference ($p > 0.05$) in total lengths was found between the specimens from the two sampling areas, suggesting that both groups are equally represented in the sample and making it possible to directly compare the concentrations of Hg and Se between them. Regional differences in the concentrations of these elements were observed in *T. lepturus*. The specimens collected at BC had muscular Hg concentrations about three times higher than those found in the specimens from IGB (mean: 1.07 $\mu gHg\ g^{-1}$ d.w. and 0.35 $\mu gHg\ g^{-1}$ d.w., respectively). However, the concentrations of Se did not differ between the sites, 1.01 $\mu gSe\ g^{-1}$ d.w. in BC and 0.96 $\mu gSe\ g^{-1}$ d.w in IGB. These patterns were also observed for the same ontogenic stages. In both areas, a significant difference was found between muscular Hg and the ontogenic stage, i. e., the biggest specimens presented the highest Hg concentrations. This pattern was not observed for Se in both areas. The differences found between Hg in *T. lepturus* from both areas were probably due to the preferential prey of each ontogenic stage, bioavailability of elements in each marine environment, and environment variables (water temperature, net primary production). As a consequence, concentrations of trace elements in the tissues of this species can be considered to be a result of the surrounding environment.

RP074 Lake Sedimentary Mercury Deposition and Fish Tissue Mercury Trends Associated with Recent Mercury Use and Emissions Changes in Massachusetts M. Hutcheson, MA Dept of Environmental Protection, Office of Research & Standards; G.T. Wallace, Univ Of Massachusetts Boston, Dept of Earth, Environmental and Ocean Sciences ; C.M. Smith, J. Rose, Massachusetts Dept of Environmental Protection, Office of Research and Standards; C. Batdorf, J. Sullivan, O. Pancorbo, Massachusetts Dept of Environmental Protection, Wall Experiment Station; C.R. West, Massachusetts Dept of Environmental Protection, Office of Research and Standards. The spatial pattern of historical (1800-2000) sedimentary mercury deposition trends inferred from analyses of 20 lake sediment cores from throughout Massachusetts will be presented in the context of historical mercury uses and atmospheric emissions in Massachusetts, with particular emphasis on trends in the last half of the twentieth century. In the last approximately 15 years there have been major state and regional regulatory efforts to reduce mercury uses and atmospheric emissions. Significant decreases occurred in total mercury concentrations in edible dorsal muscle of largemouth bass (*Micropterus salmoides*) and yellow perch (*Perca flavescens*) from these same lakes during this period (1999-2009). Fish mercury levels generally reflected the higher levels of sedimentary mercury deposited during later twentieth century high mercury atmospheric release periods, and more recently reflect substantial decreases in mercury releases to the atmosphere. The results will emphasize the time taken for aquatic resources to respond to reductions in atmospheric inputs of mercury and present modeled projections of times for these fishery resources to achieve acceptable tissue levels of mercury to be safe for routine human consumption.

RP075 Decreasing Aqueous Mercury Concentrations to Achieve Safe Levels in Fish: Examining the Water-Fish Relationship in 2 Point-Source Contaminated Streams T. Mathews, Oak Ridge National Laboratory, Environmental Sciences Division, Oak Ridge National Laboratory, Biological and Environmental Sciences Division; G. Southworth, Oak Ridge National Laboratory (retired), Environmental Sciences Division; M. Peterson, Oak Ridge National Laboratory; K. Roy, Oak Ridge National Laboratory, Environmental Sciences Division; R. Ketelle, Bechtel Jacobs. East Fork Poplar Creek (EFPC) and White Oak Creek (WOC) are two mercury (Hg)-contaminated streams located on the Dept of Energy's Oak Ridge Reservation in east Tennessee. East Fork Poplar Creek is the larger and more contaminated of the two, with average aqueous Hg concentrations currently exceeding those in reference streams by several hundred-fold. Over the past 20 years, extensive remedial actions have been taken that reduced aqueous Hg concentrations in EFPC by 85 %, but fish fillet concentrations have not responded to this decrease in aqueous Hg and remain above the Environmental Protection Agency's water quality criterion of 0.3 mg/kg for Hg in fish. The lack of correlation between aqueous and fish tissue Hg concentrations in this creek has led to questions regarding the usefulness of target aqueous Hg concentrations and strategies for future remediation efforts. White Oak Creek, located less than 10 km away from EFPC, has a similar contamination history but aqueous Hg concentrations in WOC are an order of magnitude lower than in EFPC. Despite the lower aqueous Hg concentrations, fish fillet concentrations in this creek have also been above the AWQC, making the most recent aqueous Hg target of 200 ng/L in EFPC seem unlikely to result in an effective decrease in fillet Hg concentrations. Recent monitoring efforts in WOC, however, have suggested that fish in this creek may be responding to lowered aqueous Hg concentrations. This new information could be useful to guide remedial actions in EFPC and in other point-source contaminated streams.

RP076 Mercury in Demersal and Pelagic Fish Species from Ilha Grande Bay, Brazil T.G. Seixas, I.A. Santos, L.A. Cassimiro, T.A. Cordeiro, O. Malm, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho; I. Moreira, Pontifícia Universidade Católica do Rio de Janeiro (PUC-Rio), Chemistry; H.A. Kehrig, Universidade Federal do Rio de Janeiro, Universidade Federal do Rio de Janeiro, Instituto de Biofisica Carlos Chagas Filho. Ilha Grande Bay (IGB; 22ºS, 44ºW) in Rio de Janeiro State has been subject of few mercury contamination studies. Mercury (Hg) is an exogenous and harmful metal, which accumulates in the tissues of aquatic organisms (such as fish) as they grow. It is the only trace element which biomagnifies through all level of the aquatic food web. This study assessed the concentration of Hg in the muscle tissue of seven demersal fish species (*Eugerres brasilianus* – Brazilian mojarra, N= 17; *Cynoscion jamaicensis* – Jamaica weakfish, N=12; *Prionotus punctatus* – Bluewing searobin, N=9; *Diplectrum radiale* – Pond perch, N=7; *Polydactylus virginicus* – Barbu, N=11; *Citharichthys spilopterus* – Bay whiff, N=10 and *Micropogonias furnieri* – Atlantic croaker, N=19) taken accidentally by trawl nets, during commercial captures of shrimp (*Xiphopenaeus kroyeri*) inside of IGB and also in a demersal-pelagic fish species (*Trichiurus lepturus* – Cutlassfish, N=21) that represent the voracious predator of this food web. These fish species has different feeding habit and some of them have no commercial value, but are consumed by local population. Hg concentrations were determined by CVAAS, using $NaBH_4$ as a reducing agent. The more voracious demersal fish species, Brazilian mojarra and Jamaica weakfish, presented the highest Hg concentrations (0.15 and 0.12 $\mu g\ g^{-1}$ w.w., respectively). While, the lowest Hg was found in less voracious demersal fish species: Pond perch (0.08 $\mu g\ g^{-1}$ w.w.) > Barbu (0.06 $\mu g\ g^{-1}$ w.w.) > Atlantic croaker (0.05 $\mu g\ g^{-1}$ w.w.) > Bluewing searobin (0.04 $\mu g\ g^{-1}$ w.w.) > Bay whiff (0.03 $\mu g\ g^{-1}$ w.w.). The voracious predator (Cuttlassfish) that feeds on the water column, showed lower Hg (0.05 $\mu g\ g^{-1}$ w.w.) than the more voracious demersal fish species, indicating that probably the sediments from this region are richer in Hg. The Cuttlassfish also presented higher Hg concentration than its preferential prey (Atlantic croacker),

indicating that there is a positive transference of Hg from prey to predator. According to the results, probably, Hg has been suffering the biomagnification process in this web. However, more aquatic species must be studied to understand the behavior of this element in this environment. Probably, the differences in Hg among fish species can be related to the predominant food items for each species as well as the bioavailability of Hg in the marine environment.

RP077 Arsenic Bioaccumulation in a Marine Juvenile Fish *Terapon jarbua* Z. Wei, H. Liangmin, South China Sea Institute of Oceanology, Chinese Academy of Sciences; W. Wenxiong, Hong Kong Univ of Science and Technology. Arsenic (As) is a ubiquitous toxic metalloid causing a widespread public concern. Recent measurements indicated that marine fish in China can be seriously contaminated with As, but the biokinetics and bioaccumulation pathway of As in fish remains less well studied. In this study, we employed a radiotracer technique to quantify the dissolved uptake, dietary assimilation and subsequent efflux of As(V) in a marine predatory fish, *Terapon jarbua*. Dissolved uptake of As showed a linear pattern over a range of dissolved concentrations from 0.5 to 50 μg L-1, with a corresponding uptake rate constant of 0.0012 to 0.0017 L g-1 d-1. The dietary As assimilation efficiencies (AEs) were only 3.1-7.4% when the fish fed on different preys (copepods, clams, prey fish, and artificial diet), and were much lower than its partitioning in the trophically available metal fraction (TAM) in the prey clam and fish. The dietary AEs were independent of the As(V) concentrations in the artificial diets. The efflux rate constant of As in fish following the dietary exposure was 0.06 d-1. Modeling calculations showed that dietary uptake could be the primary route for As bioaccumulation in fish, and the corresponding contribution of waterborne and dietary uptake was related to the bioconcentration factor (BCF) of the prey and ingestion rate of fish. Our study showed that As(V) had a low bioavailability to marine fish.

RP078 Investigation of Toxicity of Multi-wall Carbon Nanotube in *Caenohabditis elegans* Using Functional Toxicogenomics Approach J. Roh, Univ of Seoul; M. Bruno, Y. Ge, USEPA; J. Yi, Seoul National Univ; J. Choi, Univ of Seoul, School of Environmental Engineering. Carbon nanotube (CNT) has a wide application in industrial and biomedical fields, which could end up their occurrence in the environment. Associated hazard and risk should, therefore, be investigated, before their widespread use. In this study, toxicity of multi wall carbon nanotube (MWCNT) was investigated in the soil nematode, *Caenohabditis elegans* using integrated systems toxicology approaches. Toxicity of MWCNT was first tested using survival and reproduction. Toxic mechanism of MWCNT was investigated using microarray based gene expression analysis. Integrated bioinformatics tools were applied to gain an insight of worm`s global response to MWCNT exposure and quantitative PCR analysis was followed on the selected genes. Functional analysis was subsequently conducted, analyzing gene expression data coupled with phenotypic measurements. Overall results indicate that a combination of multiple pathways, including oxidative stress and inflammation, may be required toxicity of MWCNT in *C.elegans*, which was frequently observed in mammalian in vitro and in vivo models. It is important to note that negative or insignificant results at the organism level should not be considered as MWCNT being "safe" nanomaterials, as significant alteration on the gene expression was revealed by microarray and subsequent PCR and functional analysis, which may eventually be manifested at higher level after long term exposure. Results also suggest that system-based integrated toxicogenomic approach is particularly valuable to investigate toxicity of new chemicals of which mode of action is not fully understood or incompletely characterized, such as, MWCNT. This work was supported by the National Institute of Environmental Research, the Ministry of Environment of Korea and the Ministry of Education, Science and Technology of Korea [2010-0016195].

RP081 Comparison of Carbon Nanotube and Asbestos Exposure on the Gill and Liver Histology of Fathead Minnows A. Edgington, Clemson Univ, Biological Science and CU-ENTOX, Clemson Institute of Environmental Toxicology; K. Donohue, J. Laird, D.R. Johnson, J. Stanley, J.A. Steevens, US Army Engineer Research and Development Center, Environmental Laboratory; S.J. Klaine, Clemson Institute of Environmental Toxicology, Clemson Univ. Carbon nanotubes (CNTs) are graphene cylinders with a long common axis resulting in a fiber-like characteristic. Carbon nanotubes have unique characteristics that include durability and high aspect ratio (ratio of length and width) that has been compared to that of asbestos fibers. These similarities between asbestos and CNTs have raised concerns about potential toxicity. Many inhalation studies have shown the potential for asbestos to cause physiological effects to lung tissues often resulting in carcinomas. But little research has been done on aquatic exposures of asbestos to fish species. The objectives of this project were to compare the physiological effects of CNT and asbestos exposure to *Pimephales promelas*, commonly called the Fathead Minnow (FHM). Comparisons were made using two forms of CNTs, single-walled and multi-walled nanotubes, and two forms of asbestos, crocidolite and chrysotile. Adult FHM were exposed to 0.125, 0.25, and 0.5 mg/L of suspended CNT or asbestos in a solution of Suwanee River water and tanks were renewed daily. Organisms were sacrificed at days 0, 7, and 14 and gills and livers were collected and fixed in gluteraldehyde. Samples were sectioned, stained and examined on a microscope for physiological abnormalities. Samples were also fixed and sectioned for transmission electron microscopy (TEM) coupled with electron emission loss spectroscopy (EELS) to determine CNT absorption through the gill. Carbon nanotube and asbestos particles were characterized using TEM, zeta potential, and dynamic light scattering to determine particle characteristic effects on tissue histology and uptake.

RP082 Influence of Media Chemical Properties on Aggregation Behavior of Copper Nanoparticles N.B. Saleh, Univ of South Carolina, Civil and Environmental Engineering; V. Shah, Dowling College; A. Afrooz, Univ of South Carolina, Civil and Environmental Engineering; F. Rispoli, Dowling College, Dept of Mathematics. Unique physical, chemical, and biological properties of copper nanoparticles (CuNPs) have generated considerable interest in environmental and medical fields. This study focuses on the fundamental mechanism of aggregation of CuNPs in influence of nine different chemical parameters. Parameters selected for the study include: pH, concentration of mono- and di-valent cations (K^{+}, Ca^{+2}, Mg^{+2}), natural organic matter, bovine serum albumin, and sugars (alginate and fructose). Aggregation behavior was measured using time-resolved dynamic light scattering. Aggregation structure is further studied in suspension by cryo transmission electron microscopy. Furthermore, temperature dependent size measurement is performed to probe the secondary minima of these colloids to study reversible attachment. The findings from this study can help carefully probe CuNP aggregation mechanism in diffusion limited aggregation regime and will shed light onto the role of secondary minima in reversible attachment of such particles.

RP083 Toxicity Effect of Ferrous Sulfide and Zero Valent Iron Nanoparticles on *Escherichia coli* Growth Under Anaerobic Conditions T.M. Olson, M.R. Higgins, Univ of Michigan, Dept of Civil and Environmental Engineering. In situ, passive technologies for remediating contaminated groundwater offer potential economic and environmental advantages over ex situ, active extraction methods. Most in situ technologies involve emplacing reactive materials in the path of a contaminant plume with the goal of transforming or sequestering contaminants in the reactive zone. Approaches to effectively create the reactive zones, known as permeable reactive barriers (PRBs), have typically involved the use of reduced iron materials, such as zero valent iron (ZVI), but more recently other iron mineral nanoparticles, such as ferrous sulfide, have been investigated. Ferrous sulfide readily forms as mackinawite nanoparticles at ambient temperature and offers similarly reactive capacity as ZVI. Although incorporating nanoparticles into PRBs is potentially beneficial due to their high reactive surface area, their release risk and toxicity have not been extensively tested. In this study, the toxicity of nano FeS particles to model bacteria, *Escherichia coli*, was evaluated in terms of their effect on growth rates in anaerobic cultures. The experiments demonstrate that *E. coli* growth is inhibited by the presence of FeS, however, the inhibition is not significantly different than that observed in particle-free sodium sulfide solutions at FeS-sulfide saturation concentrations. Growth inhibition, therefore, was not directly caused by the nano-FeS itself. The toxicity effects of nano-ZVI and FeS will be compared and implications for the use of these materials in PRBs will be discussed.

RP084 Multi-linear Regression Methods to Develop an Integrated Addition Model for Predicting Mixture Toxicity J. Kim, KIST Europe, Knowledge Research Group, Univ of Koblenz-Landau, Institute of Environmental Sciences; S. Kim, KIST Europe, Chemical Management Lab.; G.E. Schaumann, Univ of Koblenz-Landau, Institute of Environmental Sciences. Living organisms are actually exposed to chemical mixtures. However,

chemical risk assessment frequently places less focus on chemical mixtures than individual substances. In addition, recent studies on mixture toxicity shows that single substances at levels below no-observed-effect concentrations (NOECs) may cause toxicity due to the mixture toxicity among substances. For human health and the environments, the mixture toxicity thus needs to be considered in mixtures risk assessment. The concepts of additive toxicity, concentration addition (CA) and independent action (IA) models, are often applied to predict the mixture toxicity of similarly- and dissimilarly acting chemicals, respectively. However, living organisms and the environments are exposed to both types of chemicals at the same time and space. Hence, it needs to develop an integrated model to predict mixture toxicity from different chemicals practically. The objective of this study is to develop an integrated addition model based on the multi-linear regression for estimating mixture toxicity in the environment risk assessment. In this study, different multi-linear regression (MLR) methods are employed to integrate the CA and IA models, and then evaluated to select the best MLR method. The results show that the prediction capability of the integrated addition model based on MLRs is outstanding as compared with the conventional CA and IA models. Ridge- and Partial Least Squares-based regression methods outperform the other MLR methods.

RP085 A Watershed-scale Ecosystem Services Life Cycle Impact Assessment Approach to Water Risk Assessment M. Matlock, Univ of Arkansas, Centre for Agricultural and Rural Sustainability; G. Thoma, Univ of Arkansas, Dept of Chemical Engineering. Water resources are a global concern but a local issue. Measuring the impact associated with manufacturing consumer package goods at a specific site is difficult. Current impact assessment methods are primarily geared towards agricultural water use and lack the ability to effectively measure the potential risks or impacts associated with industrial freshwater use and depletions at the site level. We will present an approach to water resources risk assessment based on a watershed-scale site life cycle impact assessment framework. Site-specific local water scarcity were evaluated at watershed scale and the percent sector (e.g., industrial, agricultural, domestic) water usage were determined for 150 manufacturing facilities in the food, beverage and agriculture sector in order to analyze the magnitude that each sector contributes to local water consumption. This analysis was the baseline for the Level 1 Impact Assessment. The Global Water Tool (GWT) developed by the World Business Council was used to evaluate the total renewable water resources per person and the percent of the population with access to improved water and sanitation at each site. The GWT data was linked with Pfister et al.'s Water Scarcity Index (WSI) to determine per capita annual renewable water supply, projected per capita annual renewable water supply for 2025, the mean annual relative water stress index, and Pfister's WSI. The Level 2 Water Impact Assessment was developed from data provided by companies participating in the prototype project. A water use inventory for each category of facility was developed and distributed to participating companies, and data were analyzed on a site basis. Parameters that were analyzed include water use impact on scarcity, water use impact on water quality, and water use impact on ecosystem services. Facility discharge water quality parameters were evaluated for potential risk to ecosystem services and human health based on the waste load in the wastewater discharge. The wastewater discharge was characterized from survey information. The effectiveness at measuring risk at the facility level was evaluated by comparing sites globally. Areas of evaluation included potential damage to human health, ecosystem services, and biodiversity.

RP086 Addressing Risk and Uncertainty in USACE Ecosystem Restoration Projects B.C. Suedel, US Army Engineer Research and Development Center, CEERD-EP-R, US Army Engineer Research and Development Center, Environmental Laboratory, Waterways Experiment Station EP-R; J.T. Vogel, US Army Engineer Research and Development Center; M. Convertino, Univ of Florida, Agricultural and Biological Engineering; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center; J. Valverde, T.S. Bridges, US Army Engineer Research and Development Center. Several factors constrain effective use of risk and uncertainty tools and techniques in ecosystem restoration. Even though risk is a crucial driver in assessing effectiveness of ecological restoration and risk assessment has evolved both as analytical method and regulatory tool, its application to ecosystem restoration projects has not been formalized or fully explored. Further, tools and techniques for addressing uncertainty developed for other disciplines have been applied to few ecosystem restoration projects. The purpose of this work was to frame and document the application of risk management concepts and methods for ecosystem restoration as practiced within the USACE. Case study examples of recent USACE district projects employing risk and uncertainty best practices for ecosystem restoration projects were identified and described, including those addressing the Sensitivity of the Barataria Basin Barrier Shoreline Wetland Value Assessment Model, the Upper Mississippi River System Navigation and Ecosystem Sustainability Program, and Quantifying and Communicating Model Uncertainty for Decision Making in the Florida Everglades. Tools and techniques representing the state of the science for addressing risk and uncertainty were then identified that could further advance the application of risk and uncertainty to ecosystem restoration. A hypothetical case study developed for the work will also be presented, illustrating how risk management and uncertainty tools and techniques can be integrated into the USACE ecosystem restoration projects.

RP087 An Ecosystem Services Framework in Practice: An Assessment of Fruit Production in Southern Europe G. Reub, ENVIRON International Corp, Ecology and Sediment Management; S. Deacon, ENVIRON UK Ltd; G. Greene, ENVIRON International Corporation, Ecology & Sediment Mngmt; S. Norman, Dow Agrosciences. In this pioneering proof-of-concept study an ecosystem services framework was developed and applied to a case study in support of the re-registration of a well-known insecticide for use in Southern European countries where citrus growing is particulalry important both economically and culturally to the communities in these regions. The study focusses on Southern Spain where generations of farmers have grown citrus fruits. The re-registration is in compliance with the European Plant Protection Products Directive. The European Food Safety Authority (EFSA) recently developed and published a framework for developing specific protection goals for the environmental risk assessment of pesticides that includes an ecosystem services approach. This ecosystem services concep takes a holistic view of environmental, social and economic factors. The ecosystem services approach identifies and values the primary environmental services that a land cover type may provide given different land uses and actions. The type, quantity, and quality of environmental services provided are influenced by management actions on the land. A systematic evaluation of such changes in service flows is provided to allow for consistent comparisons across two alternatives that examine mangement actions and include the use of certain pesticides among other activities that affect ecosystem services. The framework allows for the formal quantification (semi-quantification) of ecosystem service values associated with different land cover types and the anthropogenic influences within each cover type. The approach relies on gathering existing data and development of an analytical framework. The approach governs the collection and analysis of data on a detailed land cover type scale, establishing existing capacities of ecosystem services (baseline conditions). The results produce a composite measurement of baseline conditions expressed in a standard metric or "currency" (e.g., service hectares) allowing ecosystem service levels to be compared. Results are then estimated for conditions after a change in a management action (such as the application of a pesticide) and the net ecosystem service gains and losses between scenarios or condition levels may be compared. Ecosystem services include those related to physical, chemical, biological, and human use and non-use categories.

RP088 Agrochemical Mitigation of Three Aquatic Macrophytes: Implications for Ecosystem Services H.L. Tyler, USDA ARS National SEdimentation Laboratory; M.T. Moore, USDA-ARS, National Sedimentation Laboratory, USDA-ARS National Sedimentation Laboratory, National Sedimentation Laboratory; M.A. Locke, USDA ARS National SEdimentation Laboratory. Agricultural runoff containing nitrogen and phosphorus is a major contributor to eutrophication in aquatic systems. Vegetated drainage ditches lining agricultural fields have been investigated for their potential to mitigate runoff, acting similarly to a wetland as they filter contaminants. The efficiency of three aquatic macrophytes, cutgrass (Leersia oryzoides), cattails (Typha latifolia), and bur-reed (Sparganium americanum), to mitigate ammonia, nitrate, and phosphate from water was investigated. Replicate mesocosms of each plant species were exposed to water enriched with ammonia and nitrate for 6 h and flushed with clean water for an additional 6 h to simulate storm events. After termination of the simulated runoff, all vegetated treatments lowered total Kjeldahl nitrogen loads exiting mesocosms by greater than 50%, significantly more than unvegetated controls. Leersia and Typha were more efficient at lowering dissolved nitrogen, lowering ammonia 42 and 59% and nitrate by 67 and 64%, respectively. Leersia

and Typha decreased the loads of dissolved phosphate exiting mesocosms by 50% while Sparganium only decreased dissolved phosphate by 15%. All treatments decreased ammonia and nitrate concentrations within mesocosms by more than 86% after one week, though Typha and Leersia acted more rapidly. In determining the agrochemical mitigation efficiency of different plant species, vegetation in drainage ditches can be better maintained for optimal remediation of agricultural runoff.

RP089 Ecosystem Restoration: Development of Project Level Objectives and Metrics J.T. Vogel II, K. McKay, B. Suedel, M. Convertino, I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center. Accounting for the benefits of ecosystem restoration projects requires defining multiple metrics corresponding to ecosystem structure, function, and processes. Metrics measure progress toward goals and objectives, raise awareness and understanding, and support restoration decision making, especially in cases where uncertainty is prevalent. Multiple metrics may be defined which have a varying degree of utility for restoration managers. This presentation will describe the underlying scientific principles and best practices for the development and application of metrics for environmental benefits analysis. We will also present decision analysis techniques as a means for integrating large amounts of varied types of information. This optimizes decision-making processes as they relate to developing objectives and metrics for ecosystem restoration projects. Decision analysis allows for the investigation of the costs and benefits of different decisions available and the assessment the trade-offs between restoration options. These principles and practices will span three sub-topics related to metrics, namely: (1) identification of metrics corresponding to project objectives; (2) analytical techniques for comparing and trading-off metrics; and (3) application of metrics within a restoration decision hierarchy, from the programmatic to the regional level. The regulatory realities in which restoration projects must take place (i.e., NEPA and Clean Water Act) are also addressed.

RP090 A Compendium of Transcriptomic Effects of Endocrine Disrupting Chemicals on the Fathead Minnow Ovary T. Habib, BTS; L. Escalon, US Army, Engineer Research & Development Center; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; D. Bencic, USEPA, Office of Research and Development, USEPA; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division; N. Garcia-Reyero, Jackson State Univ. Understanding potential hazards of chemicals released into the environment is challenging not only due to the large and growing number of chemicals and materials that need to be screened, but also to the bioavailability, exposure conditions, and species differences among others. Examining effects on critical pathways resulting in adverse outcomes of interest such as reduced reproduction provides a broader measure of the potential hazards of a chemical. Effective mining of complex relationships, effects and potential impacts can be gained through meta-network analyses derived from expression data. The Hypothalamus-Pituitary-Gonadal (HPG) Axis is an evolutionarily conserved endocrine pathway principally responsible for the control of reproduction. Measuring impacts of chemicals on the HPG axis provides a functional measure of the chemical's reproductive hazards. Therefore, analysis of steroidogenesis and the biological elements controlling it can be used to understand chemical effects and key events leading to adverse reproductive outcomes. Here, we used network inference approach to investigate the impacts of chemicals on steroidogenesis. Fathead minnows (*Pimephales promelas*) were exposed to known endocrine disruptors and impacts on steroidogenesis were examined through network analysis of a large compendium of ovarian gene expression and hormone data sets. The compendium contained 1,472 microarrays, with data from twenty-three different in vivo exposure experiments encompassing 13 different chemicals, 1 complex mixture, 5 ovary stages, multiple time points, and multiple chemicals doses. Transcriptional networks were obtained from two different sources: 1) all 23 exposures and 2) seven individual chemicals (fadrozole, flutamide, prochloraz, trenbolone, vinclozolin, trilostane, and ketoconazole). Gene networks inferred by both approaches were consistent with minor differences and both were able to detect important interactions from genes involved in reproduction and development pathways (such as estrogen and progesterone signaling). Common interactions between the combined and individual networks can offer insights about the common mechanism whereas the difference in the interactions can provide the specific chemical effect.

RP091 Analysis of Gene Expression in Endosulfan Exposed *H. americanus* Larvae Using an Oligonucleotide Microarray M. Bauer, Univ of Prince Edward Island, Dept of Pathology & Microbiology, Atlantic Veterinary College, Univ of Prince Edward Island, Environment Canada; S. Greenwood, Univ of Prince Edward Island, Dept of Biomedical Sciences, Atlantic Veterinary College; P. Jackman, Environment Canada, Toxicology Laboratory. Agriculture, aquaculture and fisheries are essential industries in Atlantic Canada that must be sustained while also implementing measures to reduce their environmental impact. The use of pesticides in agriculture and aquaculture are a cause for concern in regards to the chronic and acute effects on non-target organisms. Endosulfan is a moult inhibiting organochlorine pesticide that is sprayed on potato fields on Prince Edward Island to eliminate insect pests. Following rain events, endosulfan has been found in nearby marine and aquatic environments as a result of soil run-off and is hypothesized to have negative effects on marine crustaceans. The current research project focuses on the effect of endosulfan on the American lobster (*Homarus americanus*), an important commercial resource. Stage III larvae were chronically exposed to environmentally relevant concentrations of endosulfan (0.01, 0.03, 0.1 0.3 & 1.0 ug/L) and were found to exhibit developmental delays in development to stage IV and mortality. Microarray analysis was used to detect changes in genes expression between each concentration and to identify pathways being affected by endosulfan exposure. The results of this study will identify the effects of endosulfan on lobster larvae development, survival and the potential impact on the lobster population.

RP093 Polyploidy in Leukemic *Mytilus* sp. Haemolymph: A Biomarker for Population Health E. Vassilenko, Univ of British Columbia, Chemical and Biological Engineering; S. Baldwin, Chemical & Biological Engineering, Univ of British Columbia. Mussels have been used for environmental monitoring since the 1970's. Leukemia or haemic neoplasia (HN) is a sublethal endpoint that can be used for assessment of mussel population health. HN is associated with cell morphology alterations and with abnormal ploidy in haemocytes. We used flow cytometry (FC) to analyze haemocyte ploidy and haemocytology to assess percentage of neoplastic-looking cells in the haemolymph of two species, *M. trossulus* and *M. edulis*. We analyzed samples of mussel populations collected during an exposure experiment conducted in 2010 in the Vancouver area (BC, Canada). The experiment had a 2x2 factorial design with two control samples of non-exposed populations at the beginning and at the end of the experiment. *M. trossulus* were collected from two different beach locations and *M. edulis* were purchased from a farm in April. Both species were exposed on submerged frames from April to October at two sites, one urban and the other remote. In October additional sampling of beach populations were conducted. Using a new approach to FC ploidy analysis and classification of the detected ploidy patterns, our results show that progression of HN is different in natural beach populations and in populations on the submerged frames. As well we show that the prevalence of late-stage HN and the amount of animals with abnormal ploidy were higher for the urban exposure site compared with the remote site. We suggest that the ploidy analysis might be considered as a sensitive marker for monitoring of mussel population health.

RP094 The Copepod *Calanus finmarchicus*: A Promising Cold Water Model Species for Ecotoxicology and Environmental Genomics Related to Oil Exposure B. Hansen, SINTEF Materials & Chemistry, Marine Environmental Technology; D. Altin, BioTrix; A.J. Olsen, Dept of Biology, NTNU; T. Nordtug, SINTEF Materials and Chemistry; K. Degnes, SINTEF Materials and Chemistry, Biotechnology; T.R. Storseth, SINTEF Fisheries and Aquaculture; H. Sletta, SINTEF Materials and Chemistry, Biotechnology; K.E. Tollefsen, NIVA, Ecotoxicology & Risk Assessment. In recent years there has been an increasing emphasize on the significance of invertebrates for assessing environmental impact of oil spills. In the event of accidental oil spills in sub-Arctic and Arctic marine environments planktonic organisms like copepods are realistic targets for oil toxicity based on their significant role in the food web, their abundance and their large lipid content. For many years the SINTEF/NTNU culture of *Calanus finmarchicus* has functioned as relevant model for standard ecotoxicity testing of North Atlantic crude oils, and a large database of ecotoxicity data exists for this species. Parameterized experimental data on the effects of oil (single oil

components, water soluble fraction of oil, and dispersed oil) on copepod survival and reproduction are used as input for development of numerical models for environmental risk and damage assessment. The accessibility of a continuous copepod culture provides homogeneous specimen in terms of developmental stage and lipid content. This, along with sophisticated experimental systems, is a major foundation for investigating effects of stressors on molecular systems. A 60K oligonucleotide microarray has been developed based on a combination of available NCBI expressed sequence tags (ESTs) and 260,000 ESTs sequenced by FLX454 technologies. Several methods, like 1H-nuclear magnetic resonance and mass spectrometry, have also been developed and applied in order to investigate metabolic profiles and alterations. Together these complementary methods give valuable supporting information to well known fitness-related endpoints, as they contribute with modes of toxic action of stressors, and output data may also be used to determine effect limits. The presentation will include results from experiments aimed at investigating the effects of chemically and mechanically dispersed oil, their modes of toxic action, and proposed effect limits of toxicity based on fitness-related endpoints as well as molecular profiling.

RP095 Atrazine Residue and Glutathione S-Transferase Response of Freshwater Mussel *Uniandra contradens* Living in Agricultural Catchments, Northern Thailand T. Thitiphuree, Chulalongkorn Univ, Chulalongkorn Univ, Dept of Biology, Faculty of Science; J. Kitana, Chulalongkorn Univ, Dept of Biology, Faculty of Science; P. Varanusupakul, Chulalongkorn Univ, Dept of Chemistry; N. Kitana, Chulalongkorn Univ, Dept of Biology. Northern part of Thailand is known as an origin of several rivers and tributaries as well as a fertile area for agricultural activities. Seasonal cultivation in this area leads to widely uses of agrochemicals especially atrazine herbicide. To examine whether an intensive use of atrazine could lead to contamination in aquatic environment, the sediment and water were collected from agricultural catchment basin in Nan province, northern part of Thailand during 2010–2011 and subjected to analysis for atrazine by gas chromatography-mass spectrometry. The results showed that detectable levels of atrazine residue were found in water (maximum value 0.16 mg/L) and sediment (maximum value 0.23 mg/kg) of the catchment area. Since atrazine is also known to cause disruption of organ systems of animal, it is thus important to monitor its effects on representative species of aquatic animal. In this study, a freshwater mussel *Uniandra contradens* was used as a sentinel species for potential health effects of atrazine contamination in aquatic environment. Freshwater mussels were collected from the agricultural catchment area during July 2010 to June 2011. Mussels were subjected to tissue residue analysis for atrazine by high performance liquid chromatography and examine for specific activity of glutathione s-transferase (GST), a biotransformation enzyme, in their hepatopancreas by spectrophotometric assay. The results on seasonal profiles of atrazine residue and specific activity of GST will be presented. Association between environmental and tissue residues of atrazine and potential oxidative stress condition of the freshwater mussel will be discussed. The information from this study could be used as an early warning of health effects of low level atrazine contamination on freshwater animals and the potential link to other organism in the area including human.

RP096 Evaluation of Algal Estrogen Exposure Scenario Focusing on Gengorobuna as a High-exposure Group Y. Hida, The Univ of Shiga Prefecture, Ecosystem Studies, The Univ of Shiga Prefecture; Y. Fujimoto, K. Kitao, M. Nakamura, T. Shibata, H. OOkura, Y. Yamada, S. Kuribayashi, T. Kurata, The Univ of Shiga Prefecture. A class of chemicals called endocrine disruptors, which were pointed out in 1990s, still has been an "unknown" type of risk in the society. While clear cause-effect relationships about endocrine disruptors have not yet been established, in some countries, the concern that the uncertainty in their risk estimation may be excessive large results in the society's decision-making to avoid them completely. Thus, if the current risk assessment methodology of endocrine disruptors is that its do not affect the society's decision-making, efforts should be improved to reduce its uncertainty. In this sense, it is critical to fundamentally characterize endocrine-disrupting action itself using field data. Since 2004, we have shown that algae (phytoplankton), which are ubiquitous in the aquatic environment, have weak estrogenic activities, are taken up passively, and act on gonadal development by temporarily suppressing maturation and the seasonal maturation phase in round Crucian carp (Nigorobuna). In this study, we focused on Gengorobuna as a group that is highly exposed to algae among Crucian carp species, which are supposed to eat zooplankton or aquatic animals generally. Gengorobuna is the only carp which are supposed to eat phytoplankton, and since it has almost twice the number of gill rakers as Nigorobuna, it is probably more affected by algae exposure. Therefore, by comparing gonadal development in these two carp, we can show the one example about the effects of algae on fish based on the actual amount of algae they are exposed to in nature. When 5-month-old Gengorobuna and Nigorobuna maintained under the same cultivation environment with excessive algae flourished were compared, serum vitellogenin (VTG) concentrations in Gengorobuna were lower in both sexes, and the gonadosomatic index (GSI) was skewed to low values, __particularly in males. Seasonal variations in GSI and VTG in mature Gengorobuna in Lake Biwa are nearly always lower than those in Nigorobuna throughout the year in both sexes. Furthermore, in breeding experiments with Gengorobuna exposed to Chlorella, which have estrogenic activity, gonadal maturation phase was preceded in a control group of males compared with that in an exposed group and lagged in females, and the difference was clearer in both sexes of Gengorobuna when compared with Nigorobuna. These results are consistent with the hypothetical scenario that fish are exposed to estrogenic substances through algae consumption in nature.

RP097 Integrating Toxicity Test and Experimental Ecosystem Data to Better Define Aquatic Risks D.R. Mount, US Environmental Protection Agency, ORD; R.J. Erickson, USEPA, Mid-Continent Ecology Division. Aquatic risk assessments based on species sensitivity distributions can be uncertain regarding the nature and magnitude of the effects being addressed. The use of inconsistent endpoints and the failure to consider complete effects/exposure relationships contribute to this uncertainty. What percentile is selected as a level of concern in the distribution also represents a major uncertainty. Better definition of risks can be achieved by more fully exploiting information from toxicity tests, using more consistent endpoints, and relating results from toxicity tests to effects in experimental or natural ecosystems. Using atrazine effects on aquatic plants and plant communities as an example, this talk will discuss an index for better describing the level of toxicity to an assemblage of species as a function of concentration and time, and how experimental ecosystem data can be used to support risk characterizations based on this index.

RP098 Putting "Health" Back into Ecosystem Health Assessment K. Munkittrick, Univ of New Brunswick, Canadian Rivers Institute, Univ of New Brunswick, Dept of Biology. There are many different purposes to collecting information, and trying to merge predictive and retrospective frameworks is very difficult. A major challenge is that situations where toxicity is strong show positive results across a spectrum of responses, including laboratory and field approaches. Regardless of the assessment purpose, objectives, approach, design and analysis, indicators have to be practical, simple, and consistent, with a low type II error rate. Laboratory approaches sacrifice ecological relevance, while field approaches have to make compromises in terms of conflicting requirements for protection, detection, reversibility, causality and ecological relevance. Ecosystem health assessment has largely followed a human health medical paradigm, where reference collections seek to define the level of natural variability in terms of spatial and temporal fluctuations that can mask impacts. Historically, definitions of "normal" levels of responses are used to detect deviations from normal and the absence of "health". There is perhaps a more useful paradigm, where the ability of organisms to integrate responses can be used holistically to evaluate performance. Under this effects-based paradigm, study designs seek out natural variability, and a system self-defines its level of health, thresholds of responses, and triggers to inform management decisions. Relationships also translate ecological information into currencies relevant for land use planning, natural resource management and impact mitigation. It represent a simpler site-specific approach that requires a commitment to baseline monitoring, consistency, and commitment to long term planning that is usually absent in current situations.

RP099 Relationships Between Atrazine Contamination and Biologic Response of Paddy Crab, Esanthelphusa nani, in Agricultural Area of Nan Province, Thailand R. Maneein, Chulalongkorn Univ; W. Khonsue, Chulalongkorn Univ, Dept of Biology; P. Varanusupakul, Chulalongkorn Univ, Dept of Chemistry; N. Kitana, Chulalongkorn Univ, Dept of Biology. A variety of herbicides has been used intensively in agricultural activities at Nan province, northern part of Thailand. Although adverse effects on non-target organisms of these herbicides, especially atrazine, have been reported,

information on exposure-response relationships of atrazine on freshwater invertebrate is still limited. Gas chromatography-mass spectrometry analysis for residue of atrazine in soil and water of paddy fields in Nan province showed that detectable level of atrazine (0.15 mg/L) can be found in water of the intensive herbicide utilization area. Therefore it is crucial to monitor atrazine contamination and potential health hazards to the non-target organisms living in the herbicide utilization area. A rice field crab ESANTHELPHUSA NANI has been selected as a sentinel species because it lives in paddy fields with direct exposure to herbicide contaminated soil and water. In this study, crabs were field collected for one year from two study sites: a reference site where no herbicides were used and a contaminated site where herbicides were used intensively. Crabs were subjected to contaminant analysis for atrazine in tissue by HPLC technique and determination of specific activity of glutathione S-transferase (GST), a detoxify enzyme in hepatopancreas, by spectrophotometric assay. Seasonal change in levels of atrazine tissue residue and a biologic response of the crab to atrazine contamination in term of GST activity will be presented. Association between environmental and tissue residues of atrazine and potential oxidative stress condition of the freshwater crab will be discussed and used for assessing a potential impact of atrazine contamination on non-target organisms in agricultural environment.

RP100 Modifying Foods and Feeding Regimes to Optimize the Performance of *Hyalella azteca* During Chronic Toxicity Tests J.R. Hockett, T.L. Highland, D.J. Hoff, D.R. Mount, USEPA, Mid-Continent Ecology Division; T.J. Norberg-King, USEPA; T.R. Valenti, National Research Council, c/o USEPA. The amphipod *Hyalella azteca* is commonly used to assess the toxicity of sediments and waters. However, laboratories have reported varying success in maintaining healthy cultures and in obtaining consistent growth and reproduction (where applicable), especially during tests conducted for longer durations (i.e., 28 and 42 days). Even where control survival criteria are met during 10-d tests, poor growth and reproduction observed during longer tests under similar conditions may bring into question whether the results of shorter tests provide a reliable measure of toxicity. Some of the challenge to consistency in testing with *H. azteca* may stem from uncertainties regarding environmental conditions necessary for successful culture and testing of this species; an informal survey of laboratories indicated a wide variety of water types and feeding regimes in use. Until these uncertainties are resolved, it seems reasonable that laboratories could prove the adequacy of their test conditions for *H. azteca* by demonstrating good survival, growth, and reproduction in a 42-d control exposure using a neutral substrate, such as clean quartz sand. Previous work in our laboratory showed that 10-d amphipod growth could be markedly improved by amending Lake Superior water with 10 mg chloride/L (added as NaCl). As part of evaluating this water's suitability during 42-d tests as described above, we also included treatments using some different diets and ration sizes. Although the amended Lake Superior water did appear to support good organism performance, we found evidence that the standard feeding rate of 1 ml YCT/chamber/day (based on current EPA and ASTM guidance) was not sufficient to sustain optimal growth and reproduction for periods longer than the initial 10 days of the test. Following from this observation, additional studies were conducted to more thoroughly evaluate different foods, combinations of foods, feeding rates, and temporally increasing feeding rates (intended to account for the changes in organism mass over the course of the test). Detailed comparisons within and between experiments are discussed. While work to define a new feeding regime for use with *H. azteca* is not yet complete, we believe the results thus far strongly indicate that the standard feeding rate of 1 ml YCT/chamber/day should be increased in latter portions of 28-d or 42-d tests with *H. azteca*. This abstract does not necessarily reflect EPA policy.

RP101 Well Past Time to Stop Using NOEL/LOELs W.G. Landis, Institute of Environmental Toxicology, Western Washington Univ, Western Washington Univ, Institute of Environmental Toxicology, Western Washington Univ, Institute of Environmental Tox. & Chem.; P.M. Chapman, Golder Associates Ltd. In the popular song, *Hotel California*, by the band the Eagles, "they just can't kill the beast". That is exactly our situation – we (and many others) have not yet been able to kill the "beast" that comprises No Observed Effect Levels (NOELs) and Lowest Observed Effect Levels (LOELs). Given that the concentration-response curve is one of the founding paradigms of environmental toxicology it is absurd that hypothesis testing continues to be used to report toxicity. We submit that NOEL/LOELs do not meet the criteria of reporting concentration-response and the only scientifically defensible measure of toxicity is the description of the concentration-response "curve". If toxicity tests are going to be research tools, then the data analysis must accurately describe toxicity. Since the 1970s the "curve" has been demonstrated to provide detailed information including the slope, the ECx values and the error term. Software is available that makes the computation straightforward. Bayesian curve fitting has been developed that allows estimation of a true No Effect Concentration. The Bayesian curve fitting also provides credibility limits for the range of the curve. Since it is clear that the use of the "curve" is the only rational approach we propose 5 recommendations for the SETAC journals. 1. Papers that rely on NOEL/LOELs should not be considered for publication in journals. 2. Curve fitting is the preferred model for concentration/dose response relationships, ideally including confidence intervals and with supporting data. 3. NOEL/LOELs and similar data derivations should not be used as descriptions of concentration/dose-response. 4. Papers that rely on historic NOEL/LOELs should only do so after every attempt has been made to replace these data derivations with concentration/dose-response data. 5. Papers that treat NOEL/LOELs as data for further analysis such as the derivation of SSDs should receive extraordinary scrutiny. Although it is understood that for many tests these are the only results from toxicity tests that remain, the uncertainties in the accurate representation of the concentration-response curves result in unacceptable uncertainty to any inferred information. The broad implications of these recommendations to the journals and the field of environmental toxicology have not escaped us.

RP102 Characterizing the Influence of Environmental Conditions on the Toxicity of Mine Effluent Constituents to Standard and Non-standard Coldwater Fish D. Moore, Univ of Guelph, School of Environmental Sciences; D. Poirier, Ontario Ministry of the Environment, Laboratory Services Branch; P. Sibley, Univ of Guelph, School of Environmental Sciences, Dept of Environmental Biology; K. Solomon, Univ of Guelph, Centre for Toxicology, School of Environmental Sciences. A major critique facing the use of standard aquatic toxicology methods is their potential failure to protect against adverse effects seen under non-standard, real-world conditions. This may be, in part, due to their admitted limits found manifested in applied 'uncertainty factors'. However, rather than discard these familiar, proven methods of assessment and their wealth of historical comparative data, current standards should be actively amended and adapted to represent new advances - their uncertainty gaps shrinking as new data becomes available. Our study aimed to characterize the variability of mine-effluent-constituent toxicity across a range of cold-water fish species and environmental conditions to assess whether the current standard test is protective enough to cover this variation. Sixteen contaminants (Al^{3+}, Cd^{2+}, Cr^{3+}, Cu^{2+}, MoO_4^{2-}, Ni^{2+}, As^{3+}, Se^{2+}, NO_2^-, NO_3^-, SO_4^{2-}, NH_4OH, KCL, $MgCl_2$, CaCl, NaCl) were tested using five species of fish native to Northern Canada (rainbow trout, arctic charr, lake trout, lake whitefish, and arctic grayling) across a range of pH (5.5, 6, 6.5, 7, 7.5, and 8), temperature (5,10, and 15°C), and hardness (30, 60, and 120ppm) conditions and their observed effects modeled as 24,48,72, and 96-hour LC50 values. By comparing these 'amended standard' (varied conditions) acute toxicity assay results to those of the standard rainbow trout test (pH 7.5, 120ppm,15°C), we have characterized the effect of pH, temperature, and water hardness on contaminant toxicity and time-to-toxic effect within and between species while relating these differences to the ecological protection afforded by the current standard risk assessment method. The data suggests that, in some instances, the standard surrogate is not the most sensitive species - but more importantly, that by gathering more data, we can model this sensitivity/toxicity dynamic between species and water conditions so as to create a more accurate and representative standard method.

RP103 Development and Initial Evaluation of a Reconstituted Water Formulation that Better Represents Natural Waters S.M. Hoheisel, US Environmental Protection Agency, Student Contract Services; R.J. Erickson, T.L. Highland, J.R. Hockett, US Environmental Protection Agency, Mid-Continent Ecology Division; D. Hoff, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; T.J. Norberg-King, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; T.R. Valenti, US Environmental Protection Agency, National Research Council Grantee; D.R. Mount, US Environmental Protection Agency, ORD. The use of reconstituted waters is deeply entrenched in

many standardized aquatic toxicity testing protocols. The primary appeal of reconstituted waters is inter-laboratory comparability, such that experiments performed in different laboratories can be conducted in (nominally) identical waters. While several formulations of reconstituted waters have been developed over the years, many aquatic toxicity test protocols from the USEPA and ASTM use a formulation that has its roots in a publication by Marking and Dawson (1973). While widely used, the ionic composition of these waters is not typical of North American surface waters; for example, the molar Ca:Mg ratio in EPA/ASTM water is 0.70, but is averages about 2.2 in US waters. More dramatic are the differences in molar $Cl:SO_4$ ratio, which is 0.0632 in EPA/ASTM water, but is more typically in the range of 1 to 2 in US waters. We have developed a new reconstituted water formulation based on an analysis of natural waters from across the US Hardness was chosen as the master variable from which the remaining composition is calculated. The subsequent relationships that define the water composition are alkalinity v. hardness, Ca:Mg ratio, $Cl:SO_4$ ratio v. hardness, and K as a proportion of Na + K. Exactly mimicking natural waters is tedious in the laboratory, because natural waters gain alkalinity from calcium and magnesium carbonates, salts which are difficult to dissolve; this formulation uses only readily soluble salts, though this logistical convenience sacrifices some fidelity to the central tendency of natural waters. Recipes for water of any hardness (recommended bounds of 10 to 400 mg/L as calcium carbonate) can be calculated in a simple spreadsheet. Initial evaluation of these waters in chronic tests with *Ceriodaphnia dubia* and *Daphnia magna*, and short-term chronic tests with fathead minnows (*Pimephales promelas*), have shown performance in our proposed reconstituted water to compare favorably with Marking and Dawson-based waters or natural Lake Superior water. Additional testing with *Chironomus dilutus* and *Hyalella azteca* is planned. Using reconstituted waters that are more representative of natural waters should improve assessment of chemicals whose toxicity is influenced by the ionic composition of the water (e.g., many cationic metals), and may also improve performance of some organisms found to be sensitive to the ionic composition of water (e.g., *Hyalella*).

RP104 Evaluation of the Influence of Bromide or Iodide on the Performance the Amphipod *Hyalella azteca* in Reconstituted Waters C.D. Ivey, US Geological Survey, Columbia Environmental Research Center, USGS – CERC, Dept of Toxicology; C.G. Ingersoll, USGS, Columbia Environmental Research Center; N.E. Kemble, US Geological Survey, Columbia Environmental. Research Center, USGS – Biological Resources Division, Columbia Environmental. Research Center; J.L. Kunz, USGS; D.R. Mount, US Environmental Protection Agency, ORD; R.J. Hockett, US Environmental Protection Agency. Survival, growth, or reproduction of the amphipod *Hyalella azteca* (HA) is reported to be poor when some reconstituted waters have been used to conduct chronic (>14-d) water-only or sediment toxicity tests; including ASTM reconstituted hard water (with no addition of Bromide). USEPA held a workshop in Chicago in March 2010 with participants experienced in culture or testing of HA in water or in sediment. Participants at the workshop reported good performance of HA cultured or tested in Borgmann (1996) reconstituted water (with the addition of Bromide). In contrast, limited success was reported for laboratories conducting long-term water-only exposures of HA in Smith et al. (1997) reconstituted water (with no addition of Bromide). The suggestion was made at the workshop to evaluate Iodide based on the conclusion that the protective mechanism of Bromide and Iodide may be similar in improving performance of HA in reconstituted waters. The influence of Bromide (Br as NaBr) or Iodide (I as NaI) on the response of the HA under water-only 42-d exposures was evaluated in Borgmann or Smith et al. reconstituted waters along with well water (300 hard) and well water diluted with deionized water to 100 mg/L hardness as $CaCO_3$ (100 hard). Endpoints included 42-d survival, growth, biomass, and reproduction. Bromide was tested at three concentrations (0, 0.08 and 0.8 mg Br/L) in Borgmann, Smith et al., and 100 hard waters (0.8 mg Br/L is the concentration recommended for Borgmann water). Iodide was tested at three concentrations (0, 0.005 and 0.05 µg I/L) in Borgmann and Smith et al. waters. Good performance of HA was observed in the 300 hard and 100 hard waters, and addition of Br did not improve performance of HA in 100 hard water. Addition of Br or I in Borgmann water increased survival, growth, biomass, and number of young, with Br having a stronger influence compared to I. Good performance of HA was observed in Smith et al. water without the addition of Br or I which may have been due to an increase in the amount in YCT fed (up to 3 ml/day). In general the addition of Br (at 0.08 or 0.8 mg Br/L) had a stronger influence on the performance of HA compared to addition of I. Additional testing with Br is planned to determine if environmentally lower and more relevant concentrations of Br might improve performance of HA in chronic water or sediment exposures with various reconstituted waters.

RP105 Freshwater Mussel Growth and Survival in Sediments Influenced by Agricultural and Industrial Land Use P.D. Hazelton, Univ of Georgia, Warnell School of Forestry & Natural Resources, Univ of Georgia, graduate research assistant; R. Bringolf, Univ of Georgia, Interdisciplinary Toxicology; M.L. Urich, USGS-Patuxent Wildlife Research Ctr., Warnell School of Forestry and Natural Resource; P.J. Lasier, USGS-Patuxent Wildlife Research Ctr., Univ of Georgia. Freshwater mussels (order Unioniformes) are among the most critically imperiled taxa worldwide. In North America, greater than 70% of the native mussel species are listed as Endangered, Threatened, or species of special concern, and environmental pollution is often cited as a major contributor to this loss of diversity. To date, standardized methods and most toxicity research on freshwater mussels have focused on the effects of water borne contaminants on the survival of larval and juvenile stages within the mussel lifecycle. However, juvenile mussels acquire the majority of their nutrition through pedal feeding in the sediment and exposure to contaminants through sediments and pore water is likely a more realistic route of toxicity than through water-only exposures. We used existing methodologies for 28-day sediment-toxicity assessments to investigate the effects of sediments from a river impacted by agricultural and industrial land use on the growth and survival of juvenile (approx. 4 month old) mussels (fatmucket, *Lampsilis siliquoidea*). Sediments were collected from sites along the Conasauga River (northwest Georgia, US) that receive agricultural runoff and perfluorinated compound (PFC) pollution. A reference sediment was collected from outside of the watershed. We normalized effects of confounding sediment characteristics (i.e., total organic carbon, sediment size) as statistical covariates, and therefore isolated the effects of the contaminated sediment. Growth and survival differed among sites, leading to identification of river reaches that are most impacted by the various land uses. Results from our assay are particularly useful for ecological risk assessment since they incorporate exposures to environmentally realistic contaminant concentrations but minimize the confounding variability and logistic complexity of in situ studies.

RP106 It is Time for a Paradigm Shift in the Analysis of Toxicity Data for Regulatory Applications J. Diamond, Tetra Tech, Inc.; D. Denton, USEPA Region 9, c/o SWRCB. The whole effluent toxicity (WET) program in the US currently requires multi-concentration testing of effluents. While multi-concentration testing of chemicals is desirable for regulatory and scientific reasons, we believe this requirement is not as efficient for evaluating effluent compliance in a WET program. The key regulatory question of concern is whether an effluent is toxic or not, which is best answered statistically using a hypothesis approach, not a point estimate approach. However, the traditional hypothesis approach currently recommended does not reward high within-test precision. This paper describes the need for a paradigm shift in the analysis of WET compliance data consisting of three parts: (1) restate the null hypothesis so that test power is now associated with demonstrating that the effluent is not toxic; (2) use EPA's Test of Significant Toxicity (based on non-inferiority or bioequivalence approach) to define what is considered unacceptable toxicity as well as acceptable effects and to identify each condition with a high probability; and (3) evaluate only the test control and the critical concentration of concern (e.g., instream waste concentration). We demonstrate that together, instituting these three changes would provide: positive incentives for permittees to produce high quality WET data; a transparent analysis approach in which the permittee could have greater control over regulatory decisions based on WET test results; and potentially a less expensive testing program because fewer effluent concentrations need to be examined within a test. As a result, WET test frequency or increased within-test replication could be increased for the same cost as current testing programs while providing better characterization of effluent quality.

RP107 The Stream Pollution Trends (SPoT) Program: A Framework for Monitoring Long-term Water Quality Trends in California's Watersheds K. Siegler, Univ of California – Davis, Environmental Toxicology; J. Hunt, Univ of California – Davis, Dept of Environmental Toxicology; B. Phillips, Univ of California – Davis, Environmental Toxicology; B. Anderson, Univ of California – Davis, Dept of Environmental Toxicology; J. Voorhees,

Univeristy of California – Davis, MPSL – Environmental Toxicology; R. Tjeerdema, Univ of California – Davis, Environmental Toxicology. The Stream Pollution Trends (SPoT) program is a California statewide monitoring program designed to determine long-term trends in stream contaminant concentrations and effects, relate water quality indicators to land-use characteristics, and to establish a network of sites throughout the state to use in collaboration with local, regional, and federal monitoring programs. Sites at the base of 96 watersheds have been monitored for sediment toxicity and a suite of pesticides, trace metals, and industrial compounds since 2008. In 2008 23% of the sediments were significantly toxic to *Hyalella azteca* in 10-day tests when tested at 23 degrees Celsius. This trend continued in 2009 (39%) and 2010 (28%). Percent land use was calculated throughout the watersheds, and urban land uses had the most significant correlations with contaminant concentrations. Sediment toxicity was also significantly correlated with mixtures of pyrethroid pesticides. In 2010 a subset of 24 sites was also assessed using amphipod tests conducted at 15 degrees. Twice as many samples were toxic when tested at 15 degrees (42%), suggesting pyrethroid pesticides contributed to the observed toxicity. Data from this program are intended to detect changes in contamination and toxicity as management initiatives are implemented to reduce pesticide loading in California watersheds.

RP108 Use of Field Collected Aquatic Macroinvertebrates to Determine Acute Zinc Toxicity S.M. Pargee, GEI Consultants, Inc; S.P. Canton, GEI Consultants, Inc., Ecological Division. Toxicity of zinc to typically sensitive aquatic macroinvertebrates (mayflies, stoneflies, and caddisflies or "EPT taxa") in Colorado steams is relatively unknown and of particular interest when considering applicable zinc standards for coldwater trout streams. The lack of laboratory-derived zinc toxicity data using standard test methods for aquatic macroinvertebrates is likely due to unavailability of cultured test organisms and uncertainty associated with field collected organisms. We successfully collected, transported, and acclimated a mayfly (*Drunella grandis*), a stonefly (*Isoperla* sp.), and a case dwelling caddisfly (*Lepidostoma* sp.) from the South Fork Cache la Poudre River, Colorado, a stream unaffected by heavy metals from mining activities. We were unable to run tests with two other collected aquatic insects, the mayfly *Baetis* tricaudatus and the free-living caddisfly *Dolophilodes aequalis*, either as a result of sensitivity to handling stress from collection, transport, and test set up (*Baetis*), or inability to acclimate to laboratory test conditions (*Dolophilodes*). Static-renewal 96-hr acute toxicity tests were conducted using standard test methods in soft, hard, and very hard reconstituted lab water. Differences in toxicity and acclimation to laboratory conditions were observed within and between Orders. *Drunella grandis* performed very well both in the field collection phase and under laboratory conditions (LC50 >6.29 mg/L in hard water and >3.05 mg/L in soft water). Similarly, Lepidostoma sp. performed well (LC50 >38.8 mg/L in hard water and >81.7 mg/L in very hard water). No acute toxicity was observed for zinc concentrations up to 27 mg/L for *Isoperla* sp. Overall, toxicity values for these field collected EPT taxa were much greater than predictions based on comparisons to other sensitive macroinvertebrates or zinc tolerance values reported from field observations of aquatic insects near inputs of heavy metals (e.g., mining areas). This study demonstrated that with proper handling, and species specific considerations, use of field collected native species may be a valuable tool to help assess toxicity in aquatic environments.

RP109 Use of Water-only Chronic Toxicity Test Methods to Compare Life History Characteristics of Four Genetically Distinct Populations of *Hyalella azteca* K. Major, Univ of Illinois at Urbana-Champaign, Illinois Natural History Survey, Illinois Natural History Survey; D.J. Soucek, R. Giordano, Univ of Illinois at Urbana-Champaign, Illinois Natural History Survey. The epibenthic amphipod *Hyalella azteca* has long been used as a model organism for toxicity bioassays because of its importance to food webs, its adaptability to culture, and its wide distribution across North America. However, current morphological identification of this amphipod is proving to be insufficiently descriptive. Recent studies using allozymes and/or mitochondrial cytochrome *c* oxidase (COI) gene sequences have provided evidence for the existence of numerous undescribed species within wild North American populations of *H. azteca.* Furthermore, the extent to which *H. azteca* laboratory populations are accurate representatives of wild populations has not been established. Because life history characteristics are the basis for chronic toxicity test endpoints, identifying differences in these characteristics among different populations is critical. Therefore, our goal was to collect samples from various *H. azteca* populations, identify the populations genetically by sequencing the entire COI gene, and investigate whether genetically distinct populations differed in terms of life history attributes. First, we determined complete COI sequences for wild populations of *H. azteca* from sites in the US and Canada, as well as for several laboratory populations from commercial sources, US and Canadian regulatory agency laboratories, and academic research groups. Phylogenetic analysis with maximum parsimony yielded five distinct clades. Each of the five clades exhibited low within-clade percent divergence (< 3%), indicating that members of the same clade were conspecific. However, high across-clade percent divergences (17-20%) indicated that all clades exhibited species-level divergence from one another based on average COI divergence rates among other crustaceans. Next, we sought to compare life history characteristics of the different clades. Representative populations from four of the five clades were acclimated to laboratory conditions for at least three generations to eliminate potential differences due to environmental and/or maternal effects. 42-day chronic water-only toxicity test methods were used (with populations acting as treatments) to show that in addition to genetic differences among these clades, life history characteristics, namely body mass and male-to-female body mass ratio, differed significantly.

RP110 What Food and Feeding Rates Are Optimum for the *Chironomus dilutus* Sediment Toxicity Test Method? T.J. Norberg-King, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; T.L. Highland, J.R. Hockett, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; D.R. Mount, US Environmental Protection Agency, ORD; T.W. Valenti, National Research Council; US Environmental Protection Agency, National Research Council. Laboratory tests with benthic macroinvertebrates are commonly used to assess the toxicity of both contaminated sediments and individual chemicals. Among the standard procedures for benthic macroinvertebrates are 10-d, 20-d, and life cycle exposures using the midge, *Chironomus dilutus*. This presentation describes a series of studies conducted to evaluate and optimize feeding regimes for midge toxicity testing. Current ASTM and USEPA test guidelines specify feeding a fine suspension of flake fish food (i.e., blended in water) at a rate of 6 mg dwt/day to each replicate chamber of 10 organisms. In 10-d exposures in which the initial stocking density varied from 6 to 12 organisms per replicate, the final weight of larvae increased markedly as stocking density decreased, suggesting that food quantity or accessibility does limit midge growth under standard test conditions. Additional experiments evaluating higher feeding rates confirmed higher midge growth is obtained if daily rations were increased. However, higher rations of the standard food preparation also result in the depression of dissolved oxygen, which in turn can limit midge survival and growth. Experiments examining several other diets and preparations did not identify an alternative food source that supports both strong larval growth and not create problematic oxygen demand. However, when presenting flake fish food as a suspension of fine flakes (passing through a No. 50 sieve) rather than the blended preparation we observed improved growth. The fine flake food may have allowed food particles to more readily settle to the sediment surface as these treatments yielded high growth rates with lower feeding rates. A series of 10-d toxicity tests were conducted and subsamples for growth measurements were taken at 4, 7, and 10 d of the testing exposure in an effort to optimize a progressively increasing ration design. We discuss the implications of these findings for midge toxicity tests and provide recommendations on improved feeding regimes. Note: This abstract does not necessarily reflect USEPA policy.

RP111 Effective Risk Communication to an Ever Increasing Cynical Public A.E. Goldberg Day, ARCADIS, RAES. Risk communications became prominent in the mid-1980s, when regulatory agencies realized that the risk management policies proposed by environmental specialists often were complex and were not necessarily acceptable to the wider public. Since that time, risk communication has evolved from human health risk assessment methodology from research on how individuals perceive risk. It is defined as an interactive process of exchange of information and opinion among individuals, groups, and institutions. It often involves multiple messages about the nature of risk or expressing concerns, opinions, or reactions to risk messages, or to legal and institutional arrangements for management. During the presentation, the USEPA's key rules for effective communication will be presented. The goal of the discussion is for the attendees to gain tools to aid them in their own risk communication endeavors. KEY RULES FOR

EFFECTIVE COMMUNICATION (from the USEPA) • Accept and involve the public/other consumers as legitimate partners. • Plan carefully and evaluate your efforts with a focus on your strengths, weaknesses, opportunities, and threats. • Listen to the public's specific concerns. • Be honest, frank, and open. • Coordinate and collaborate with other credible sources. • Meet the needs of the media. • Speak clearly and with compassion.

RP113 Life Cycle for Microalgae-based Biofuels: Reducing Footprint and Production Costs by Using Waste from Sugar/Ethanol Plants as Raw Material J.A. Neto, H.L. Maranduba, Santa Cruz Univ, Dept of Agricultural and Environmental Sciences; I.A. Nascimento, Federal Univ of Bahia, Dept of Biology. In the actual world energy scenario, ethanol and biodiesel are pointed out as partial substitutes for petroleum products to attend the transportation sector. Regarding ethanol, Brazil ranks second worldwide with a production of 31 billion L, while for biodiesel the installed production capacity is 5.5 million L/year, able to replace diesel by 5%, according to National Energy Policies. This replacement is attractive due to the availability of agricultural land and the wider variety of oil-seed species. However, the expansion of crops leading to land use changes, may release the CO_2 stored in soil and nitrogen gases, intensifying the GHGs effects, thus negating the benefits of biofuels to curb emissions. Microalgae emerge as a viable solution as feedstock for biofuels. In relation to land-crops, microalgae have higher productivity and higher capacity of CO_2 sequestration. However, the proliferation of microalgae cultivation systems depend on their footprints and production costs reduction. Based on life cycle analysis and converting all GHGs and energy usage to tone of carbon dioxide equivalent/year, three alternatives to the two isolated processes of producing ethanol from sugar–cane and biodiesel from microalgae cultivated in open ponds have been compared to different associations of both processes : (i) biodiesel production based on microalgae biomass output, by using CO_2 from ethanol production and biodigested vinasse as source of nutrients; (ii)-the same conditions as alternative (i), plus the harvest water recycling; (iii)-the same conditions as (i) and (ii), plus the production of methane from the residual biomass and carbon-free electricity. The results highlight the benefits of all the three alternatives involving the co-production of biofuels from microalgae cultivation process inserted into the sugar/ethanol plants and indicate the approach (iii) as the most viable to reduce production costs and to decrease biodiesel and ethanol footprints.

RP114 Study on the Greenhouse Effect Assessment of Land Use Based on LCA S. Chen, X. Yang, Beijing Univ of Technology. The greenhouse gas emissions from land use every year are 11 times the emissions from fossil fuel. The greenhouse effect caused by the process of land use on global climate change is crucial. In this study, based on the impact assessment method of land use in life cycle assessment and models of IPCC, the calculation models of GHG emissions of two types land use including land occupation and land transformation were established. According to the proposed models and land use situation in China_the classifications of land are natural forests ,man-made forests, grassland, paddy fields and dry farmland. Based on the study of GHG emission regarding of different types land in various climatic zone, we proposed the greenhouse effect factors of different types land in various climatic zone in China. We also summed up the length of one type land being transformed to another in China. In addition, with the land occupation of buildings and the land transformation of forests being taken as case studies, the greenhouse effects of land use were estimated using the proposed models in China. The research is sponsored by the Twelfth Five-year National Science & Technology Support Program (NO. 2011BAC04B03 & NO. 2011BAC04B04)

RP115 Modeling Biodiversity Impact into Environmental Life Cycle Assessment B. Neupane, Univ of Maine, graduate research assistant; A. Halog, Univ of Maine, Research Group of Industrial Ecology, LCA and System Sustainability (IELCASS), Univ of Maine, Assistant Professor of Industrial Ecology and LCA. A clean and sustainable source of energy is important for economic development of a nation. One of the tools to assess the environmental sustainability of energy systems is life cycle assessment (LCA). The major life cycle impact categories considered in current LCA practice include climate change potential, acidification potential, eutrophication potential, photochemical oxidants, fossil fuel depletion, fresh water toxicity, etc. This, however, does not account for biodiversity impacts and land use implications. The study attempts to develop a framework to incorporate biodiversity impact category into conventional LCA method. This framework is applied in the context of woodchips production used in biorefinery for ethanol production. In the proposed framework, the Landscape Management System (LMS) tool is used to model forest management activities for a set of harvesting systems under consideration. Forest stands level information, such as habitat type and stand-development stages, are used to prepare a habitat-species relationship matrix. This matrix information was incorporated into LCA inventory modeling to prepare a set of characterization factors. Habitat type classifications and corresponding area calculations are spatially represented using Geographical Information Systems (GIS). Different biodiversity impact indicators (e.g., species richness and habitat naturalness, etc.) are used to model the biodiversity impact. The results show that biodiversity impact increases as the ethanol blending proportion to gasoline is increased. The potential biodiversity impact is found to be higher in the first decade of the considered time frame, and it shows a flattening trend towards the next decades. From our analysis, it can be concluded that when a whole rotation length of forest is considered, the potential biodiversity impact is relatively unchanged after the first few decades.

RP116 Spatially Differentiated Worldwide Midpoint and Endpoint Characterisation Factors for Acidification P. Roy, CIRAIG, CIRAIG; L. Azevedo, M. Huijbregts, Radboud Univ; L. Deschenes, M. Margni, M. Margni, CIRAIG. With the globalization of markets, assuming that the entire life cycle emissions of a product system occur within a specific geographical area (e.g., Europe or Canada) is no longer a suitable assumption for regional impact categories, since the impact of a same elementary flow varies from an emission location to another. Furthermore, current LCIA approaches do not allow to consistently assess and compare emissions occurring from different continents as the characterization factors (CF) are obtained from different characterization models. Thus, a model covering a worldwide scale, but also able to account for local conditions, needs to be developed to provide consistent regionalised CFs worldwide. This work presents a new global characterization model able to consistently evaluate acidifying emissions at both the local and global scale for the acidification impact category. The emission location based midpoint and endpoint CFs for emissions of NO_x, SO_2/SO_4 and NH_3 were obtained on a 2x2.5° (latitude x longitude) spatial grid resolution. The CFs from this resolution were then aggregated to provide other CFs at coarser resolutions: worldwide, continental and country level (states and provinces resolution were also provided for the US and Canada). Midpoint CFs were obtained from the multiplication of an atmospheric fate factor (FF) and a receiving environment sensitivity factor (SF). FFs [keq deposited/ha/yr, kg N or S emitted/yr] derivation was based on the global atmospheric model GEOS Chem. SFs [mol/L ha, keq deposited /ha/yr or ha, keq deposited/ha/yr] were evaluated through the variation, caused by a marginal change in emission/deposition, of, respectively, two different soil chemical indicators: H+ concentration (linked to pH) and the base cations (Ca^{2+}, K^{+}, Mg^{2+}) on aluminum (Al) ratio. Variations in soil chemical indicators were evaluated using the PROFILE steady-state model and a developed global dataset. Endpoint CFs were obtained from the multiplication of the previously mentioned FFs and SFs with an effect factor (EF). The biome specific EF [-, mol/L] curves links change in the potential occurrence of species (PNOF) due to a change in soil's pH. The results showed that both midpoint and endpoint CFs were highest at emission location where soils have limited buffer capacity (e.g., boreal forest).

RP117 Use of Lifecycle Tools to Optimize Sustainable Energy Campuses J. Fava, Five Winds International; E. Beaver, Carbolytic Materials Company; S. Baer, PE International, 20 Paoli Pike. This paper describes the use of GaBi (TM) Life Cycle software to optimize the design of a Sustainable Energy Campus based upon feed of scrap automobile and truck tires. Further, once the Sustainable Energy campus is defined, the software and related tools are used to compute the benefits of reduced lifecycle consumption of fossil fuels, emission of greenhouse gases and other wastes and the overall energy savings. The SEC combines multiple technologies from different industries to create a truly sustainable "waste-to-profit" campus where the waste from one technology be becomes the input to another technology that utilizes that waste to create highly profitable fuel products. GHG are reduced, materials recovered, energy optimized and virtually no emissions. Further, the reality is highly profitable.Thus, waste-to-profit. Technologies from the rubber, chemical and petroleum industries are at play in the Sustainable Energy Campus. A Carbon Black recovery production line takes scrap tires and uses a vacuum pyrolysis process to convert those tires into

a product called Carbon Black Alternative and a stream of pyrolysis oil. Carbon Black is present in 75-85% of all new tires produced worldwide. A cracking and reaction technology combined with a sophisticated separation process converts the pyrolysis oil into raw materials for gasoline, kerosene, diesel, naphtha, jet A fuel base and liquified low molecular weight hydrocarbons (propane, butane and pentane). While each step can be profitable independently, combining them in a single site with cogeneration allows for energy and materials optimization as well as maximizing revenue. Further, minor components are captured and isolated which have extremely high value. The key materials are cyclic terpenes and high been recovered at high yields and high purities. A single scrap tire weighs approximately 21 pounds and one tire is produced per year per person in industrialized countries, the SEC provides a means of producing massive amounts of valuable products which otherwise would be produced from incremental fossil fuels and raw materials at significant cost to society and the environment. A full scale tire pyrolysis unit utilizing this teechnology has been in operation for more than a year producing more than ten million pounds of carbon black along with the co-products. The data related to mass of products, energy savings and net environmental impact will be presented and discussed.

RP118 Normalization and Weighting Using Multi-criteria Decision Aids Under High Uncertainty T. Seager, Arizona State Univ, School of Sustainable Engineering & Built Environm; V. Prado, Arizona State Univ, School of Sustainable Engineering & the Built Environment; S. Tylock, Sustainable Intelligence, LLC. Existing ISO recommendations call for *external* normalization of characterized life cycle inventories relative to nation- or multi-nation accounts, such that all mid-point categories are expressed as a dimensionless fraction. This approach is problematic in several respects, especially in cases where the primary purpose of the life cycle assessment is for comparing emerging or prospective technological alternatives. For example, previous research has demonstrated that the ISO approach can mask aspects of a life-cycle decision that may be critically important. Moreover, ISO provides little guidance on handling uncertainty – either in reference data or in weight sets. This presentation demonstrates a novel approach to normalization and weighting in impact assessment that is especially applicable to conditions of novel technology comparison that adapts established methods of multi-criteria decision analysis developed to support environmental management. Most notably, the new method uses *internal* normalization, thereby obviating the need for a reference dataset, and is designed specifically to allow stakeholders to explore the sensitivity of preferred rank orderings to uncertainties of several types, including weight sets. The results can potentially facilitate deliberative dialogue among stakeholders with competing value systems, or serve to prioritize additional research. We propose that the new method be adopted at the earliest stages of product or policy development, where both the uncertainties and the stakes may be highest.

RP119 Bridging Generic Inventory with Spatialized Characterization Factors: First Results G. Bourgault, P. Lesage, R. Samson, CIRAIG. Spatialization of impact assessment methods results, for each elementary flow, in a set of characterization factors (CFs) whose choice depends on the longitude/latitude coordinate of the emission. Regardless of the impact category, recent findings revealed that variability of CFs over space covers several orders of magnitude when using a subwatershed or very fine air grid delineation. Inventory, on the other hand, typically provides spatial information on emissions at a much coarser resolution, for example at the country level. This situation is likely to stay unchanged in the near future. In the absence of the necessary spatial information in the inventory, a choice has to be made in the set of CFs for each emission. Since they cover such a wide range of values, the outcome of the LCA is likely to be sensitive to the choice, and the criteria for choosing particular CFs should be transparent and rigorous. In the present project, TRI (USA) and NPRI (Canada) are used to localize each emission site for each elementary flow. This localization allows for a) proper weighting of the spatialized CFs in the calculation of a site-generic CFs based on the spatialized CFs, and b) a quantification of the uncertainty created by the lack of spatial information in generic databases. Preliminary results show a very unequal distribution of emissions throughout North America, underlining the necessity of taking into account this information in the calculation of a site-generic CFs.

RP120 Creating a US National Standard for Life-Cycle Environmental Performance Assessment B.H. Karsell, Independent Environmental Consultant. A committee is developing a US national standard for type III life-cycle impact profile declarations for products, services and systems sufficient to support public declarations and claims. The committee is following the ANSI standard development process, and is sponsored by the Leonardo Academy, the only ANSI-accredited standard development organization to require participation by environmental interests. The standard will include the following attributes: Compliant with ISO 14044 Use best available science Quantify all relevant environmental impacts Include no value judgements Allow no aggregation of impacts among impact categories Produce consistent and auditable results To date the draft standard includes 25 different categories of environmental impacts. The committee is actively seeking engagement with and vetting of the standard practice by all interested stakeholders. We expect to produce a final standard in 2012.

RP121 Field and Laboratory Boron Toxicity Results and New Understanding of Boron Bioavailability, Fate and Transport: Implications for Guideline Development G.J. Huber, A.L. Knafla, Equilibrium Environmental Inc.; D. Lintott, Exova. Boron is a metalloid micro-nutrient for plants which can also be phyto-toxic at elevated concentrations. It is a common co-contaminant found with salts such as sodium chloride, and may be introduced into soil and groundwater from produced water from oil and gas operations. It is also used in agriculture as a fertilizer, and in industrial processes such as fibreglass manufacturing. Boron can also be found in elevated concentrations in groundwater in arid regions such as California, where irrigation with boron-laden groundwater can cause significant toxic effects on plants. Soil quality guidelines for boron are currently based on older plant toxicity data, with limited integration between toxicity data from irrigation water and measured concentrations in soil. Consequently, research has been performed over the last several years in Canada with the aim of developing updated, risk-based soil quality guidelines for boron. These would integrate updated plant toxicity and bioavailability results along with enhanced groundwater fate and transport modeling. The updated plant toxicity testing was based on a combination of field and laboratory tests, with laboratory toxicity testing protocol from Environment Canada providing standardized methodologies for evaluating adverse effects on plant growth. These laboratory toxicity tests suggest that toxic thresholds may be significantly higher than the Canadian soil quality guidelines of 2 mg/kg "hot-water soluble" (HWS) boron. Recent field studies performed with a variety of agricultural species also suggest that toxic thresholds are above existing soil guidelines. Traditional soil tests such as the HWS method were compared to potential alternative test methods to evaluate their relevance to the bioavailability of boron to plants and other receptors along with fate and transport properties. The HWS boron methodology was found to be unsuitable for measuring the bioavailable amount of boron in soil to terrestrial rodent wildlife species, livestock, humans, and plants, with alternative test methods showing improved relevance. The HWS methodology was also found to not provide a good representation of the amount of mobile boron in groundwater. Enhanced transport modeling based on alternative soil tests to other groundwater receptors such as aquifers and surface aquatic systems will allow integration of drinking water guidelines, irrigation guidelines, and aquatic life guidelines into updated soil guidelines in the future.

RP122 Variation in Metal Bioaccessibility in the Canadian Maritimes M. Dodd, Royal Roads Univ, School of Environment & Susttainability, Royal Roads Univ, School of Environment & Sustainability; A. Rencz, Natural Resources Canada – Geoligical Survey of Canada, Geoligical Survey of Canada; P. Friske, Natural Resources Canada – Geological Survey Canada; W. Beirsto, Golder Associates. The North American Geochemical Landscapes Project was initiated to provide a soil geochemical database for a broad-based group of users in the field of environmental and human health. The survey is based on low-density sampling (within a 40 km by 40 km grid) in Canada, the United States and Mexico yielding 13,212 sites in total. This Tri-national survey will ultimately produce a database of the regional natural-occurring differences in concentrations and physicochemical characteristics which can be used to assess background conditions and identify anthropogenic impacts. The Canadian part of the project was initiated by Natural Resources Canada – Geological Survey of Canada (GSC) in partnership with other provincial and federal agencies including Health Canada. Sampling has been completed in the Canadian Maritimes comprising Nova Scotia, New Brunswick, Prince Edward Island and Newfoundland. A sub-set of the samples collected from the surface (0-5 cm), B and C horizons were analyzed for metal bioaccessibility using a simplified physiologically based extraction test as a surrogate for biovailability. The data indicated variation

in metal bioaccessibility among the provinces. Differences in metal bioaccessibility for the three soil horizons were also noted. There were also some statistically significant relationships between metal bioaccessibility and geochemical data including total metals, soil pH, total organic carbon and loss on ignition. It is anticipated that this data will form the basis for the continuing studies aimed at completing a national picture of metal bioaccessibility in background soil samples and its relevance to human and ecological health risk assessment in Canada.

RP123 Geochemical and Biological Factors Allow Better Understanding of Sedimentary As, Cd and Cr Uptake in a Deposit-feeding Polychaete *Nereis succinea* Z. Baumann, N. Fisher, Stony Brook Univ, School of Marine and Atmospheric Sciences. Contaminant metals are not irreversibly bound to sediment, hence they can pose risks to resident biota and, following trophic transfer, they can also pose human health risks from seafood consumption. It is therefore important to understand the extent, pathways and mechanisms of toxic metal bioaccumulation in contaminated coastal waters. To better quantify metal bioaccumulation in a benthic invertebrate, the assimilation efficiency (AE) of ingested As(V), Cd, and Cr(III) were assessed in the deposit-feeding polychaete *Nereis succinea* feeding on estuarine sediments. Uptake of metals from pore water and efflux rate constants following dietary or aqueous metal exposures were also determined. To measure metal concentrations, water, sediments and polychaetes were collected from three different estuarine sites – two in Chesapeake Bay and one in San Francisco Bay. Patterns of geochemical partitioning of As, Cd and Cr were also determined in the laboratory and were linked to observed bioaccumulation of these metals in the field-sampled polychaetes with good correlations (r^2 = 0.84 – 0.87). To incorporate the geochemical link into bioaccumulation modeling we modified a commonly used bioaccumulation model by incorporating the geochemical fractionation of the metals in the sediments. The model indicated that >97% of metals are acquired by worms via ingestion. To further explore the ingestion pathway, we investigated possible mechanisms of As assimilation in *N. succinea*. The release of As from sediment particles into gut fluid extracted from *N. succinea* was related to As AEs, however As released from inorganic particles (e.g., goethite) was largely unassimilated, whereas As bound to organic compounds and released from algal cells was assimilated very efficiently. Thus, the likelihood of As assimilation is higher when it is bound to an organic compound that is of nutritional value to the polychaete.

RP124 Impact of the Earthworm *Lumbricus terrestris* on the Mobility and Speciation of Arsenic T. Sizmur, Univ of Reading, Soil Research Centre, Univ of Reading, Soil Science Dept; M. Watts, B. Palumbo-Roe, British Geological Survey; J. Charnock, Univ of Manchester; M. Hodson, Univ of Reading. Human activities have resulted in an increase in the concentrations of As in both urban and rural soils. In order to properly assess the risks that As poses to the environment a greater understanding on how soil biota influence the fate of As in soil is required. The bioavailability of As in soil is greatly dependent on its mobility and speciation but little is known about the effect of passage through the earthworm gut on the mobility and speciation of As. Earthworms burrow in the soil and create casts that are chemically different to the surrounding soil. These casts are often produced on the surface of the soil and there is therefore potential for As to be leached out of the casts into water courses at a rate greater than that predicted by models used in risk assessment. We carried out experiments to determine the impact of passage through the gut of a UK native anecic earthworm; *Lumbricus terrestris* L. on the mobility and speciation of As in soil (1130 mg kg^{-1} As) collected at Devon Great Consols, an abandoned Cu and As mine situated on the bank of the river Tamar, UK. *L. terrestris* were cultivated in the As-contaminated soil and the casts collected. Water soluble As increased from 1.6 mg kg^{-1} in the bulk soil to 18 mg kg^{-1} in the casts. Casts were then aged and this effect was still present 56 days after soil excretion. HPLC-ICP-MS analysis coupled with synchrotron based techniques (EXAFS/XANES) indicated that no reduction of As(V) to As(III) occurred, despite passage of the As through the anoxic rear-gut of the earthworm. Observed increases in As mobility in casts were due to release of As(V) from soil particles during the digestion process as a result of increases in pH and increased concentrations of disolved organic carbon. The mobilisation of As (and other elements) from contaminated soils in the environment by cast production may allow for accelerated leaching or uptake into biota which is under-estimated in current risk assessments and models based on analysis using soils in the absence of soil biota. This research therefore has implications for the risk assessment of As contaminated sites and for As biogeochemical cycling.

RP125 The Effect of Road Salt on the Metal Binding Ability of Adsorptive Media A. Whiting, Towson Univ; R. Casey, Towson Univ, Urban Environmental Biogeochemistry Laboratory, Towson Univ, Dept of Chemistry; S.M. Lev, D. Ownby, Towson Univ, Urban Environmental Biogeochemistry Laboratory. Many studies have verified the connection between increasing urbanization and declining water quality in tributaries of the Chesapeake Bay. Urban stormwater runoff is currently one of the most significant causes of aquatic habitat degradation. To mitigate the effects of stormwater, researchers have studied the effectiveness of different media as stormwater filters. However, the effect of road salt on the effectiveness of those media is often overlooked. This project evaluated possible media solutions to road salt-impacted stormwater runoff. Stormwater was collected from the scuppers of two highway bridges and analyzed for dissolved ions, metals, and total suspended solids. Highest metal and salt concentrations collected were 95 µg/L Zn, 55 µg/L Cu, 48 µg/L Cr, 39 µg/L Pb, 4 µg/L Ni, 1713 mg/L Na and 2609 mg/L Cl. The second part of the project evaluated filter media provided by Contech Construction Inc. and Imbrium Systems, Inc. to remove stormwater contaminants from runoff before they reach the aquatic environment. Batch tests were conducted to quantify media effectiveness. Treatments for the batch tests included three salt concentrations (none, 2.5 g/L, 5 g/L NaCl) mixed with a standard combination of metals as their nitrate salts (500 _g/L Zn, 100 _g/L Cu, 50 _g/L Pb, 50 _g/L Cr, and 50 _g/L Ni). Metals and salt concentrations used in the treatments were reflective of values found in the highway bridge runoff sampled. Batch tests included two blank tests (deionized water and artificial stormwater with no metals or salt added). Deionized water exchanges revealed that all Imbrium media released Na+ (3.5 – 1181 mg/L), and all but one released SO42- (3 – 2929 mg/L). A zeolite tested released a small amount of Zn (10 µg/L) while a compost based media released 80 mg/L K+ and 10 mg/L Cl- on average. After completion of batch tests, column studies will be conducted on the most effective media.

RP126 Weathering Transformations of Sorption Properties of Biosolids for Metals and Their Possible Environmental Implications I. Twardowska, E. Miszczak, S. Stefaniak, Polish Academy of Sciences, Institute of Environmental Engineering. Stabilized sewage sludge has a long tradition of use in agriculture as biolsolids (BS) in North America. In the European Union, the environmentally safe way of its application in agriculture is encouraged by the Sewage Sludge Directive 86/278/EEC that sets out limit values for metals concentrations in sludge and sludge-amended soil. In parallel with increasing quantities of sewage sludge generation, the controversies with respect to the environmental safety of BS are also growing, and the need of the revision of the Sewage Sludge Directive is being currently assessed. The BS application to soil is an irreversible process, thus its temporal weathering transformations should be strongly considered in view of long-term alterations of sorption capacity and binding strength for metals, which may cause metal mobilization. To contribute to clarification of the effect of weathering onto BS capacity for metal binding, a preliminary study was carried out, with use of a unique material – sewage sludge of a known age (0, 5-, 10- and 15 years old) stored in the 24 open shallow lagoons at the Bytom-M (Silesia, Poland) urban wastewater treatment plant . Experimental design comprised assessment of the age-related BS properties exerting a crucial effect on the sorption capacity, such as water content, pH, OM, CECt, exchangeable cations, TOC, functional groups, trace metals (Ni, Zn, Cd, Cu, Cr, Pb) and other elements (Ca, Mg, Fe, Mn), and their binding strength. Also, batch metal sorption experiments were conducted to evaluate age-related changes of BS sorption capacity. Long-term exposure of BS to atmospheric conditions resulted in pH decrease, reduction of OM, TOC, amorphous Fe and declining of HS functional groups involved in metal binding onto humic substances. Since the sorption capacity of BS for trace metals appeared to be up to several orders of magnitude higher than their initial content in BS, no initial metal loads release from BS over time was observed. At the same time, decrease of pH and OM caused a significant decline of weathered BS sorption capacity for metals. This lead to the conclusion that weathering transformations in principle do not affect mobility of metals initially present in BS applied to soil as amendment. On the other hand, at use of BS as sorbents in permeable barriers and protective layers against metal migration, the clear decrease of BS sorption capacity over time may result in metal release and adverse environmental implications.

RP127 Elucidating a Biosynthetic Pathway for Arsenobetaine in the Terrestrial Fungus *Agaricus bisporus* M.M. Nearing, Environmental Sciences Group, Royal Military College of Canada, Dept of Chemistry and Chemical Engineering; I. Koch, Environmental Sciences Group, Royal Military College of Canada, Royal Military College of Canada; K.J. Reimer, Environmental Sciences Group, Royal Military College of Canada. Arsenic can be taken up by fungi from contaminated soils and thus subsequently enters food chains. This can cause concern since some arsenic compounds are toxic. Fungi in the class Hymenomycetes collected from arsenic contaminated soils produce fruiting bodies that have been found to contain a variety of arsenic compounds. In many cases arsenobetaine (AB), a non-toxic organoarsenical, comprises the majority of arsenic compounds present in these terrestrial fungi. *Agaricus bisporus* is an example of an edible species of mushroom in which AB is found to be the major arsenic compound. We recently confirmed this was true at ambient concentrations in locally farmed white and brown varieties of *A. bisporus*. The life stage at which the fungus produces AB is still unknown, as is whether the fungus, alternatively, accumulates AB from the surrounding environment. That is, the surrounding microbial community in the soil may produce AB or its precursors and these may be selectively taken up by the fungus. In order to elucidate a potential biosynthetic pathway for AB in the terrestrial fungi the vegetative (mycelium) and reproductive life stages (fruiting bodies) of the fungus *A. bisporus* were cultivated under axenic conditions and exposed to various arsenic compounds including monomethylarsonic acid (MA^V) , dimethylarsinic acid (DMA^V) , and trimethylarsine oxide (TMAO). Mycelium was cultivated in a liquid medium containing 250µg/L of MA^V, DMA^V or TMAO for 21 to 30 days. Arsenic compounds extracted from the mycelium and surrounding growth medium were identified using high-performance liquid chromatography coupled with inductively-coupled plasma mass spectrometry (HPLC-ICP-MS). *A. bisporus* mycelium was capable of accumulating MA^V (566 – 674µg/kg dry weight), DMA^V (426 – 749µg/kg dry weight) and TMAO (269 – 1159µg/kg dry weight) from the surrounding growth medium. No biotransformations were observed in any of the treatments indicating that very little arsenic metabolism occurs during this life stage and AB is not produced at the vegetative life stage of *A. bisporus*. Further mycelium exposure experiments using longer exposure periods and other arsenic compounds, for example arsenate (As^V), are currently being conducted to confirm this finding. The results of the exposure experiments will contribute to the understanding of how AB is synthesized in the terrestrial environment.

RP128 68Zn:66Zn Ratio of *L. terrestris* Fed on a Diet of 68Zn Spiked Oat Bran K. Linford, Towson Univ, Urban Environmental Biogeochemistry Laboratory; R.E. Casey, Towson Univ, Dept of Chemistry. This study is part of a larger effort to quantify the pool of soil zinc bioavailable to *Lumbricus terrestris*. Enriching *L. terrestris* with ^{68}Zn can enable us to observe the subsequent decrease of ^{68}Zn: ^{66}Zn in *L. terrestris* organ tissues, which previous work has shown is related to soil zinc bioavailability. Previous work in this laboratory evaluated the bioavailable zinc pool in the soil by enriching *L. terrestris* with ^{68}Zn using ^{68}Zn-spiked soil. Subsequent experiments showed that the zinc in these zinc-spiked soils becomes unavailable to *L. terrestris* over time (1 year). Thus, Zn spiked food may be a preferable source of enrichment. Studying the effects of zinc dietary exposure was necessary to determine a zinc application rate that would not result in stress to the organism or zinc accumulation in the tissues. Zinc accumulation in the tissues may result in increased zinc tolerance over time. Oat bran was selected as a food item due to its very low background zinc concentration of 11.23 mg/kg and its palatability. An initial experiment showed that feeding oat bran spiked with $ZnCl_2$ up to 300 mg/kg resulted in no decline in growth rate of the worms. Additionally, no Zn accumulation occurred in the epidermis, gut, or organs of *L. terrestris* upon feeding oat bran spiked with $ZnCl_2$ (0-500 mg/kg). A feeding rate of 200 mg/kg $ZnCl_2$ was selected in order to avoid decline in growth. Currently, a kinetic experiment is being performed to determine the amount of time needed to achieve an adequate enrichment of ^{68}Zn:^{66}Zn in *L. terrestris* organ tissues through dietary exposure.

RP129 Developing a Copper Isotope Ratio Method for Estimating Copper Availability to *Eisenia fetida* M. Mazzei, Towson Univ; S.M. Lev, D. Ownby, Towson Univ, Urban Environmental Biogeochemistry Laboratory. Determining the extent of uptake and accumulation of micronutrients from the environment by an earthworm such as *Eisenia fetida* is challenging given the organisms ability to regulate internal levels. Trace metals such as Zn and Cu fall into this category and as a result, make terrestrial risk assessment challenging for sites contaminated by these metals. This is particularly problematic for an element like copper given the plausible risk of trophic transfer as well as toxicity and biomagnification. The use of stable isotopes to trace the exchange (turnover) of metals from the environment into the earthworms' body was demonstrated to be a useful tool for Zn in soil systems. This study extents the method to Cu with three goals: 1) use isotope turnover in the organism as a measure of bioavailability, 2) link toxicity with isotope turnover, and 3) investigate the kinetics of Cu uptake and elimination in *E. fetida*. Cu turnover can be measured using the change in stable copper isotope ratios in the organism after exposure. A 10d copper accumulation and elimination test was performed to understand general turnover rates with respect to two things: our ability to get the enriched ^{65}Cu isotope into the earthworms and how quickly they would eliminate it once returned to clean soil. All earthworms began in spiked isotope top soil (^{65}Cu-enriched) for accumulation and were transferred to non-spiked top soil (^{63}Cu-natural abundance) for elimination. This experiment demonstrated that the elimination of ^{65}Cu occurs within 24h of exposure. A second accumulation and elimination test was performed with two modifications to the above procedure: tighter spaced sampling intervals within a 24h experiment and three concentrations of non-spiked top soil were utilized in the elimination phase. Elimination of ^{65}Cu occurred within 2h of returning earthworms to natural isotope abundance soil. With estimating bioavailability, that small window of time made measuring bioavailable Cu difficult. The most prominent information gained throughout this endeavor dealt with the kinetics of Cu within *E. fetida*. The isotope ratio method showed that these worms exchange Cu rapidly from an environment where Cu is readily available. This detected physiological exchange would not be possible using an unlabeled soil. Therefore, the drastic isotopic ratio drop does support that Cu was bioavailable from the soil environment, not from internal Cu pools of the earthworm.

RP130 Geographic Distribution of Heavy Metal Concentrations in Feathers of the Declining Rusty Blackbird S.T. Edmonds, BioDiversity Research Institue, Wetland Bird Program, Acadia Univ, MSc student; D. Evers, Biodiversity Research Institute; J. Murimboh, Acadia Univ, K.C. Irving Environmental Science Centre; N. O'Driscoll, Acadia Univ, Acadia Univ, Dept of Earth & Environmental Sciences. The Rusty Blackbird has undergone a population decline of over 90% since the 1960s and no consensus has been reached as to the dominant driving factors. Recent studies have shown that mercury concentrations within New England and Maritime Canada are elevated and may potentially act as a negative stressor. We analyzed Rusty Blackbird flight feathers for a suite of heavy metals and selenium from breeding birds in New England, Maritime Canada, and Alaska, and from wintering birds in the southern US to assess the potential for other toxicant stressors and identify those elements that may require additional investigation. Eastern breeding individuals had significantly greater concentrations of cobalt (8x greater, mean = 0.68 ppm), manganese (12x greater, 197 ppm), and lead (1.3x greater, 1.12 ppm) than Alaskan birds, while Alaskan breeding birds had 4x the concentrations of arsenic (0.45 ppm). While few to no studies have examined the effect of these heavy metals on blackbirds, the concentrations observed for manganese (138 ppm) and chromium (5.31 ppm) appear to exceed levels of concern reported for other avian species and warrant further investigation.

RP131 Realistic Risk: Importance of Site-specific Biota Data for Quantifying BAFs A. Shortelle, AMEC Environment & Infrastructure; E. Curtis, AMEC Environment & Infrastructure, Project Manager – Ecological Risk Assessment; M. Bystedt, N. Ruberti, T. Glover, AMEC Environment & Infrastructure. A site-specific terrestrial invertebrate bioaccumulation study on arsenic, cadmium, copper, lead, and zinc was conducted for a site in western Georgia using the approach presented in Development and Validation of Bioaccumulation Models for Earthworms (Sample et al., 1998). The bioaccumulation factors (BAFs) and slopes provided in Sample's study are typical of literature based soil-to-biota bioaccumulation factors, but these values have a layer of conservatism, the upper prediction limit, built in for use at sites with no available invertebrate data. The BAFs in Sample (1998) are often used for estimating metal concentrations in biota tissue in food-web modeling in the absence of site-specific biota tissue data. However, the use of the upper predictive limit often leads to overestimation of metal concentrations in biota tissue. The site-specific dataset obtained from the terrestrial invertebrate bioaccumulation study was small and displayed

limited variability. A relationship between soil and tissue concentrations was developed by combining site-specific data with the biota BAFs developed from the larger Sample dataset (1998). Using this approach, a more realistic quantification of risk for ecological receptors was determined than was provided by the sole use of the literature-based BAFs.

RP132 Risk Assessment and Aquatic Macrophytes: A Method to Test Six Species Individually in a Laboratory Setting A. Kirkwood, E. Wilson, B. Dinius, J.R. Hoberg, Smithers Viscient, Ecotoxicology. Recently there has been increased concern whether duckweed (*Lemna gibba*) toxicity test results are appropriate for evaluating sensitivity of other aquatic macrophytes. A standardized guideline supported by regulatory agencies is not available for testing aquatic macrophytes. However, an exposure system for this type of test was described by Kubitza and Dohmen (2008) and is presently under inter-laboratory validation with two species: *Myriophyllum spicatum* and *M. aquaticum*. Smithers Viscient validated this method with the above two species as well as four additional aquatic macrophytes: *Ceratophyllum demersum*, *Elodea canadensis*, *Stuckenia pectinata* (formerly *Potamogeton pectinatus*),and *Vallisneria americana*. The expansion of this test method to include additional species helps to provide toxicity information across four different families. Shoot dry weight is the test endpoint most commonly used for evaluation of toxicity; an increase of ≥2X in dry weight over 14 days is typical for each species. Therefore, test results are appropriate for species sensitivity distribution in the risk assessment of chemicals. This poster presents a description of the exposure method and control growth data for each species mentioned above.

RP133 A Proposed OECD Test Guideline for the Submerged, Sediment-rooted Macrophyte, *Myriophyllum* J. Davies, Syngenta, Environmental Safety; P. Dohmen, BASF AG, Landw. Versuchsstation, APD/RO, BASF SE, Ecotoxicology dept; G.H. Arts, Alterra Wageningen Univ and Research Centre, Centre for Water and Climate, Environmental Risk Assessment. Under current EU pesticide regulation, regulatory tests are required for the aquatic macrophyte, *Lemna*, and two algal species for herbicides. In 2008, the SETAC – AMRAP (Aquatic Macrophyte Risk Assessment for Pesticides) workshop identified the potential need for regulatory tests with submerged, rooted macrophyte species in cases where root uptake from sediment is considered an issue or where the sensitivity of standard algae and *Lemna* species is believed not to be representative of other macrophyte species. In light of existing experience, *Myriophyllum* species were selected as the potential second macrophyte test species and a work group was established to develop an appropriate test method. Over the past 3 years, the suitability of the proposed method has been evaluated in a series of ring-tests performed in >12 laboratories. In 2011, the method was proposed and accepted as an OECD test guideline project and is currently undergoing a further phase of ring-testing. Progress to date will be described in this presentation.

RP134 Evaluation of Biomarkers in *Spartina alterniflora* from Galveston Bay, Texas, Related to Ambient Environmental and Heavy Metal Stress C.L. Howard, Univ of Houston-Clear Lake, Dept of Biological & Environmental Sciences; C. Gauthier, J. Borski, Univ of Houston Clear Lake, Biological and Environmental Science. Tidal wetlands are among the most productive ecosystems in North America. In Gulf of Mexico estuaries, these wetlands are dominated by the perennial halophyte *Spartina alterniflora*. *S. alterniflora* exhibits multiple height morphs and varying physiological characteristics, which have been shown to exert a significant impact on the overall function of marsh ecosystems. For the past six years, we have been studying stress biomarkers (peroxidase, catalase, glutathione reductases and protein), ecotypes and sediment heavy metal distribution in 15 S. alterniflora marshes bordering Galveston Bay, Texas. The populations at each site vary in history (reference, created, pollutant-impacted), salinity and tidal regime, dominant growth form, productivity and sediment heavy metal content. The objective of the present work was to assemble the data from several years' collections and determine patterns in biomarkers and growth forms that can be related to heavy metal exposure, separate from normal environmental stressors. A total of 720 individual plants were collected from the 15 populations over a 3-year period; field parameters, growth metrics and chlorophyll (SPAD-1500) data were recorded on site. Shoot peroxidase (POD), catalase (CAT), and glutathione reductase (GSR) activities and protein (PTN) concentration were determined in the lab using standard spectrophotometric assays. Shoots and sediments were acid digested and heavy metal concentrations were measured by ICP. ANOVA and PCA were used to determine that qualitative and quantitative differences in stress biomarkers, growth metrics and productivity are related qualitatively and quantitatively to heavy metal exposure in the 15 populations.

RP135 Monitoring Diurnal Variations of pH and Oxygen as Indicators of Macrophyte and Algae Productivity in Mesocosms P. Ebke, L. Doering, MESOCOSM GmbH; U. Hommen, Fraunhofer IME. Mesocosms studies are an established tool to assess the impact of herbicides on primary producers (algae & macrophytes) in aquatic ecosystems Additional to the endpoints surface coverage, biomass or growth rate of macrophyte as well as abundances and community structure of phytoplankton and periphyton, the OECD Guidance Document on Simulated Freshwater Lentic Field Tests recommends also the measurement of primary productivity e.g., by monitoring diurnal fluctuations of the oxygen concentration in the water. However, these diurnal oxygen measurements require high efforts, i. e. due to the need of values taken before sunset to get the lowest diurnal oxygen level. Within an ongoing research project on effects of multiple stressors on aquatic organisms and ecosystems an automatic measurement system is developed for the use in outdoor mesocosms, which is also applicable in field monitoring as well as laboratory studies. The system provides online pH- and oxygen data in combination with phytoplankton analysis based on delayed fluorescence spectroscopy for pigment analysis of the water samples. The system has been tested in different mesocosms over several weeks yet. The quasi-continuous pH and oxygen data provide information on total daily oxygen consumption and production. In addition, the delayed fluorescence spectroscopy analysis provides information on the phytoplankton pigment concentration (chlorophyll a) and community composition (with respect to five algae groups differentiated according to their pigment composition). Thus, toxic effects can be detected on the level of the phytoplankton community as important structural endpoint and on the level of total primary productivity as functional endpoint. The poster will present first results revealed with this online measurement system and will demonstrate the added value for the assessment of chemical effects on primary producers in aquatic mesocosms.

RP136 Rapid Injury Assessment of Submerged Aquatic Vegetation Communities in the Northern Gulf of Mexico Following the Deepwater Horizon Accident R. Burdge, M. Barth, A. Meyers, Cardno Entrix. In response to the Deepwater Horizon accident, federal and state trustees and BP scientists are cooperatively assessing injury to the submerged aquatic vegetation (SAV) communities as part of the initial phase of the Natural Resource Damage Assessment (NRDA). The cooperative team conducted a rapid habitat assessment survey between August 24 and September 16, 2010 that examined the health and environmental conditions of SAV communities potentially exposed to MC-252 oil. Based on oiling exposure trajectories and shoreline cleanup assessment technique (SCAT) information, 72 sample sites at risk for exposure in the Northern Gulf of Mexico, from Louisiana to Florida, were identified and sampled. Rapid habitat assessments consisted of visual surveys of the health and condition of SAV habitats, including percentage of SAV cover, presence of new SAV growth, and incidences of oiling. Additionally, sediment, water, and invertebrate and plant tissue samples were collected for chemical analysis, fingerprinting, polycyclic aromatic hydrocarbon (PAH) concentrations, and presence of dispersants. Overall health and environmental conditions of SAV beds surveyed were comparable to pre-impact assessments, but additional habitat evaluations are necessary before determinations can be made as to the extent of potential injury or restoration potential for SAV habitats impacted by the accident. This poster will describe methods used and provide a visual examination of data collected during the rapid habitat assessment survey.

RP137 A Novel Weight of Evidence Approach to Distinguish Between Toxicological Impairment and Nutrient Enrichment Impacts in an Oligotrophic Lake R. Stevenson, Golder Associates; G. MacDonald, Diavik Diamond Mine Inc.; P. Chapman, Golder Associates. Diavik Diamond Mine is located on Lac de Gras, an oligotrophic lake, in NWT, Canada. Annually, the Mine conducts an Aquatic Effects Monitoring Program (AEMP) to examine the impacts of Mine operations on the aquatic resources of Lac de Gras. A risk-based weight of evidence (WOE) framework has been developed to integrate the AEMP findings and evaluate two competing impact hypotheses for Lac de Gras. The Toxicological Impairment Hypothesis postulates that toxicity to aquatic organisms could occur due to metals released to Lac de Gras. Alternatively, the Nutrient Enrichment Hypothesis

postulates that eutrophication could occur due to the release of nutrients to Lac de Gras. For each hypothesis, the WOE framework integrates endpoints representing nutrient/contaminant exposure and biological response with a priori weighting factors, direction weighting factors and a posteriori weighting factors to provide a categorical ranking of the Evidence of Impact on lake productivity, the benthic invertebrate community, and the fish community. A higher rank represents a greater strength of support for a particular hypothesis. The weighting factors quantify professional judgement with respect to the ability of specific endpoints to indicate impacts, how much a particular biological response supports each hypothesis, and the degree of coherence/causality in endpoint responses. Thus, the process for arriving at AEMP conclusions is communicated in a transparent fashion and the influence of specific judgements on study findings can be evaluated. This approach is seen as a significant augmentation to WOE approaches that have typically only addressed contaminant-related toxicological impairment. This is particularly important for Diavik Diamond Mine, where mild nutrient enrichment, rather than toxicological impairment, is expected to be the primary impact on Lac de Gras. Review of the WOE application over the past 4 years can inform refinement of the AEMP by highlighting the main drivers of annual AEMP conclusions. The WOE framework will be presented along with recommendations and lessons learned.

RP138 An Aquatic and Terrestrial Hazard Evaluation of Petroleum Coke J.P. Swigert, EcoTox Assessments, LLC; C. Lee, ExxonMobil Biomedical Sciences, Inc.; D.C. Wong, Shell Oil Company – Shell Health; P. Podhasky, American Petroleum Institute. Aquatic and terrestrial ecotoxicity tests were conducted as part of the USEPA High Production Volume (HPV) chemicals programs in order to assess the hazard of petroleum coke (CAS 64741-79-3) to representative aquatic organisms and terrestrial soil-dwelling invertebrates and vascular plants. Acute toxicity test species included a fish (*Pimephales promelas*), an aquatic invertebrate (*Daphnia magna*), and an alga (*Pseudokirchneriella subcapitata*). Aquatic exposure solutions were prepared as water accommodated fractions (WAFs) and attempts were made to analytically quantify 19 polyaromatic hydrocarbon compounds (PAH) and seven inorganic constituents (Fe, S, As, Se, Cu, Ni, and V) of petroleum coke in the WAF solutions. All results of these analyses were below minimum detection limits. Petroleum coke used in aquatic tests had a mean particle size of 2 mm. This facilitated segregation of the solid particles from the WAF and avoided potential physical entrapment of the coke in the respiratory membranes of the test organisms. In all aquatic tests, the 96-h or 48-h LL/EL50 values were greater than the maximum WAF loading rate of 1000 mg coke/L. Terrestrial toxicity tests were conducted with the earthworm (*Eisenia fetida*) in a 14-d exposure, and three vascular plant species, corn (*Zea mays*), radish (*Raphanaus sativus*), and soybean (*Glycine max*) each in a 21-d growth test. Terrestrial tests were run with a powdered form of petroleum coke added directly to the soil to maximize contact with earthworms and plant roots. The mean particle size of the powdered coke was 3.3 µm. The earthworm test showed a 14-d EC50 of >1000 mg coke/Kg soil. Terrestrial plant tests resulted in 21-d LC50 values of >1000 mg coke/Kg soil for all species. Analysis of test soil for PAHs and the inorganic components associated with coke was not done based on calculations that none of the constituents would exist above minimum detection limits or soil background levels. Under the conditions of these tests, the results indicate a low potential for petroleum coke to cause adverse effects in the aquatic or terrestrial environment.

RP139 Apparent Algal Toxicity of a Poly-anionic Polymer Mitigated by the Stoichiometric Addition of Calcium J. Carbone, G.A. Hazelton, Dow Chemical Company, Toxicology, Environmental Research and Consulting; J. Manna, Dow Chemical Company, Home and Personal Care; K.R. Lampe, Dow Chemical Company, Toxicology, Environmental Research and Consulting; S. Dyer, The Procter & Gamble Company, Central Product Safety, The Procter & Gamble Company, Miami Valley Innovation Center; K. Softcheck, Smithers Viscient. Dow has developed a poly-anionic polymer for use as a substitute for phosphates in automatic dish detergents. The polymer functions as a calcium chelator and soil re-deposition inhibitor. The ecotoxicity of the polymer was tested in acute Fathead Minnow and *Daphnia magna* studies. The polymer was also tested with the green algae *Pseudokirchneriella subcapitata* employing the three tiered testing approach from Nabholz, et al., 1993. Test 1 used standard Algal Assay Procedure (AAP) medium (hardness of approximately 15 mg/L as $CaCO_3$). Test 2 used standard AAP medium supplemented with calcium (Ca^{2+} as $CaCl_2 \bullet 2H_2O$) on a stoichiometric basis at a 1:2 mole ratio with the carboxylate groups of the test substance. Test 3 used AAP medium which had been adjusted to a hardness of 150 mg/L as $CaCO_3$, using a 2:1 calcium:magnesium addition. The purpose of these tests were to define the toxicity of the test substance under standard algal test conditions in a low hardness medium (Test 1), after the active carboxyl groups were bound with calcium (Test 2) and within algal medium adjusted to moderately hard water conditions (Test 3). Test 3 was also used in conjunction with the *Daphnia magna* and Fathead Minnow studies in order to determine species sensitivity. The results of the Fathead Minnow, *D. magna* and *Pseudokirchneriella subcapitata* toxicity studies with culture media supplemented with $CaCO_3$ at 150 mg/L indicated that *Pseudokirchneriella subcapitata* was the most sensitive species. Based on cell density the 96-hour EC50 was 130 mg active ingredient as polymer, whereas for fish and *D. magna* the EC50's were > 950 and 710 mg a.i./L, respectively. The EC50 of Test 1, with the non supplemented AAP algal medium equaled 4.2 mg a.i./L. For test 2 with the standard AAP medium with calcium added on a stoichiometric basis, the EC50 was found to be >140 mg a.i./L. The results indicated that the apparent algal toxicity of a poly-anionic polymer can be mitigated via the stoichiometric addition of calcium. The algal toxicity endpoints for Test 1 and Test 2 were employed in the USEPA Sustainable Futures risk assessment paradigm. Results of the risk assessment demonstrate a negligible potential for adverse environmental effects.

RP140 Application of Unique Test Design in Determining the Chronic Toxicity of Boron to *Lumbriculus variegatus* in Whole-sediment Tests W. Hall, ENVIRON International Corporation, Ecotoxicology, ENVIRON; M. Harrass, Rio Tinto Minerals; R. Lockwood, ENVIRON. Presentation Type: Poster Preferred Track: Aquatic Toxicology and Ecology Session: Aquatic Toxicology and Ecology General Abstract Title: Application of a Unique Test Design in Determining the Chronic Toxicity of Boron to *Lumbriculus variegatus* in Whole-Sediment Exposures Authors: Scott Hall, Rick Lockwood – ENVIRON International, Nashville, TN Michael C. Harrass, Ph.D. – Rio Tinto Minerals, Hoffman Estates, IL Abstract: The chronic toxicity of boron (as boric acid) to the freshwater benthic worm *Lumbriculus variegatus* was evaluated in a 28-day study with spiked natural sediment in a flow-through test system. Following the OECD Method 225 procedure, sediments were spiked in a range-finding test. Approximately 20% of the overlying water was replaced per day in the flow-through test system. The initial tests showed rapid dissolution and removal of the water-soluble boric acid from the sediments. To achieve a more constant exposure in the definitive test, boric acid was added to the replacement waters in concentrations nominally equal to the whole-sediment values. This approach resulted in excellent agreement (generally within 10 percent) between nominal and measured total boron concentrations in each medium (overlying water, sediment pore-water, and whole sediment) throughout the 28-d test. Chronic endpoints (IC25) for survival and growth were 102.4 and 235.5 mg B/kg dry sediment, respectively. The modified procedure proved highly reliable in maintaining overlying water quality conditions (dissolved oxygen, pH, and ammonia) and whole-sediment boron concentrations during the 28-d study.

RP141 Aquatic Hazard Characterization of Commercial Naphthenic Acids from Crude Oil Origin J.P. Swigert, EcoTox Assessments, LLC; D.C. Wong, Shell Oil Company – Shell Health; C. Lee, ExxonMobil Biomedical Sciences, Inc.; P.M. Fedorak, Univ Alberta; P. Podhasky, American Petroleum Institute. Naphthenic acids (NAs) are naturally-occurring carboxylic acids (formula CnH2n+ZO2) present in crude oil and oil sands bitumen. Refining of crude oil concentrates NAs in the middle distillate streams, from which they are removed during the finishing of the fuel products. Extraction of bitumen from oil sands generates oil sands process-affected wastewaters (OSPW) that also contain NAs. To quantify the acute aquatic toxicity of NAs, studies with representatives from three trophic levels (fish, invertebrate, algae) were performed. Test exposures were based on water accommodated fractions (WAF) of crude oil refined commercial NAs product and included GC-MS characterization and quantification of NAs. Results showed fish (*Pimephales promelas*) to be more sensitive to NAs exposures than invertebrates (*Daphnia magna*) or algae (*Pseudokirchneriella subcapitata*). Acute endpoints (LL/EL50) for fish, invertebrates, and algae based on WAF loading of total NAs were 9.0 mg/L, 24 mg/L, and 25 mg/L, respectively. Endpoints (LC/EC50) based on mean measured concentrations were 5.6 mg/L, 20 mg/L, and 18 mg/L, respectively. These new data establish the acute aquatic toxicity of a commercial NAs preparation for standard test organism endpoints not previously reported. GC-MS characterization showed that the test substance and the WAF-soluble NAs were composed

mostly of 1-ring and 2-ring isomeric structures with carbon numbers most commonly observed in the 12 or 13 range. Acyclic acids were the third most prevalent acids followed by NAs having 3-, 4-, and 5-ring structures. Commercial NAs that was used in these tests differ from those found in OSPW in that the NAs in OSPW are reported to be predominantly 2- and 3-ring compounds.

RP142 Assessing Water Quality Impairment by Quantifying Metal Concentrations in Aquatic Invertebrates in the Absence of Water Data J.L. Ullman, Univ of Florida, Agricultural & Biological Engineering; S.J. DeBano, D. Wooster, Oregon State Univ, Dept of Fisheries and Wildlife; D. Horneck, Oregon State Univ; X. Lu, Washington State Univ; J. Snyder, Oregon State Univ, Entomology Program. The Umatilla River Basin in eastern Oregon is a highly impacted watershed that receives inputs from agriculture and municipal sources. In addition to other pollutants, metals are a concern as segments of the watershed have been declared water quality limited under Section 303(d) of the Clean Water Act for iron and manganese. However, water quality data for metals is essentially nonexistent due to resource limitations. This study quantified metal accumulation in aquatic invertebrates to examine potential metal impacts on biota in the absence of water data. Crayfish and stoneflies were collected at fifteen locations along the river, which included sites selected to delineate inputs associated with major tributaries impacted by agriculture and two wastewater treatment plants, as well as a reference site in the wilderness area of the upper watershed. Crayfish and stonefly tissues were digested and analyzed for heavy metals using inductively-coupled plasma mass spectrometry (ICP-MS). The pollutants considered here include arsenic, cadmium, chromium, copper, lead, mercury, silver and zinc. Despite numerous potential metal inputs throughout the basin, analysis of the invertebrates revealed no clear overall trends in bioaccumulation along the river. The reference site frequently exhibited metal levels as high or higher than the "impacted" sites downstream, indicating natural inputs. While copper concentrations in stoneflies generally increased from means of below 10 µg/g to about 30 µg/g when progressing downstream, zinc accumulation in crayfish actually decreased from 74.5 to 41.9 µg/g between the upper-most and lowest sites and arsenic showed a significant linear decrease moving downstream. The concentrations for all elements were comparable to other studies in similar watersheds except for chromium, which reached levels of 21.06 µg/g (comparable rivers did not exceed 2.5 µg/g). Although wastewater treatment plants are often sources of metal pollutants and agricultural fertilizers are known to introduce cadmium into the environment, no significant increased concentrations were observed for any of the metals in relationship to known inputs from these sources. This study highlights the need to conduct a robust assessment of water quality impacts on aquatic habitat before mandating remediation activities, especially when water quality data are lacking.

RP143 Chloride Toxicity in an Urban Missouri Stream C. Cole-Neal, Central Methodist Univ; A.L. Allert, USGS – Biological Resources Division, Columbia Environmental Research Center, USG.S. – Columbia Environmental Research Center, Biologial Resources Division; J. Fairchild, USGS – Biological Resources Division, Columbia Environmental Research Center. Urbanization leads to increases in impervious surfaces such as rooftops, parking lots, and roads. Surface run-off transports increased levels of sediment and contaminants to streams due to accelerated water flow associated with storm-water runoff. In northern climes impervious surfaces are frequently treated during winter with deicers such as sodium chloride (NaCl) and calcium chloride (CaCl2) for public safety. Long-term effects of increased chloride concentrations in subsequent storm-water runoff can cause a wide range of adverse effects in aquatic environments such as loss of sensitive species and changes in community structure, diversity, and productivity. We conducted a study of winter storm-water runoff in Columbia Missouri to evaluate the chronic effects of road-salt based chloride on survival and reproduction of *Ceriodaphnia dubia*. Water was collected from seven mainstem and tributary sites of Hinkson Creek. Chloride concentrations at two sites exceeded the US chronic water quality criterion of 235 mg/L chloride during the 7-day *Ceriodaphnia dubia* toxicity test. The highest measured concentration (1252 mg/L chloride) was about the concentration of published acute 48-hr LC50 toxicity values for NaCl (1960 mg/L) and chloride (1189 mg/L). Mortality was significantly higher and total reproduction was significantly lower in *C. dubia* in test water collected from this site during the laboratory study. Comparison of the response distributions of *C. dubia* exposed to field-collected stream samples and a separate single-chemical (NaCl) study gave similar results, indicating that chloride was the likely toxicant of concern. These data indicate current deicing practices in the Hinkson Creek watershed are likely having adverse effects on aquatic life in receiving waters and that adaptive management procedures including use of alternative de-icers or GIS-based mapping of geomorphological conditions and salt applications could protect aquatic life in this urban stream.

RP144 Combined Toxic Effects of Surfactants and PPCPs on Aquatic Organisms K. Kagota, Univ of Tokushima, faculty of integrated arts and science. Surfactants have been reported to increase the fluidity of cell membrane molecules, which may be resulted in the change in membrane permeability of the chemical compounds with different physical-chemical properties. Most of pharmaceuticals and personal care products (PPCPs) have been designed to have a certain physiological activity and could exert adverse effects on aquatic organisms at relatively low concentration. Numerous researchers have reported the ecotoxicity of individual surfactants and PPCPs on aquatic organisms, but their combined effect remained unknown. The objective of this study is to evaluate the combined effects of surfactants and PPCPs by acute, and sub-chronic toxicity tests, and several biomarkers using Japanese medaka (*Oryzias latipes*), zebrafish (*Danio rerio*) and *Daphnia magna*. An anionic surfactant C12-LAS was used as a model surfactant and combined effects with major pharmaceuticals such as propranolol, mefenamic acid, and triclosan were examined. Combined toxicity tests were carried out with the concentration addition mode based on LC50, EC50 and EC10 values of the individual compounds. Additive effects were found for the combination of C12-LAS and mefenamic acid for all the tested organisms. Whereas nearly the additive effects were found for the combination of C12-LAS and propranolol in short term toxicity test using *Danio rerio*, slight synergistic effects were evident in acute toxicity test using *Oryzias latipes*. In cotrast, additive effects were found for the combination of C12-LAS and triclosan in acute toxicity test using *Oryzias latipes*, but antagonistic effects were evident in the sub-chronic toxicity test using *Danio rerio*. The differences in fish species, membrane formulations, and physiological effects (mode of actions) could cause the difference in combined effects in acute tests using juvenile medaka fish and sub-chronic tests using embryo-larvals of zebrafish.

RP145 Constructed Wetland Treatment Systems for Energy-derived Produced Waters: Treating Selenium for Surface Water Discharge J. Rodgers, Clemson Univ, Forestry and Natural Resources; J. Castle, Clemson Univ, Environmental Engineering and Earth Sciences; M. Spacil, Diamond V; C. Ritter, Clemson Univ. Energy derived produced waters (EDPWs) are generated in relatively large volumes (~3.3 million m^3 annually) from a variety of sources, and these waters may contain constituents from source formations as well as process chemicals that were added. Selenium (Se) is a common constituent requiring treatment prior to discharge or beneficial reuse. An effective and reliable approach is needed to treat Se in EDPWs to meet stringent water discharge limits established under the National Pollutant Discharge Elimination System (NPDES) and the Clean Water Act. This study focused on an effluent containing Se that was produced as a byproduct of petroleum refining. Pilot-scale constructed wetland treatment systems (CWTSs) were designed and built at Clemson Univ to evaluate removal of Se from simulated refinery effluent (SRE). Specific objectives were to: 1) chemically and physically characterize a specific petroleum refinery effluent for simulation and confirm Se as a constituent of concern, 2) design and conduct bench-scale experiments to measure Se removal in response to organic carbon additions, 3) design and build a pilot-scale CWTS using information from the bench-scale experiments, and 4) measure performance of the pilot-scale CWTS in terms of rate and extent of Se removal in response to organic carbon additions. The treatment goal (i.e., Se removal) for this study was to decrease the Se concentration in SRE from ~50 μg/L to less than 5 μg/L. Samples were collected from the inflow and the outflows of each wetland cell in the pilot-scale CWTS. In order to determine rates and extents of Se removal and factors that may influence performance, parameters measured included elemental analysis of Se, dissolved oxygen concentration, conductivity, pH, alkalinity, hardness, and temperature. With organic carbon additions to the SRE inflow, outflow Se concentrations ranged from 3.4 to 9.8 μg/L, depending on the experimental treatment. This pilot-scale study illustrates that CWTSs can enhance Se removal from a SRE and required performance (i.e., removal of Se to < 5 μg/L) can be achieved to meet stringent discharge limits.

RP146 Continued Investigation into Potential Endocrine Disruption in Cacapon River Populations of the Freshwater Mussel *Elliptio complanata* D. Sovic, Ohio State Univ; R. Lanno, Ohio State Univ, Dept of Evolution, Ecology, and Organismal Biology. A high prevalence of intersex condition, or the appearance of oocytes in the testis, found in male smallmouth bass collected from populations throughout the eastern panhandle of West Virginia has provided evidence of the possible endocrine disruptive potential of surface waters in this area. To investigate the potential that other aquatic species are being similarly affected, a study has been undertaken to evaluate possible endocrine disruption in two populations of the freshwater mussel, *Elliptio complanata*, located in West Virginia's Cacapon River, in areas of both high and low agricultural activity. Data suggest significant differences in sex ratios between the two populations, as mussels sampled in close proximity to high levels of agricultural activity and in forested regions exhibited approximately 2.5:1 and 1.3:1 female-to-male ratios, respectively. Additionally, histological evidence of gamete developmental asynchrony, particularly within female mussels of the agriculturally associated population has been observed. Rates of viable and nonviable ova, as well as mean ova diameters from biopsies collected in Spring 2010 support differential reproductive development between populations. Changes in total mass, as well as shell length, width, and height between Autumn 2009 and Autumn 2010 indicate positive growth in only that population associated with low agricultural activity. Groups from each population were relocated between sites in Autumn 2010. These individuals will be recaptured and reevaluated to determine whether any differences observed are population or site specific. Sediment and surface water extracts collected periodically between Summer 2010 and Fall 2011 will be tested for total estrogenicity with the recombinant yeast-based estrogen assay (YES). In addition, the potential for utilizing mussel hemolymph as an indicator of exposure to estrogenic compounds will be explored.

RP147 Designing Constructed Wetland Treatments Systems for Ammonia in Produced Water D. Beebe, Y. Song, J. Castle, Clemson Univ, Environmental Engineering and Earth Sciences; J. Rodgers, Clemson Univ, Forestry and Natural Resources. Constructed wetland treatment systems (CWTSs) can be engineered to create the biogeochemical conditions needed to promote pathways for treatment of constituents of concern in impaired waters so that they may be used beneficially. In this study, pilot-scale CWTSs containing Typha latifolia (broadleaf cattail) were designed to remove ammonia from simulated post-reverse osmosis produced water to concentrations required to meet stringent discharge or beneficial use requirements (< 1.2 mg/L as N). The objectives of this research were to (1) identify the biogeochemical conditions required for microbial nitrification and denitrification, (2) construct a pilot-scale CWTS with amendments designed to provide the required treatment conditions, (3) determine ammonia removal performance of the amended CWTS, and (4) compare ammonia removal of the amended CWTS with a CWTS containing no amendments. Based on biogeochemical conditions required for microbial nitrification and denitrification (e.g., dissolved oxygen, pH, and alkalinity) a Typha pilot-scale CWTS was designed and constructed with amendments including mechanical aeration to increase dissolved oxygen concentrations, metered sucrose additions to serve as a source of electron donors, crushed oyster shell additions to stabilize pH and alkalinity, and an 8-day hydraulic retention time (HRT). Ammonia removal and related chemical parameters from the amended CWTS were compared with an unamended Typha CWTS operating on a 4-day HRT. Results indicate that the amended CWTS was capable of lowering ammonia-N concentrations from approximately 20 mg/L to non-detectable levels (< 0.1 mg/L) versus 12.6 mg/L for the unamended CWTS. Calculated rate coefficients for the amended CWTS ranged from 1.35 to 1.39 d-1 versus 0.071 to 0.111 d-1 for the unamended CWTS. Measured explanatory parameters related to ammonia removal (e.g., dissolved oxygen, pH, and alkalinity) were within the required range for the amended CWTS indicating that the selected amendments were capable of promoting the biogeochemical conditions needed for ammonia removal. Pilot-scale Typha CWTSs designed to promote microbial nitrification and denitrification pathways can successfully treat ammonia to concentrations required for reuse or discharge.

RP148 Disruption of E2-induced Non-genomic Signaling by Combinations of Bisphenol A and Nonylphenol R. Vinas, Univ of Texas Medical Branch – Galveston, Dept of Biochemistry & Molecular Biology, Univ of Texas Medical Branch – Galveston, Pharmacology & Toxicology; C.S. Watson, Univ of Texas. Medical Branch – Galveston, Dept of Biochemistry & Molecular Biology. Xenoestrogens (XEs) can mimic or antagonize the effects of physiological estrogens by binding to membrane bound estrogen receptors (mERα,mERβ, GPER/GPR30). Detected in appreciable amounts in human serum and urine (nM range), 4-nonylphenol (NP) and bisphenol A (BPA) are environmental pollutants known for their estrogenic effects. Previous studies from our lab in pituitary cells have demonstrated that these steroid-mimicking compounds potently and rapidly exert their effects via activation of non-genomic signaling pathways (e.g.mitogen activated protein kinases, Ca^{2+} firing, prolactin release). This study aimed to characterize the combined effect of XEs (BPA & NP) with a physiological estrogen, estradiol (E2), on kinase signaling pathways. Using the GH3/B6/F10 rat pituitary cell line we quantified phosphorylations of estrogen-induced extracellular signal-regulated kinases (ERKs) by a quantitative high-throughput plate immuno-assay. BPA and NP both activated ERKs in a dose-(fM-nM) and time-dependent (2.5-60 min) manner. E2 [1nM] was used as a standard for each experiment. Low XE concentrations (sub-pM) enhanced, while higher concentrations (pM-nM) diminished ERK activation, resulting in non-monotonic dose-responses. Combination of XEs with E2 [1nM] did not result in the expected additive effect, but instead attenuated ERK activation. BPA or NP at two different concentrations (10fM and 10nM) in combination with E2 [1nM] activated ERKs throughout the 60 min time course study, but caused temporal response patterns different from E2 [1nM] alone. Cell exposure to the combination of BPA [10fM], NP [10nM], and E2 [1nM] resulted in a drastic inhibition of ERK activation, but simultaneously activated c-Jun-N-terminal kinase (JNK) over 60 min. In conclusion, combinations of BPA and NP at environmentally relevant concentrations disrupt E2-induced non-genomic signaling. Risk assessment of chemical mixtures should therefore be more carefully addressed with respect to concentration and time, as these results suggest that XEs disrupt the normal functions of estrogens in the pituitary, which may affect functions during key life phases such as development, reproductive cycling, and pregnancy.

RP149 Ecotoxicity Issues Encountered in Complying with REACH Requirements K. Mierau, ENVIRON International Corp.; S. Deacon, ENVIRON UK Ltd. The European REACH (Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals) Regulation requires all manufacturers and importers of chemicals to identify and manage risks associated with the substances they manufacture. As part of the hazard assessment, predicted no-effect concentrations (PNECs) are estimated for long- or short-term exposure within an environmental compartment, (e.g., freshwater, marine, sediment, soil, etc.). PNECs are derived from ecotoxicity data using extrapolation methods such as species sensitivity distribution or assessment factor approaches. Grouping, read-across, and equilibrium partitioning methods can also be employed where data gaps exist. Although REACH Guidance describes the process for PNEC development, alternative approaches may be needed for complex chemicals or non-standard issues, such as endocrine disrupting properties, hydrocarbon compounds with moderate solubility, nanoparticles, and speciation. Additional issues may arise for those constituents that simply have a lack of reliable ecotoxicity data available. This poster presentation will discuss some of the ecotoxicity issues that were encountered during the REACH registration dossier preparations for multiple chemicals in support of the November 2010 deadline.

RP150 Ecotoxicological Assessment of the Clinch River, Virginia, to Determine Major Contributors of Trace Metals and Implications for Unionid Impairment B.S. Echols, D.S. Cherry, Virginia Tech, Dept of Biological Sciences. Analysis of sediments and interstitial water (porewater) indicate higher concentrations of trace metals in samples from sites located above both a power plant (CRP) and Dumps Creek mining influences. The furthest upstream sampling site located near Pounding Mill, Virginia (CR-PM) had higher concentrations of aluminum (2,250.9 mg/kg), copper (5.9 mg/kg) and iron (12,322.6 mg/kg) in sediment compared to samples collected directly below the Dumps Creek confluence (site CR-2). Similar results were obtained from bioaccumulation in situ tests with the Asian clam (Corbicula fluminea) in 2009. Aluminum (7.81 mg/kg), Fe (48.25 mg/kg) and Zn (7.69 mg/kg) were accumulated in higher concentrations at CR-PM site than CR-2. However, the site located below the CRP effluent discharges (CR-3L) on the left bank had substantially higher concentrations of Al (14.19 mg/kg), Cu (6.78 mg/kg), Fe (88.78 mg/kg) and Zn (7.75 mg/kg) than both CR-PM and samples collected directly opposite of this site at CR-3R. Bioconcentration Factors (BCF) calculated for clam tissues and

porewater metals (Al, Fe, Cu, Zn) were higher for samples downstream of the CRP effluent than right bank samples, which are primarily influenced by Dumps Creek. For example, BCF values were highest for Cu (2,196.7) at CR-3L, but substantially lower (798.8) at CR-3R. Benthic invertebrate surveys below the CRP also indicate a shift in taxa composition below the CRP, further indicating a substantial influence of discharges on river biota. Multiple sources of impact, including unidentified sources upstream, active coal mining in the Dumps Creek subwatershed and discharges from the CRP power plant are contributing to continual metal contamination in the Clinch River. This chronic exposure may be contributing to depressed unionid recruitment at downstream reaches. Additionally, these stressors in addition to past insults have caused biological impairment and unionid decline in the Clinch River and ultimately have affected the resiliency of the river.

RP151 Effects of a Model 3β-Hydroxysteroid Dehydrogenase Inhibitor, Trilostane, on Reproductive Endocrine Function in the Fathead Minnow K.M. Jensen, USEPA, Mid-Continent Ecology Division; J.E. Cavallin, E.J. Durhan, M.D. Kahl, E.A. Makynen, USEPA; D. Martinovic-Weigelt, Univ of St. Thomas, Dept of Biology, USEPA, Mid-Continent Ecology Division, Mid-Continent Ecology Division, Univ of St. Thomas, Biology; L. Wehmas, USEPA; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division. Inhibition of enzymes involved in the synthesis of sex steroids can substantially impact developmental and reproductive processes controlled by the hypothalmic-pituitary-gonadal (HPG) axis. A key steroidogenic enzyme that has received little attention from a toxicological perspective is 3β-hydroxysteroid dehydrogenase (3β-HSD). A number of environmental contaminants and plant flavonoid compounds have been shown to inhibit 3β-HSD activity, indicating that this may be an environmentally-relevant mechanism of HPG axis disruption. In these studies we exposed reproductively-mature fathead minnows (*Pimephales promelas*) to the model 3β-HSD inhibitor trilostane at test concentrations ranging from 50 to 1500 µg/L for up to 21 d. Shorter-term time-course exposures included a clean water recovery phase. Exposure to trilostane caused a significant reduction in fecundity. Plasma concentrations of 17β-estradiol (E2) in females were rapidly depressed within hours of exposure and were accompanied by decreases in plasma concentrations of the estrogen-responsive protein vitellogenin (VTG). Decreased vitellogenesis in vivo was consistent with inhibition of in vitro production of E2 by fathead minnow ovaries. Plasma E2 and VTG concentrations quickly returned to control levels during the recovery phase. Up-regulation of ovarian expression of gene products for follicle stumulating hormone receptor (*fshr*), and the cytochrome P450-based enzyme aromatase suggested active compensation in trilostane-exposed animals. The effects on HPG function in exposed males were less pronounced, however, trilostane significantly increased gonadosomatic index and, similar to females, caused up-regulation of gonadal *fshr*. The results of these studies support the hypothesis that 3β-HSD inhibition can cause reproductive dysfunction in fish. The data obtained from the time-course studies provide additional insights as to direct impacts, compensatory responses, and recovery from effects associated with 3β-HSD perturbation. The return of E2 and VTG to control levels in fish removed from the trilostane exposure demonstrates the highly dynamic, adaptive nature of the HPG axis in response to stressors. This information is important to the design and interpretation of approaches for assessing the occurrence and effects of HPG-active chemicals both in the lab and field. This abstract does not necessarily reflect USEPA policy.

RP152 Effects of Androstenedione on Fathead Minnow (*Pimephales promelas*) Reproduction and Development Z. DeQuattro, Univ of Wisconsin, Madison, Zoology, Univ of Wisconsin, Zoology; J.C. Hemming, Wisconsin State Laboratory of Hygiene; T. Barry, Univ of Wisconsin. The androgen, 4-androstene 3, 17-dione (A4, androstenedione), was found (>250 ng/L) in runoff from manure fertilized agricultural fields and livestock feeding operations in southern Wisconsin. Androstenedione is an active androgen in fishes and is a substrate in the biosynthetic pathways of other key fish steroid hormones (e.g., testosterone and estradiol-17β). The purpose of the present investigation was to determine if exposure to exogenous A4, at ecologically relevant concentrations, adversely affects fish reproduction and early development. Reproductively mature fathead minnows were exposed for 26 days to nominal concentrations of 0, 10, 100, and 1000 ng/L A4 in a flow through system and various key reproductive endpoints (e.g., fecundity, fertilization success) were measured. Fertilized fathead minnow eggs were exposed to nominal concentrations of A4, in static cultures, so to assess early development and hatching success. At termination of the fish short term reproduction assay adults were euthanized, animals were weighed for whole body mass, and secondary sexual characteristics were assessed for abnormalities. Livers were collected to measure Vtg mRNA expression. Gonads were collected and weighed for GSI determination. These data will be discussed along with possible future research directions.

RP153 Evaluation of the Acute Toxicity of Pesticide Mixtures to *Ceriodaphnia dubia* J. Westfall, A. DeSmet, S. Turpin, C. Ocab, C. Barton, Sanitation Districts of Los Angeles County. Toxicity thresholds are routinely based on laboratory exposures to single compounds in controlled, laboratory, environments. This scenario is not representative of real world conditions. In this study, we investigated the potential for interactions between multiple stressors on *Ceriodaphnia dubia*. The pyrethroid bifenthrin was coupled with the phenylpyrazole fipronil and the organophosphate chlorpyrifos to evaluate the effect of pesticide blends. Organism response was assessed to each individual stressor, along with two-compound mixtures in 48-hour, static, water-only exposures. Each compound elicited a toxic response, singularly. While the observed effects of the bifenthrin/fipronil combination did not differ substantially from the sum of components' individual effects, the bifenthrin/chlorpyrifos blend appeared to exhibit a synergistic effect. Low chlorpyrifos concentrations paired with non-toxic levels of bifenthrin enhanced the toxic response 200 – 500%. These results suggest that the commonly co-occurring pesticides, bifenthrin and chlorpyrifos are more toxic in tandem than individually.

RP154 Evaluation of the Effects of POPs in Monitoring Reference Sites in Mexico M. Guzman Martinez, Universidad Autonoma Metropolitana, Dept of Hidrobiologia; P. Ramirez Romero, Universidad Autonoma Metropolitana, Hidrobiologia, U.A.M. Iztapalapa, Depto. De Hidrobiologia; A.D. Nava Montes, Instituto Nacional de Ecologìa, CENICA. Monitoring is an important tool in environmental management; it allows the evaluation of temporal and spatial tendencies of the environmental quality. In order to comply with the Stockholm protocol and other international agreements, a National Monitoring Program of persistent substances (PRONAME, by its Spanish acronym) has been implemented in Mexico since 2007; this includes the long term monitoring of chemicals in different sites with a variety of anthropological influences as well as reference sites. The objective of this work was to develop an ecotoxicological baseline, as a complement to the chemical analysis in two reference sites (Celestun in the Yucatan Peninsula and Manantlan in the State of Jalisco). Sediment and soil samples were obtained and transported to the laboratory. Extraction was performed through sonication and toxicity was evaluated with lettuce seed bioassays. Results for Celestun showed toxicity only in one sample, which was associated to a nearby road that could leach pollutants to the adjacent soil. In a similar fashion none of the Manantlan samples showed toxicity. For this site a second sampling and bioassay analysis confirmed the previous results. When the chemical analysis data of the samples were obtained the lack of toxicity was correlated to the fact that only trace amounts of phenanthrene, anthracene, naphthalene and pyrene were found. To increase the bioassay analysis power another biological assay will be introduced (Microtox) in future samplings, since histological analysis seem to show the beginning of biological problems in Celestun, where more compounds have been detected.

RP155 Evaluation of Tools Towards Improved Assessment of Copper Bioavailability and Toxicity at Contaminated Sediment Sites M. Colvin, San Diego State Univ Research Foundation; G. Rosen, SPAWAR Systems Center Pacific, Environmental, SPAWAR Systems Center Pacific, Scientist; I. Rivera-Duarte, SPAWAR Systems Center Pacific, Scientist; P. Earley, B. Swope, SPAWAR Systems Center Pacific. In an effort towards improved understanding of the bioavailability and toxicity of copper (Cu) in marine sediments and, ultimately, an improved ability to accurately assess ecological risk from copper, a series of sediment toxicity experiments were conducted. The experiments employed four different benthic organisms commonly used in sediment quality assessment, with multiple concurrent manipulations and measurements to: a) assess the promising potential for improved prediction of toxicity based on the organic carbon-normalized Cu concentration of the < 63 µm sediment fraction, as reported elsewhere; b) support improved predictive models by measurement of physicochemical parameters

in the dissolved and particulate phases; and c) evaluate the utility of passive sampling devices for assessing labile Cu (and Zn) concentrations in sediment porewater. The experimental organisms, two amphipods (*Leptocheirus plumulosus* and *Ampelisca abdita*), one polychaete (*Neanthes arenaceodentata*) and bivalve embryos (*Mytilus galloprovincialis*), were exposed to both whole-sediment copper-spiked sediments and field-collected contaminated sediments using standard protocols. Copper spiked sediments ranged in concentration from 0 to 4500 mg/kg in order to calculate LC50 or EC50 values. All Cu spiking manipulations were conducted under anoxic conditions, allowed to mix for 28 d to achieve equilibrium, and pH adjusted as necessary to prevent unrealistically high concentrations in the porewater. The passive samplers (diffusive gradient in thin films) were coupled with several of the exposures, and compared to both Cu uptake and toxicity. Physiological chemistries measured included pH, SEM/AVS, total and dissolved organic carbon, grain size, and metal concentration in both dissolved and particulate fractions as well as metal concentrations in the polychaete tissues. All species exhibited a clear dose response to the Cu spiked sediments, with isolated responses observed to the field collected sediments. A summary of these experiments and current perspective on the utility of the various tools will be presented.

RP156 Hypothesis Testing (NOEC) Versus Regression Endpoint Estimation (ECx) in Chronic Ecotoxicity Tests S.E. Belanger, The Procter & Gamble Company, Environmental Stewardship Organization, The Procter & Gamble Company, Central Product Safety Dept; J. Oris, Miami Univ, Dept of Zoology. A long standing controversy in aquatic toxicology has revolved around the use of hypothesis testing versus endpoint estimation by regression techniques. Hypothesis testing commonly utilizes parametric analysis of variance followed by a post hoc one-sided test to compare treatment means versus the control resulting in NOEC and LOEC conclusions. Endpoint estimation requires the fitting of a regression to the exposure-response curve to estimate a prescribed effect levels such as an EC10. In this study, we summarize representative chronic green algae (Scenedesmus and Pseudokirchneriella), *Daphnia magna*, and fish toxicity data to quantitatively assess hypothesis versus endpoint estimation techniques as part of a larger investigation devoted to assessing the statistical power of current chronic ecotoxicity tests. The objectives were to evaluate the relationships of NOECs, LOECs, and various ECx levels for each test type and develop objective recommendations based on the empirical results. Algae (OECD 201), *Daphnia magna* (OECD 211), and fish (OECD 210) chronic ecotoxicity test results were derived from complete study reports, including raw data. All NOECs, LOECs, and ECxs were recalculated to harmonize the statistical approaches across studies and to enhance reliability of further comparisons. Comparison of hypothesis test and endpoint estimation included parametric and orthogonal regression. In addition to comparison of effect conclusions within the taxonomic group, an additional analysis was performed using two categories of chemicals 9alcohol ethoxylates and linear alklybenzene sulfonates) with exceedingly rich chronic toxicity data. In this set of analyses the NOEC or LOEC conclusions were compared to ECx conclusions across a wider array of taxa. Several common themes emerged: (1) The amount of variation explained by the regressions were close to the lines of 1:1 correspondence; (2) slopes of the relationships were all approximately 0.9 to 1.0 and indicate the likelihood of over- or under-predicting is equivalent for both statistical processes; and (3) overall NOEC and EC10 comparisons were consistent with each other indicating that the EC10 does not provide biased conservatism or liberalism for interpreting effects of chemicals. A more complete discussion of advantages and disadvantages of the approaches will be presented.

RP157 Influence of Select Physiochemical Parameters on the Toxicity of Atrazine to Green Algae L. Baxter, Univ of Guelph, School for Environmental Science; M. Hanson, Univ of Manitoba, Dept of Environment and Geography, Univ of Manitoba, Faculty of Environment; K. Solomon, Univ of Guelph, School of Environmental Sciences, Univ of Guelph, Centre for Toxicology, School of Environmental Sciences; A. Hosmer, Syngenta Crop Protection, LLC.; R. Brain, Syngenta Crop Protection, LLC., Dept of Environmental Risk Characterization. Surface waters in agricultural regions, particularly in the Midwestern United States, are typified by both spatial and temporal variability of parameters that can influence the growth and development of primary producers. Surface waters in certain areas may experience elevated turbidity and high levels of nutrients, along with low temperatures at the time of spring crop planting. Therefore, applying toxicity data obtained under only one specific set of conditions can lead to uncertainty in understanding the potential for effects in the field. Existing evidence indicates that increased turbidity, increased nutrients, and lower temperatures can reduce the toxicity of the herbicide atrazine to aquatic plants. Atrazine requires light as a dependent mechanistic co-factor in order to effectively inhibit photosynthesis, growth rate slows under cool temperature conditions, and high nitrogen and phosphorous can up-regulate specific metabolic processes and influence growth characteristics. Consequently, a series of studies evaluating the influence of light intensity (used as a surrogate for turbidity), nutrient content, and temperature on the toxicity of atrazine to the green algae *Pseudokirchneriella subcapitata* were conducted in order to assess the toxicity of atrazine to primary producers under conditions reflective of Midwestern streams in the United States. The results of these algal experiments will be presented.

RP159 Liver PAH Determination in *Brevoortia tyrannus* and *Brevoorta patronus* R. Hawke, C.S. Bentivegna, Seton Hall Univ, Biological Sciences; J. Sowa, Seton Hall Univ, Chemistry/Biochemistry. The April 2010 BP® oil spill has caused great concern for ecological impacts in the Gulf of Mexico. Crude oil contains polycyclic aromatic hydrocarbon (PAHs) and oil spills increase the exposure of aquatic organisms to this class of chemicals. The overall health effects of PAHs depends on the time of exposure, the concentration of PAH, and the toxicity of the PAHs in the mixture. *Brevoortia tyrannus* and *Brevoorta patronus* are a filter feeding fish commonly known as menhaden and account for over 40% of the commercial industry fisheries catch. As primary consumers, they are a major link in the food chain. In this study, liver metabolites of PAHs were measured in menhaden using scanning fluorescence spectrophotometry. Standardized curves were effectively established for 3-hydroxypyrene and 2-napthanol. Liver PAH analyses were performed on fish samples from both Atlantic and Gulf coasts with the anticipation of comparing a BP oil signature with ones from urban environments. Adult menhaden were collected from Delaware Bay, NJ (September- November 2010) the lower Chesapeake Bay, VA (November-December, 2010) and Grand Isle, LA (November 2010). Preliminary analyses revealed that naphthanol-like PAHs were higher in LA fish, while NJ and VA fish had higher levels of hydroxypyrene-like PAHs. Further work needs to be done comparing the fluorescent spectra to other PAH standards.

RP160 Long-term Variability of Reference Toxicant Tests with Five Freshwater Species T. Horsley, ENVIRON, Laboratory Services Manager – Ecotoxicology; L. Minella, ENVIRON, Scientist. Reference toxicants are used to evaluate the overall health and sensitivity of toxicity test organisms, and to determine the precision of the tests conducted under specific laboratory conditions. Individual reference toxicant test results are compared to control charts to determine acceptability based on test precision. The coefficient of variation (CV) for the tests (LC50 value for acute tests, IC25 value for chronic tests) provides a measure of test precision. For whole effluent toxicity (WET) testing, EPA compiled frequency distribution data for inter-laboratory CVs for reference toxicant tests from a national database established in 2000. The EPA data allow laboratories to compare their test precision with that of other laboratories. The variability of NaCl reference toxicant tests with five freshwater species used in the National Pollutant Discharge Elimination System (NPDES) discharge monitoring program was measured over a ten-year period. Acute freshwater test species were the cladocerans *Ceriodaphnia dubia*, *Daphnia pulex*, and *D. magna*; and fish species *Pimephales promelas* (fathead minnow) and *Cyrinella leedsi* (bannerfin shiner). The variability associated with chronic *C. dubia* and *P. promelas* tests was also determined. The results of these evaluations were compared to test precision previously documented by USEPA, and the inherent precision associated with each test species and test format (acute and chronic) was also determined.

RP161 Modeling the Chronic Effects of Pharmaceutical Mixtures on the Life History Strategies of *Ceriodaphnia dubia*: A Multigenerational Study K. Lamichhane, Univ of North Texas, Environmental Science; T.W. LaPoint, Univ of North Texas; D.L. DeAngelis, Univ of Miami, Dept of Biology. Trace quantities of pharmaceuticals (carbamazepine and ivermectins) are continuously discharged into the environment, causing concern among scientists and regulators regarding their potential long term impact on aquatic ecosystems. These compounds and their metabolites are continuously interacting with organisms at various life cycle stages, and may differentially influence development of embryo, larvae, juvenile, and adult

stages. Rather than choose a single chemical to study, we recognize that aquatic organisms live in a "soup" of chemicals. Hence, to fully understand the cumulative effect of exposure to multiple chemicals, a multigenerational approach will be taken. We will examine and model the chronic toxicity of selected pharmaceutical mixtures at environmentally relevant concentrations on life history and morphological parameters over four generations on *Ceriodaphnia dubia*. Model endpoints will include survival, growth, reproduction, brood size, interbrood duration, sex ratio, and life span. The model will predict the effects of chronic toxicity of *C. dubia* individual behavior under laboratory conditions. Model results will be extrapolated to populations in the natural ecosystem. This approach will establish the consequence of multigenerational exposure to these chemicals and may provide a tool with which to understand the effect of chemical on individual organisms and predict population level effects over time and space.

RP162 Perfluorinated Chemicals in Surface Waters and Sediments from Northwest Georgia, USA, and Their Bioaccumulation in *Lumbriculus variegatus* P.J. Lasier, USGS-Patuxent Wildlife Research Ctr., Univ of Georgia; J.W. Washington, USEPA – National Exposure Research Lab; S.M. Hassan, Univ of Georgia; T.M. Jenkins, USEPA – National Exposure Research Lab. Concentrations of perfluorinated chemicals (PFCs) were measured in surface waters and sediments from the Coosa River watershed in northwest Georgia, USA to examine their distribution downstream of a suspected source. Samples from eight sites were analyzed using liquid chromatography-tandem mass spectrometry. Sediments were also utilized in 28-d exposures with the aquatic oligochaete, *Lumbriculus variegatus*, to assess PFC bioaccumulation. Concentrations of PFCs in surface waters and sediments increased significantly below a land-application site (LAS) of municipal/industrial wastewater and were further elevated by unknown sources downstream. Perfluorinated carboxylic acids (PFCAs) with eight or less carbons were the most prominent in surface waters. Those with 10 or more carbons predominated sediment and tissue samples. Perfluorooctane sulfonate (PFOS) was the major homologue in contaminated sediments and tissues. This pattern among sediment PFC concentrations was consistent among sites and reflected homologue concentrations emanating from the LAS. Concentrations of PFCs in oligochaete tissues revealed similar patterns to those observed in the respective sediments. The tendency to bioaccumulate increased with PFCA chain length and the presence of the sulfonate moiety. Biota-sediment accumulation factors indicated that short-chain PFCAs with less than seven carbons may be environmentally benign alternatives in aquatic ecosystems, but sulfonates with four to seven carbons may be as likely to bioaccumulate as PFOS.

RP163 Quantifying Toxicity Effects of Different Hydrocarbon and Aromatic-based Chemicals via Tissue Extraction Method in *Leptocheirus plumulosus* G. McMennamy, M-I SWACO, Analytical; K. Nguyen, M-I SWACO, Quality Assurance; P. Tyczynski, M-I SWACO. Continuous efforts have been made by industry over the years to strengthen the sediment toxicity test which uses the benthic organism *Leptocheirus plumulosus*. Different studies have further reinforced the validity of the test which is currently employed by the US Environmental Protection Agency in Gulf of Mexico compliance programs. Research previously carried out involving *L. plumulosus* culture studies has focused on the physiological and biological aspects of the organisms, as well as the primary and secondary modes of ingestion via digestive tract and body cavity areas. The need to further explore the ways in which toxicity effects take place has resulted in study of the toxicity accumulation propensity of the organisms using hydrocarbon and aromatic-based chemicals. The rationale behind the selection of these chemicals comes from its respective worldwide offshore and applicable uses. (These chemicals are known to have different levels of toxicity results from a discriminatory power's standpoint.) Various approaches including radioisotope, biomarkers and fluorescent tagging by different scientists have been attempted when studying accumulation effects in these amphipods. One of the many challenges has been absence of sufficient sample tissue to assess as these amphipods' sizes are quite small. The purpose of this research is to quantify, by using tissue extraction techniques, the presence of compounds that may affect the health of test subjects by identifying different toxic chemicals and their concentrations via Gas Chromatography-Mass Spectrometry. Furthermore, techniques developed and refined during the ongoing research strengthen the overall efforts in reducing test variability. Preliminary data show both external adhesion and internal presence of the tested chemical via direct ingestion of the amphipods, this by measuring the presence of hydrocarbon and aromatic-based chemicals in test organisms and comparing this data to the results of the LC50 toxicity data generated during a 10-day benthic sediment toxicity test. Analyses performed on the data suggest a correlation between the presence of test chemicals inside the organisms and that of the LC50 toxicity results. This research will provide invaluable insight into how benthic sediment toxicity testing results and presence of toxic chemicals are correlated.

RP164 Renovating Fresh Oilfield Produced Waters for Beneficial Uses: Managing Constructed Wetland Treatment Systems for Performance B. Alley, J. Rodgers, Clemson Univ, Forestry and Natural Resources; J. Castle, Clemson Univ, Environmental Engineering and Earth Sciences. Energy-derived waters (EDWs) are generated in relatively large volumes (~3.3 million m^3 annually), can range from fresh (< 5,000 mg Cl/L) to hypersaline (>40,000 mg Cl/L), and contain constituents that may hinder beneficial use. Fresh oilfield produced water (FOFPW) can contain metals, metalloids, and organics such as oil. Some FOFPWs may be renovated for discharge and irrigation using efficient and effective approaches such as constructed wetland treatment systems (CWTSs). These CWTSs are designed to promote removal pathways resulting in sequestered or non-bioavailable forms of constituents. In CWTSs, pathways and processes for metals (Cd, Cu, Ni, Zn) and oil removal are dependent on specific sediment redox conditions. Sediment redox potential can be controlled by changes in water depth and may affect performance of a CWTS. This experiment was designed to illustrate the role of water depth for controlling sediment redox potential and consequently, performance of a CWTS. Replicate pairs of PS-CWTSs with four sequential cells were designed to provide oxidizing or reducing sediment conditions conducive for removing constituents in simulated FOFPW. The systems were operated with five discrete water depths (15, 23, 33, 46, 56 cm) and a hydraulic retention time of 24 h for each wetland cell. Oxidizing conditions (+15.3 to +250.1 mV) were produced in 15, 23, 33 cm water depths along with greater removal rates for oil (0.01-0.056 day^{-1}) than the 46 and 56 cm water depths (~0.001 day^{-1}) likely due to differences in rates of aerobic and anaerobic oil degradation. Reducing environments (-65 to -212 mV) were generated in 46 and 56 cm water depths and supported greater removal rates for metals (0.01-0.185 day^{-1}) than 15, 23, 33, cm water depths (no change-0.077 day^{-1}) which may be attributed to precipitation by sulfides from dissimilatory sulfate reduction. If the sediment redox potential is not within the range conducive for targeted pathways to operate, removal of constituents may not occur regardless of HRT. Water depth can influence sediment redox conditions which may enhance or suppress pathways necessary to transfer or transform constituents to non-bioavailable forms and achieve the desired performance in a CWTS.

RP165 Sex Determination in AB Strain Zebrafish (*Danio rerio*) Using Anal/Genital Morphometrics E. Kirichenko, L. White, RUTGERS Univ, Biochemistry and Microbiology; K.R. Cooper, Rutgers, the State Univ of New Jersey, Dept of Biochemistry and Microbiology. The zebrafish (*Danio rerio*) is sexually mature after approximately 90 days post fertilization and can be differentiated by secondary sexual traits. These traits include coloration, body girth and fin shape. Attempts in our laboratory to use these traits for segregating by sex at 1 month were unsuccessful. Our hypothesis was that by examining subtle changes in the anal/genital morphology (AGM) and distance (AGD) from the pectoral fin we could provide earlier indicators of sexual determination. The first study examined sexually mature fish to determine if AGM and AGD were quantifiable and was different between male and female fish. Females had AGD of 0.6 mm or less, while males had an AGD of 1 mm or more. In addition, the difference in the length of the female (> 2.1 mm) and male external gonadal/anal structure (< 2.0 mm) was different. There was no difference in the width of the male or female structure. In a second study fish were individually housed from hatch and observed for AGM and AGD from 4 to 11 weeks. The fish were sedated with MS222 and examined weekly under a stereomicroscope at 40x magnification. At 4 weeks the gonadal pore structure between the male and female could be identified based either on AGM or at later weeks on both AGM and AGD. Histopathology of the organ is being used to confirm the observations made using the stereomicroscope. Currently, this method can be used to determine gender 4 weeks of age and further refinement may allow earlier determinations. (NIEHS ARRA 432298)

RP166 The Effects of β-Sitosterol Exposure on Fathead Minnow Growth, Survival, and Reproductive Endpoints C. Flinders, W. Streblow,

R. Philbeck, National Council for Air and Stream Improvement; D.L. Cook, NCASI, Dept of Chemistry; D. Campbell, NCASI; D. Borton, R. Fisher, National Council for Air and Stream Improvement. Phytosterols are a group of steroid alcohols naturally occurring in plants, and therefore a component of pulp and paper mill effluents. Among effluent phytosterols, β-sitosterol is typically found in the greatest concentration. Studies examining the effects of β-sitosterol on aquatic organisms are limited, but estrogenicity; and effects on egg size and survival, juvenile and adult survival have been reported at concentrations of β-sitosterol that were < 20 µg/L. We exposed fathead minnow eggs to four β-sitosterol concentrations of 20, 65, 218, and 689 µg/L based on measurements of samples from exposure aquaria, a dilution water only (negative) control, an acetone control (0.6 ml/L acetone, β-sitosterol carrier), and ethinylestradiol (EE2, 15 ng/L, positive control). Fish were monitored through larval, juvenile, and adult stages, with adult fish allowed to spawn to determine egg production and hatchability. Calculated endpoints included survival; weight; gonadosomatic (GSI) and hepatosomatic index (LSI); condition factor; egg size, production, and hatchability; numbers of tubercles on heads of males and females; gonad histology; and steroid hormone (estradiol, testosterone, 11-ketotestosterone) and vitellogenin concentrations. Findings from this study differed from previous life cycle studies. There was no significant difference in fish growth or mortality with β-sitosterol exposure. Although there was a decrease in egg production in treatment groups relative to the negative control, there were no significant treatment differences relative to the acetone control suggesting that reductions were due to acetone and not β-sitosterol. All fish exposed to EE2 showed female characteristics but did not spawn. Histopathological examination of gonadal tissue showed no significant differences in the reproductive development or spawning capability of male or female fathead minnow with β-sitosterol exposure. Male fish exposed to EE2 were found to have ovarian tissue, and none were spawning capable. Hormone and vitellogenin data are still being evaluated. Preliminary findings from this study indicate that β-sitosterol exposure has a minimal impact on fathead minnow survival, growth, and reproduction, and suggests that fish response to β-sitosterol exposure may be species-specific or that methodology differences from earlier studies contributed to differences in fish response.

RP167 Toxicity of Chemically Dispersed Crude Oil to Herring Embryos C. Greer, Queen's Univ, Biology; P.V. Hodson, Queen's Univ, School of Environmental Studies. Significant declines in Pacific herring (*Clupea pallasi*) populations have followed two major oil spill events in the United States, the *Exxon Valdez* oil spill and the *Cosco Busan* oil spill. As a result of oil-related declines, the literature has been dominated by studies that have assessed the risk to Pacific herring. Although oil tanker routes also coincide with Atlantic herring (*Clupea harengus*) spawning grounds, little research has been done to study the risk of oil exposure to Atlantic herring. The main objectives of this research were to determine if chemical dispersion of crude oil increases the toxicity to herring embryos and if Atlantic and Pacific herring embryos respond similarly to oil exposure. If the two species are sufficiently similar, available knowledge on Pacific herring can be expanded to include Atlantic herring for risk assessment. Chemical dispersion increased the concentration of oil in the water column by 100-fold, resulting in a significant increase in toxicity. Additionally, Atlantic herring appeared to be four times more sensitive to chemically dispersed oil than Pacific herring embryos, as determined by the percentage of normal embryos at hatch and the incidence of blue sac disease. This indicates that chemical dispersion of oil increases the risk to herring embryos and that exposure limits for risk assessment should be set conservatively to protect both species.

RP168 Transgenerational Effects of Contaminants: Does Parental Cadmium Exposure Affect the Cadmium Tolerance of Offspring? S. Plautz, C. Salice, Texas Tech Univ, The institute of environmental and human health. Maternal effects are non-genetic influences on offspring phenotype that occur via the phenotype of the mother or the environment she experiences. Maternal effects are one of the most important determinants of offspring phenotype and are thus influential in the adaptation and evolution of populations. When mothers experience changes in environmental conditions, they may produce offspring that are more tolerant of the new conditions, thus adaptively modifying their offspring. However, in other cases mothers may produce offspring with a lower tolerance or a lower general fitness. This effect of the maternal environment on offspring phenotype has thus far received little attention in toxicology, but the available data demonstrate an effect of maternal contaminant exposure on offspring contaminant tolerance and fitness. This is important because maternal influences on contaminant tolerance in offspring, whether in the direction of increased or decreased tolerance or fitness, will have a significant impact on population adaptation to contaminants and ultimately population persistence. To further explore the effects of maternal contaminant exposure on offspring, we exposed a laboratory strain of *Biomphalaria glabrata* snails to 0, 2, or 10 ug/L cadmium for 7 days, after which they were transferred to clean water. We then collected egg masses and exposed them to 0 or 2 ug/L cadmium in a factorial design for the duration of egg development. When hatchlings were 12 days old, we exposed them to 200 ug/L cadmium and recorded time to death with observations every 8 hours for 3 days. Among juveniles with cadmium-exposed parents, preliminary data indicate a marginally significant difference in the effect of the parental cadmium concentration (p=0.091), with snails whose parents were exposed to 10 ug/L cadmium displaying lower cadmium tolerance. Preliminary data also indicate an interactive effect of parental cadmium exposure and egg mass cadmium exposure on juvenile survival in cadmium over time (p=0.028). Taken as a whole, these results suggest that cadmium exposed parents do not impart enhanced cadmium tolerance to offspring in *B. glabrata*. We are currently exploring similar questions regarding the transgenerational effects of cadmium using wild caught *Physa pomilia* snails. Our results and results from similar studies on transgenerational effects of contaminants have important implications for understanding how populations respond to anthropogenic stressors.

RP169 A Proteomic Approach to Biomarker Discovery in *Heterocypris incongruens* Exposed to Heavy Metals Using SELDI-TOF M Y. Kim, J. Son, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences; H. Mo, Korea Univ, Division of Environmental Science and Ecological Engineering; Y. Lee, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences, Korea Univ, Environmental Science and Ecological Engineering; M. Kim, Korea Univ; K. Shin, Hankuk Univ of Foreign Studies; K. Cho, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences, Korea Univ, # 407, Division of Environmental. The use of SELDI-TOF (Surfaced enhanced laser desorption ionization-time of flight) technique has been increased recognition as a tool for screening and discovering biomarkers in environmental monitoring. In this study, the changes in protein peaks in *Heterocypris incongruens* were compared after six day exposure to the sublethal concentrations of three different heavy metals, cadmium, copper and lead using Q10 and CM10 protein chips. Obvious differences in the peak patterns (up- and down- expression of protein in *H. incongruens*) between the heavy metals were observed, implying that the effects of three heavy metals to protein expression are different. Construction of the decision tree classification algorithm was performed on the significantly different protein peaks. The decision tree algorithm applied in SELDI-TOF MS was tested for the validation group. The results showed that the sensitivity and specificity in the validation group were very high. This proteomics approach can be considered to be a valuable tool for the development of biomarker.

RP170 A Quantitative Food Web Approach for Estimating Selenium Flux in the Colorado River in Grand Canyon D. Walters, USGS, Fort Collins Science Center, USGS, Ecologist; E. Rosi-Marshall, Cary Institute for Ecosystem Studies; W. Cross, Montana State Univ, Ecology; T. Kennedy, USGS, Grand Canyon Monitoring and Research Center; C. Baxter, Idaho State Univ, Biological Sciences. Selenium (Se) biomagnifies in aquatic food webs and is toxic to fishes and terrestrial piscivores. Se concentrations exceed fish and wildlife toxicity thresholds throughout the Colorado River Basin. The Colorado River within Grand Canyon experiences enormous Se loads (30 metric tons/y of dissolved Se), yet Se data are lacking for this part of the river due to its remote access. We sampled the Colorado River food web (organic matter, invertebrates, fishes) for Se at six sites spanning ~360 river kilometers downstream of Glen Canyon Dam. Our objectives were to quantify the magnitude of Se contamination in this reach and to estimate Se fluxes within the food web. We used quantitative food web methods, which combine data on animal secondary production, gut contents analysis, energetic efficiencies, and Se concentration data, to estimate Se flux within the food web. Mean Se concentrations for organic matter, macroinvertebrates, and fishes were 1966, 3752, and 2049 ng/g wet weight, respectively, well above established risk thresholds. We estimated total Se flux of 825 µg/m^2/y through the food web at our upstream-most site (the Glen Canyon

reach). The main pathways of Se flux were from diatoms and amorphous detritus to the benthic invertebrates *Gammarus* and New Zealand mudsnail. Flux to rainbow trout (the dominant fish species) was 4 μg/m^2/y, and was primarily from amorphous detritus and algae. Se flux through the food web is approximately 2.7 kg/y within the 25 km Glen Canyon reach, a miniscule proportion of the annual Se load. Even though Se uptake within the food web is small relative to loads, concentrations within organisms reflect high risk to Se exposure.

RP171 A Survey of Pharmaceuticals and Personal Care Products (PPCPs) in a Binational River and Their Potential Impacts on Basal Trophic Levels D.A. Martinez Gomez, Univ of Texas at El Paso, Environmental Science Program; S. Baca, Univ of Texas at El Paso; R. Guerrero, Univ of Texas at El Paso, Dept of Chemistry; E. Walsh, Univ of Texas at El Paso, Dept of Biological Sciences. The Rio Grande is an important binational aquatic system serving as a primary source of drinking, irrigation and recreational water. As in other regions worldwide, the river receives wastewater inputs from industrial, urban and agricultural uses. Wastewater treatment plants are not designed to remove the pharmaceuticals and personal care products (PPCPs) pollutants and thus effluent inputs into surface waters are of increasing concern. Concentrations of PPCPs in the El Paso/Ciudad Juarez stretch of the Rio Grande have not been determined nor have their potential impacts on aquatic life. A survey of 14 selected PPCPs is being conducted in four sites along this stretch. Concentrations of PPCPs are being analyzed by HPLC-MS/MS following EPA Method 1694. The rotifer *Plationus patulus*, a basal member of riverine food webs, is being used to test for acute and chronic toxicity of 4 selected PPCPs (caffeine, acetamidophenol, cotinine, sulfamethazine). One population from the Rio Grande (downstream of the El Paso/Ciudad Juarez metroplex) and other from a remote site near Big Bend National Park (BBNP, TX) are being tested in order to compare populational differences in sensitivity. Preliminary results show the presence of caffeine, trimethoprim, erythromycin, cotinine and sulfamethazine in the river. In toxicity tests, *P. patulus* showed higher sensitivity to caffeine (BBNP: 48 hr LC_{50} 425 mg/L; El Paso/Ciudad Juarez: 372 mg/L) as compared to *Daphnia magna*. For the BBNP population, the acetamidophenol LC_{50} (25 mg/L) is also lower than that for *D. magna* (LC_{50} 40.8 mg/L); thus *P. patulus* may be a more sensitive bioindicator of toxicity of these PPCPs. For the BBNP population, chronic toxicity was assessed using a modified life cycle test in which the population growth rate (r) was calculated over a range of concentrations (caffeine and acetamidophenol). For caffeine exposures, a significant decline in population growth occured as concentrations increased. After 5 days there was a significant decrease in population growth rate between the control (0.23±0.02), 100 ppm (0.07±0.01), 200 ppm (0.06±0.012), and 300 ppm (one replicate remained at day 6; -0.08). Increasing acetamidophenol concentrations resulted in the production of non-viable eggs and, thus, negative population growth rates. Tests with additional compounds are underway. Results from this study will be provided to resource managers in order to help them better protect our water supplies.

RP172 Acute and Chronic Toxicity of Cobalt to the Planarian *Dugesia dorotocephala* A. Sternenberger, Colorado State Univ, Center for Environmental Medicine, Colorado State Univ; O.R. Arnold, Colorado State Univ, Center for Environmental Medicine, Colorado State Univ, Environmental and Radiological Sciences; H.S. Ramsdell, Colorado State Univ, Center for Environmental Medicine *Dugesia dorotocephala* is a useful invertebrate species for aquatic toxicity testing. This free-living flatworm is easy to culture and their size facilitates convenient observation and easy handling. These studies were intended to define the acute lethal concentration of a soluble cobalt salt ($CoCl_2$) for this species, to identify a sensitive sublethal effect for chronic toxicity tests and to understand how hardness may influence cobalt toxicity. Planaria were exposed to cobalt in reconstituted water formulated to achieve the required hardness value while accounting for the contribution of Co^{+2}. Exposures were conducted using static renewal protocols. In moderately hard water, a 96 hour LC_{50} of 27 mg Co/L was observed. After 168 hours of exposure, an LC_{50} of 12 mg Co/L was found. The LC_{50} values increased progressively with water hardness. A 60-day exposure to Co^{+2} was conducted in moderately hard reconstituted water. Fissioning, the mode of reproduction for this asexual planarian, was significantly suppressed at the lowest Co concentration tested, 1 mg/L. Regeneration rates and behavioral responses were less sensitive to Co^{+2} exposure. In tests where hardness was held constant but varying ratios of Ca^{+2} and Mg^{+2} concentrations were employed, it was found that Ca^{+2} exerted a greater protective effect against acute Co^{+2} toxicity than Mg^{+2}. Further studies are in progress to define a chronic no-effect level for Co^{+2} in *D. dorotocephala*.

RP173 Acute Copper Toxicity and Acclimation Using Behavioral Endpoints of Shoaling and Predator Avoidance in the Least Killifish (*Heterandria formosa*) S. Vogt, Univ of Louisiana at Lafayette, Biology; P.L. Klerks, Univ of Louisiana at Lafayette, Dept of Biology; A. Billock, Univ of Louisiana at Lafayette, Biology. Many toxicity studies use mortality as an endpoint to determine a response to heavy metals. Due to copper's neurotoxic effects, we were interested in whether a behavioral response, shoaling or predator avoidance, could be used as an indicator of copper toxicity and acclimation. Shoaling is defined as a social assembly of fish that swim with little to no structure. To answer the question of acute toxicity, we exposed least killifish (*Heterandria formosa*) to 0, 25, 50, or 100 μg/L Cu for 2 hours. For copper acclimation, fish were pre-exposed for 7 days to either 0 or 15 μg/L Cu and then exposed for 2 hours to 50 μg/L Cu. Fish were put in an observation aquarium that contained a clear plexiglass divider that contained 15 shoaling least killifish or 3 predators. The other side of the divider allowed a test fish to be monitored by video for 3 minutes. Videos were analyzed for different parameters of shoaling behavior: time to first shoaling event, total shoaling time and time spent near surface. Videos were also analyzed for different parameters of predator avoidance: time spent near bottom, time spent at surface, total time away from predator. Preliminary experiments have shown a significant decrease in total shoaling time at exposure to copper compared to controls ($F_{3,58}$=5.1137, p=0.0033). Ongoing research will examine the presence of copper acclimation using shoaling and predator avoidance.

RP174 Acute Toxicity of Insecticides on the Calanoid Copepods, *Eurytemora affinis* and *Pseudodiaptomus forbesi*, of the San Francisco Estuary S.A. Lesmeister, Univ of California at Davis, Ecology, Veterinary Medicine: Anatomy, Physiology and Cellular Biology. The calanoid copepods, *Eurytemora affinis* and *Pseudodiaptomus forbesi*, are a critical link between primary producers and fish in the San Francisco Estuary (SFE). Since these meso-zooplankton play an important role as food sources to larval fish and pelagic organisms, factors affecting their changes in abundance in recent years warrants an investigation. One potential source of decline is insecticide exposure from nearby agricultural and urban run-off into the estuary. The goal of this study was to determine and contrast the acute effects of insecticides, Chlorpyrifos- an organophosphate insecticide, Permethrin and Bifenthrin-pyrethroid insecticides, to *E. affinis* and *P. forbesi.* The 96-hour median lethal concentration (LC-50) testing indicates that *E. affinis* (803.2 ng/L) is more sensitive to Chlorpyrifos than *P. forbesi* (1211.9 ng/L). However, *P. forbesi* is two-times more sensitive than *E. affinis* to Permethrin (LC-50 values 86.0 and 158.1 ng/L, respectively). For Bifenthrin, *E. affinis* showed an LC 50 value of 13.3 ng/L, while values for *P. forbesi* are 19.40 ng/L. Ongoing studies are investigating the LC-50s of five more commonly used pesticides in the SFE, including Malathion, Chlorothalonil, Fipronil, and Diuron. Results are these studies are anticipated prior to the conference. Results indicate species specific differences in response to insecticides. Shifts in the types and timing of insecticide use may cause a decline in copepods abundance, and ultimately have a negative impact on the SFE food web.

RP175 Alterations of Biochemical Indicators in Hepatopancreas of the Apple Snail, *Pomacea canaliculata*, from Paddy Fields in Taiwan T. Hsieh, Y. Chiu, Kaohsiung Medical Univ, Biomedical Science and Environmental Biology; D. Huang, Chia Nan Univ of Pharmacy and. Science, Environmental Resources and Management; C. Chen, Chia Nan Univ of Pharmacy and Science, Environmental Resources and Management, Chia Nan Univ, of Pharmacy and Science. Although organic farming becomes popular, most of agriculture activities in Taiwan are still based on traditional methods which rely heavily on pesticides. The ecological impacts for application of pesticides on paddy fields are usually not fully acknowledged. Introducing alien species into our environment also confound the problems, especially for apple snail, *Pomacea canaliculata*, which become prevalent and a major ecological disaster in Taiwan. The purpose of this study is to investigate the status of apple snails collected from paddy fields, with or without pesticide application, throughout the islands using different biochemical indicators. Apple snails were sampled from Hsinchu, Yunlin, Tainan and Pingtung areas in Taiwan. Several enzymatic activities, namely monooxygenase (MO), glutathione-S-transferase (GST), aspartate aminotransferase (AST) and alanine aminotransferase (ALT), as well as concentrations of urea

nitrogen, creatinine and vitellogenin (Vtg) in hepatopancreas of the animals were measured and compared with those from the controls raised in our laboratory. Our result shows that the activities of MO, GST, ALT and AST in snails from some of the paddy fields were higher than those in the controls. The highest were observed in snails from a paddy field using pesticides heavily in Pingtung. By comparing to controls, the differences of MO, GST, ALT and AST were up to 8, 13, 3, 5 folds, respectively. For VTG, creatinine and urea nitrogen, levels in snails from the paddy field were also found to be significantly higher than those in the controls, as well as others fields. Snails from other fields using pesticides also shows altered either enzymatic activities or levels of VTG, creatinine and urea nitrogen, although some of the differences varied and may not be consistent. We are still gathering more data and further results will be summarized and presented at the conference.

RP176 An Ecotoxicoproteomic Approach (SELDI-TOF MS) to Biomarker Discovery in Eggs of *Ephemera orientalis* McLachlan Exposed to Heavy Metals H. Mo, Korea Univ, Division of Environmental Science and Ecological Engineering; S. Lee, Nanotoxtech Inc. ; K. Cho, Korea Univ, Division of Environmental Science and Ecological Engineering, College of Life and Environmental Sciences, Korea Univ, # 407, Division of Environmental. Proteomics provide potential in the discovery of new sensitive biomarkers for environmental pollution. We utilized SELDI-TOF MS (surface enhanced laser desorption/ionization time-of-flight mass spectrometry) to analyze the proteomic profile of mayfly eggs (*Ephemera orientalis*) exposed several heavy metals (lead, mercury, copper, cadmium and chromium). While eggs of *E. orientalis* were very sensitive to lead, mercury and copper, but high concentration of cadmium and chromium did not affect on egg hatching. The protein peak patterns of *E. orientalis* eggs exposed to heavy metals were analyzed and compared using ProteinChip® Data Manager software (version 3.0, Bio-Rad, USA). This work could be the basics to develop the novel biomarker for aquatic ecological monitoring.

RP177 An Evaluation of the Incidence of Testicular Oocytes (Intersex?) in Largemouth Bass as a Function of Land-use and Season T. Gross, Environmental Resource Consulting, Univ of Florida. Several reports have suggested the presence of testicular oocytes (female germ cells) in fish as an indicator of intersex and exposure to endocrine disruptors. However, these studies have also reported a significant incidence of testicular oocytes in animals from reference and exposed sites. The baseline incidence of testicular oocytes in is not well documented nor clear that this is an intersex condition related to endocrine disruptors. The current study utilized both: a historic dataset with sites across the US and measures of land-use conducted during the 1990's and analyses of largemouth bass within the lower St Johns River basin in FL. The historic dataset had largemouth bass and carp from sites across the US with land-use designations: agriculture, urban/industrial, and reference. A representative portion of gonad was used for histopathology to assess repro stage and incidence of testicular oocytes. The FL study utilized bass from a reference site to characterize the incidence of testicular oocytes in male largemouth bass with season and year. The incidence in the historic dataset ranged from 0% to 44% of fish collected per site for bass, and from 0% to 12% per site for carp and the incidence did not differ with land use. For largemouth bass in the St Johns River the incidence of oocytes across the total gonad using serial sections rather than a representative portion was assessed. Analyses indicate that the incidence is highest near both apices of each gonad and not consistent across the total gonad and the incidence of testicular oocytes ranged from 38 to 46% across seasons, years and sites. These data suggest that the previous utilization of a representative portion may not have been adequate for the assessment of incidence. These data suggest that appropriate and validated techniques are critical to the accurate assessment of the incidence of testicular oocytes in fish and that testicular oocytes may be a nomal remnant of sexual differentiation that varies with fish species. The relationship to endocrine disruptors and/or contaminants is not clear but exposure would have to occur during early development rather than in adults. Testicular oocytes were always at early germ cell stages regardless of season, site, land-use or year. Future efforts should quantify the number of testicular oocytes as well as incidence and utilize controlled contaminant exposures.

RP178 An Evaluation of the Sensitivity of Freshwater Mussels in 7-day Effluent Toxicity Tests Compared to Commonly Tested Species J.L. Kunz, USGS; C.G. Ingersoll, USGS, Columbia Environmental Research Center; N. Wang, US Geological Survey, Columbia Environmental Research Center; T. Augspurger, US Fish and Wildlife Service, Ecological Services; C. Hollenkamp, NCDWQ, ESS ATU. The federally endangered Tar River spinymussel (Elliptio steinstansana) is endemic only to the Tar River and Neuse River systems in North Carolina. The primary threats to the species and its habitat appear to be stream impacts associated with conversion of forest lands and loss of forested riparian buffers, impoundment and water withdrawal, and silt and other pollutants from forestry, agriculture, and urbanization. The primary objectives of this study were to (1) evaluate the sensitivity of federally endangered Tar River spinymussel and two non-endangered surrogate mussels (yellow lance, Elliptio lanceolata and notched rainbow, Villosa constricta) to currently permitted effluents and reference toxicants (copper, ammonia, and synthetic effluent), and (2) compare the mussels' sensitivity to that of two commonly tested species (cladoceran, *Ceriodaphnia dubia* and fathead minnows, *Pimephales promelas*). Short-term (7-d) static-renewal tests were conducted with yellow lance, notched rainbow, the cladoceran, and fathead minnow in two permitted effluents collected in North Carolina. Preliminary results indicate that the two mussel species were equally or more sensitive to the two effluent samples compared to the cladoceran and fathead minnow. Additional effluent tests and the reference toxicant tests with mussels and the two commonly tested species are ongoing. Tar River spinymussels have been successfully captively propagated through this project; their sensitivity relative to the surrogate mussels will be assessed when propagated in sufficient numbers for toxicity testing.

RP179 Are Male Bluegills (*Lepomis macrochirus*) Experiencing Altered Reproductive Output Due to Exposure to Chlorinated Hydrocarbons? J. Hillis, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center; M. Lydy, J. Garvey, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology. For the past two decades, the chemical disruption of the endocrine system by xenobiotics has been a topic of discussion and concern. There are many indicators showing that endocrine disrupting chemicals (EDCs) in wild fish could potentially disrupt reproduction. This includes elevated vitellogenin levels in males, high incidence of intersex, and altered steroid profiles. Some chlorinated hydrocarbons (CHs) such as polychlorinated biphenyls and organochlorine pesticides act as EDCs and have been shown to be estrogenic or anti-androgenic. Chlorinated hydrocarbons continue to persist in the environment despite being restricted from use in the United States for three decades. This includes reservoirs where fishing is an important source of recreation. Bluegills (*Lepomis macrochirus*, BLG) play an important role in these food webs. Bluegills have been stocked extensively in impoundments as a forage fish for largemouth bass (*Micropterus salmoides*) and as sport fish. Building off this knowledge, the overall objective of this study was to quantify the concentration of CHs in male bluegill in Illinois and relate these concentrations to the incidence of gonad abnormalities and the gonadosomatic index. Although there is much evidence suggesting that CHs cause adverse reproductive effects, there still is little evidence to suggest that EDCs are influencing fish and other organisms at the population level. The proposed research addresses this question by conducting a reproductive trial using wild-caught fish from lakes with whole-body CH concentrations and a control lake with less than background CH concentrations. Preliminary work has detected organochlorine pesticide (DDT, DDD, DDE, and α-chlordane) residues ranging from 3 to 65 ng/g (dry weight) in whole body tissue samples.

RP181 Assessment of Chronic Toxicity of Upper Columbia River Sediments to Early Life Stage White Sturgeon D.W. Vardy, Univ of Saskatchewan, Toxicology Centre, Univ of Saskatchewan, Ph.D candidate; J.A. Doering, S.C. Beitel, B.J. Tendler, Univ of Saskatchewan; R. Santore, A.C. Ryan, HDR|HydroQual; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science; M. Hecker, Univ of Saskatchewan, Toxicology Centre. Sturgeon (Acipenseridae) populations are threatened throughout the world and have been decreasing over the past century in North America, Asia, and Northern Europe. In North America, populations of white sturgeon (WS; *Acipenser transmontanus*) are declining in the north-western USA and British Columbia, Canada, primarily due to poor annual recruitment. Pollution has been hypothesized as one potential cause for poor recruitment in the Columbia River (CR) between Grand Coulee Dam in the USA, and the Hugh L. Keenleyside Dam in southern British Columbia, Canada. Potential past and/or present pollution sources include metallurgical facilities, pulp and paper

mills, and other industrial and municipal sources. Given the epibenthic nature of WS, there is the potential for substantial exposure to contaminated sediments within the CR. Specifically, there are concerns about the potential toxicity to WS early life stages (including the early hiding stage where fry are in proximity to sediments) of contaminants such as metals that are associated with sediments. The present study evaluated the effects of metals in sediments collected from the CR on early life stage WS. WS were exposed to field-collected sediments from areas considered to be suitable WS habitat, and containing a range of metal concentrations. Reference sediments were collected from sites in Canada, upriver from of the study area. Studies were conducted at the Aquatic Toxicology Research Facility, Univ of Saskatchewan, Saskatoon, SK, under simulated fluvial, flow-through, conditions from hatch to 60 days post hatch. Survival in the references was greater than 75% and preliminary data evaluation revealed no obvious trends in survival or growth among groups exposed to CR sediments.

RP182 Benthic Invertebrate Exposure and Chronic Toxicity Analysis for cVMS Materials – A Probabilistic Approach and Comparison to the Target Lipid Model K.B. Woodburn, Dow Corning Corporation, Health & Environmental Sciences; D.E. Powell, Dow Corning Corporation, Health & Environmental Sciences, Dow Corning Corporation, Health & Environmental Sciences (C03101); A. Redman, P. Paquin, Hydroqual. Lipophilic chemicals, such as the cyclic volatile methylsiloxane materials octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5), adsorb extensively to particles and surfaces in aqueous systems, making sediments a key sink when performing risk assessment evaluations. A widely accepted step for estimating the possible risk posed by such chemicals to sediment-dwelling species is to compare the observed sediment concentration with either published ecotoxicity guidelines or to chronic no-observed effect concentrations (NOECs) from toxicity testing with benthic invertebrates. The comparison of field concentrations with chronic NOEC levels can be done with simple worst-case simulations or using a probabilistic distribution approach. In this work, probabilistic methods were used to compare residues of D4 and D5 from sediments and organisms collected in Canada, the United States (Lake Pepin, Minnesota), the UK, and Nordic countries, including Inner Oslofjord to chronic NOEC values determined using EPA/OECD test species such as *Chironomus tentans*, *Chironomus riparius*, *Hyalella azteca*, and *Lumbriculus variegates*. The risk assessment was extended using ecotoxicity data on more than 90 chemicals and 50 species using the Target Lipid Model (TLM) database. Comparisons were made using sediment levels on a dry weight and organic carbon basis, and with organism residues on a lipid-adjusted basis. Probabilistic endpoints of 95% exposure and 5% chronic NOEC were extrapolated from the data, which were fit using log-normal assumed distributions. The cVMS acute-to-chronic ratios (ACRs) were consistent with TLM data and with a narcosis mode of action (average ACR of 2-5). Using either probabilistic techniques or the TLM database, field D4 and D5 concentrations were far below chronic threshold NOEC values with benthic invertebrates, therefore very limited risk appears to exist for benthic invertebrate species with these materials.

RP183 Benthic Macroinvertebrate Metrics Correlated with Heptageniid Mayfly Whole Body Metal Concentrations in a Stream Near a Uranium Enrichment Plant A. Wigginton, Univ of Kentucky, Dept of Civil Engineering, Univ of Kentucky, Dept of Biology; R. Umbstead, Univ of Kentucky, Civil Engineering; J. Walker, Univ of Kentucky; B.F. Brammell, Asbury Univ, Natural Sciences Dept. The Paducah Gaseous Diffusion Plant (PGDP) is currently the only active uranium enrichment facility in the United States. It is located in McCracken County, Kentucky and is bordered to the west by a first order stream, Bayou Creek (BC). The plant generates several effluents that contain output from various industrial processes including sewage waste; roof, surface, and parking lot drainage; settling pond effluents; and air conditioning condensate. Sites along Bayou Creek were sampled for aquatic macroinverterbates using a Surber sampler and steel scoop on October 24-25, 2009. At the same time, Heptageniid mayflies were sampled and analyzed for metal contamination using Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES). When considering macroinvertebrate populations in general and Chironomid populations in particular, several metrics, including the Hilsenhoff Biotic Index , Shannon Weaver and Simpson Diversity Indices, the Community Loss Index, and the EPT/Chironomid Index indicated a reduction in water quality near the plant compared to upstream reference sites. Heptageniid mayflies collected from areas of BC adjacent to or downstream from the PGDP showed significantly different average metal concentrations for Cd, Co, Cu, Mn, Ti, Zn (ANOVA, Tukey HSD, $p < 0.05$), and also, at a lower level of confidence, Ba, Fe, and P (ANOVA, Tukey HSD, 0.05

RP184 Benzotriazole UV Stabilizers and Polycyclic Musks in Bivalves from Japanese Coastal Waters: Occurrence and Source Determination A. Nishidome, H. Nakata, R. Shinohara, N. Shikata, Kumamoto Univ. Recently, the occurrence and contamination of persistent personal care products, such as benzotriazole UV stabilizers (BUVSs) and polycyclic musks have been reported in the environment. The detection of these compounds in marine mammals and seabirds suggests their bioaccumulation potentials through the aquatic food-chains. BUVSs and musks were detected in mussels collected from Asian countries, indicating their widespread contamination in Asian coastal regions. However, detail information is lacking on the concentrations and distribution of BUVSs and synthetic musks in Japanese coastal waters. In this study, we analyzed four BUVSs and two polycyclic musks in bivalves collected from 57 stations of Japanese coastal waters. BUVSs, UV-326, UV-327, and UV-328 were detected in all samples analyzed, at the mean concentrations of 1,230, 150, and 336 ng/g (lipid wt.), respectively. A significant correlation between UV-327 and UV-328 were found in bibalves, which suggest that these compounds might have been originated from same sources. To determine the source of BUVSs and musks in the environment, influent, effluent, and sludge samples of WWTPs and road dusts were analyzed in this study. BUVSs were detected in all WWTP samples, and UV-326 was the dominant compounds in influents (mean: 46 ng/L), followed by UV-328 (34 ng/L). High concentrations of HHCB and AHTN were found in liquid and solid samples of WWTP, suggesting the present use of BUVSs and musks in cosmetics and household materials. BUVSs and musks were also detected in road dusts. Significant correlations were obtained between BUVSs concentrations and traffic densities. These results indicate that WWTPs and road dust may be a potential source of BUVSs and musks in the aquatic ecosystems.

RP185 Best Management Practices as Tools for Nutrient Reductions in the Lower Mississippi Alluvial Valley: What Do We Really Know R. Kroger, Mississippi State Univ, Dept of Wildlife, Fisheries and Aquaculture, Mississippi State Univ; A. Sharpley, Univ of Arkansas, Crop, Soil and Environmental Sciences. Agricultural best management practices are utilized to reduce and mitigate nutrient concentrations and loads leaving landscapes, thus reducing the toxicological and ecological impacts on downstream aquatic systems. The current study provided a review of the scientific literature to create nutrient reduction efficiency percentages for BMPs in row-crop agriculture within the Lower Mississippi Alluvial Valley (LMAV). The review consisting of multiple agricultural and biological database searches yielded 75 articles that initially were included (search terms: BMP, agriculture, nutrients, Mississippi). Utilizing specific criteria of row-crop agriculture, clay/silt loam soils; slopes 0-5%, and LMAV resulted in 16 studies across multiple BMPs for inclusion. Best management practices included tillage management, wetlands, winter rice field management, subsurface drainage and vegetated drainage ditches. Total P and total nitrogen as well as nutrient species percentage reduction information was parsed from the scientific studies. The lack of replicate studies for BMPs within the LMAV limits the ability of discerning nutrient specific reduction efficiencies associated with various BMP applied to the agricultural landscape. This study was limited in its search criteria to row-crop agriculture in the LMAV, and ignored potentially relevant BMP studies from elsewhere in the country. This was decided extremely important as site specific conditions dictate the reduction efficiency of applied BMPs and as such data from elsewhere would be neither transferable nor applicable. This study has highlighted the lack of scientifically validated reduction efficiency information on BMPs and suggests increased BMP validation to improve understanding, which would enhance BMP driven models for landscape stewardship.

RP186 Bioavailability and Toxicity of Sediment-associated Uranium to the Freshwater Midge *Chironomus dilutus* S.E. Crawford, K. Liber, Univ of Saskatchewan, Toxicology Centre. The anticipated increase in demand for nuclear power production will result in the increased mining of uranium (U), which raises the potential for increased U levels in adjacent aquatic ecosystems. Interactions between dissolved U and solid phases can result in sediment U concentrations that are several orders of magnitude higher than those in the water column. Despite high concentrations of U found downstream from some older Canadian U mining operations, little is known

about the bioavailability of U from solid phases with respect to effects on freshwater benthic invertebrates. Physicochemical characteristics of sediment have been found to influence the bioavailability and toxicity of U and other trace metals associated with sediments. Thus, the purpose of this research is to further investigate the influence of key sediment characteristics on the bioavailability and toxicity of sediment-associated U using the freshwater midge *Chironomus dilutus* as a model organism. The objective of our first study is to determine if different clay minerals with different surface chemistries differentially influence the bioavailability of sediment-associated U in a series of 10-d sediment toxicity tests. The influence of different U sorption capacities on U bioavailability will be further investigated with experiments on particle size distribution, which may also play an important role in the bioavailability of U. The growth, survival and bioaccumulation of U in *C. dilutus* are examined and compared among treatments and experiments. All water (overlying and pore water), sediment and tissue samples are analysed for U using inductively coupled plasma-mass spectrometry (ICP-MS). The different sorption properties of different sediment components may prove to be important in the risk assessment of U contaminated sites, as well as in the incorporation of site-specific sediment characteristics in regulatory guidelines.

RP187 Biochemical and Molecular Responses of White Sturgeon (*Acipenser transmontanus*) to an Aryl Hydrocarbon Receptor Agonist J. Doering, S. Beitel, Univ of Saskatchewan, Toxicology Centre; B.J. Tendler, Univ of Saskatchewan; S.B. Wiseman, Univ of Saskatchewan, Toxicology Centre; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science; M. Hecker, Univ of Saskatchewan, Toxicology Centre. Dioxin-like chemicals in some sediments can bioaccumulate into fishes to concentrations sufficient to produce toxic effects. Benthic fishes such as sturgeon might be at greater risk of exposure to these chemicals. Despite their endangered status, little research has been done to characterize the relative responsiveness of sturgeon to dioxin-like chemicals. In a first attempt to characterize the biological effects and possible associated risks of exposure to dioxin-like chemicals in sturgeon we investigated the molecular and biochemical responses of white sturgeon to a model aryl hydrocarbon receptor agonist, β-naphthoflavone (BNF). Juvenile white sturgeon were injected intraperitoneally with BNF. Rainbow trout were used as a reference species since their responses have been well characterized in the past. Three days following injection with one of three doses of BNF (0 mg/kg, 50 mg/kg or 500 mg/kg) fish were euthanized and gill, intestine, and liver collected for biochemical and molecular analyses. In sturgeon all tissues had significantly greater ethoxyresorufin-O-deethylase (EROD) activity in exposed groups. EROD activity in liver of sturgeon exposed to 50mg/kg was 37 times greater than that of the controls, 28 times greater in the intestine, and 23 times greater in the gill. Rainbow trout had EROD activity 88 times greater than controls in the liver, but undetectable activity in the intestine and gill. EROD activity in liver of sturgeon exposed to 500mg/kg was 17 times greater than that of the controls, 51 times greater in the intestine, and 65 times greater in the gill. Methoxyresorufin-O-deethylase (MROD) activity in exposed sturgeon liver and intestine was less than EROD activity, however trout liver had activity similar to that of EROD. Based on these results, sturgeon appear to be moderately responsive to dioxin-like chemical exposure. The greater responsiveness of the intestine and gill in sturgeon suggests that these tissues might be of greater importance in the biotransformation of polyaromatic hydrocarbons in sturgeon than in trout. Further research is necessary to investigate the toxicological and evolutionary significance of the observed intestine and gill enzyme activity in sturgeon.

RP188 Bioconcentration and Bioaccumulation of Three Pharmaceuticals in Fish S. Garcia, M. Foster, Univ of North Texas, Biology; D.B. Huggett, Univ of North Texas, Dept of Biological Sciences; L.A. Constantine, Pfizer Global Research and Development, Pharmacokinetics, Dynamics & Metabolism, Pfizer, Inc., Pharmacokinetics, Dynamics and Metabolism. Laboratory bioconcentration studies are becoming an integral part of the pharmaceutical risk assessment process. The bioconcentration factors of carbamazepine, amiodarone, and dexamethasone — three commonly prescribed pharmaceuticals in the United States — were evaluated using 42d and 7d bioconcentration factor (BCF) experiments with *Pimephales* sp. and *Ictalurus punctatus*, respectively. Further, fsamplings of *Oreochromis niloticus* from the Denton Wastewater Treatment Plant were made to determine a field bioaccumulation factor (BAF). *Pimephales* sp. were continuously exposed to either a 300 µg/L carbamazepine, a 250 µg/L amiodarone, or a 400 µg/L dexamethasone during the uptake phases of the BCF studies. I. punctatus were exposed to a 125 µg/L carbamazepine or a 250 µg/L amiodarone during the uptake phases. Liver, white muscle, and blood were sampled from tilapia and catfish, while only liver and white muscle were sampled from the minnows. Tissue, exposure water, and wastewater concentrations of the three pharmaceuticals were measured by isotopic dilution liquid chromatography tandem mass spectrometry (ID LC-MS/MS). The tissue specific kinetic BCFs for carbamazepine ranged from 1.3 to 71, while amiodarone BCFs ranged from 27 to 3089. Proportional BAFs for carbamazepine in the white muscle, liver, and plasma of *O. niloticus* were 2.81, 3.78, and 2.53, respectively. Dexamethasone levels in fish tissues were below detection during the laboratory and field experiments. These data will assist researchers in prioritizing future research needs with respect to individual drugs and pharmaceutical classes.

RP189 Biomarker Responses in Sunfish and Bass from the Saluda River, South Carolina J. Mierzejewski, Clemson Univ, Dept of Biological Sciences; D. Haney, Furman Univ; P. Van den Hurk, Clemson Univ. The Saluda River watershed, in the Upstate and Piedmont regions of South Carolina, provides drinking water for more than 500,000 inhabitants. The river also receives effluents from multiple industries, urban areas and a dozen wastewater treatment plants. In 2009 the Saluda River was ranked 6th of America's Most Endangered Rivers by American Rivers, due to its high levels of phosphorous which is assumed to mostly originate from wastewater treatment plant effluents. As the Saluda River and its reservoirs are frequently used for boating, combined with the multiple point- and non-point sources contributing to the river, it is likely that other contaminants, like PAHs, metals, pesticides and pharmaceuticals are present. Little is known about the ecological health of the river. In this study, health effects from pollutants on fish in the Saluda River were examined through the application of biomarkers. A total of 159 fish from the *Centrarchidae* family (*Lepomis* spp. and *Micropterus salmoides*) were collected during June and July 2010, at 13 sampling sites throughout the Saluda River. Here we report the first results for bile fluorescence, EROD activity, GST activity, TBARs and estrogenic compounds in bile. The highest responses were observed at the sampling sites in the center of the watershed, with lower responses seen at both the upstream and downstream ends of the river.Lake Greenwood exhibited consistently low responses. Further analyses will focus on estrogenic effects in fish and tissue accumulation of heavy metals.

RP190 Chromium (VI) Induced Energy Allocation in *Daphnia schodleri* (Anomopoda: Daphniidae) Females and Their Offspring M. Arzate Cardenas; F. Martinez-Jeronimo. Cladocerans accumulate energy as proteins, lipids and carbohydrates, and the amount will depend on their physiological and reproductive conditions, as well as on their age. These macromolecules are used to define the caloric content of organisms and could be modified by physical or nutritional factors or even by toxicant exposure. Aimed to evaluate how age and chromium (VI) exposure modify the caloric content of the freshwater cladoceran *Daphnia schodleri*, neonates were exposed to 6.4, 32 y 64 µg L^{-1} of Cr ($K_2Cr_2O_7$) until they reached 5, 7, 14, 21 and 28 days old. Survivorship and fecundity were assessed during the exposure period. Neonates from different broods (at different maternal age) and reproductive females of different ages were measured; then, the caloric content of neonates and adults was assessed through macromolecules quantification and transformed by their respective combustion factor (carbohydrates 4.1 cal mg^{-1}, proteins 5.65 cal mg^{-1} and lipids 9.45 cal mg^{-1}) to energy content. Survivorship was significantly reduced in the group which was exposed to the higher chromium concentration but fecundity was reduced in all the exposed groups. Adults' size was negatively affected in individuals from 21 days and older. Although there were significant differences among neonates' size, they cannot be attributed to the chromium toxic effects but natural variation. Moreover, neonates produced by stressed daphnids showed higher energetic reserves, situation that could be interpreted as an energetic preparation for the adverse conditions they will cope with, even at maternal expense since adult females allocated resources for detoxification and reproduction, switching from quantity to quality offspring in terms of their energy reserves.

RP191 Consistency of Morphological Endpoints Used to Assess Developmental Timing in Zebrafish (*Danio rerio*) Across a Temperature Gradient A. Shaffer, M. Elrod-Erickson, R. Otter, Middle Tennessee State

Univ, Biology. Zebrafish have been used as a model toxicological system for studying developmental effects of contaminants. The combination of transparent embryonic development and a well-described genome have made this model an attractive choice for researchers interested in investigating potential teratogenic compounds. Classic methods to measure developmental delays using zebrafish have focused on the time it takes for embryos to hatch. However, this endpoint misses major developmental events during development. In this study we investigated the consistency of non-lethal developmental endpoints commonly utilized in the literature that occur prior to hatching exposed at temperatures of 24.5°, 26.5°, or 28.5° C. These endpoints were 1) time to reach a specific morphological milestone, 2) the distance between the optic cup and the otic vesicle, and 3) the distance between the optic cup and the otic vesicle divided by the diameter of the otic vesicle. The objectives of this study were to quantify the influence of temperature on each endpoint and to determine the consistency amongst endpoints. Results show a direct effect of temperature on each endpoint, with lower temperatures causing slower development. Results also show a high amount of consistency between each endpoint. Results of these studies have also led to the development of a quantifiable relationship model for each endpoint based on temperature, allowing researchers to compare results of studies at different temperatures in a more direct manner as well as development of a cost-benefit analysis of each endpoint measured.

RP192 Coupling Ecological and Process/ISO based LCA to Assess the Production of Wood Derived "Drop-in" Biofuels N. Bortsie-Aryee, A. Halog, Univ of Maine, School of Forest Resources (Research Group for Industrial Ecology, LCA & Systems Sustainability) With the ever increasing interest in biofuels production as a result of declining stocks of fossil fuels, energy independence, proven environmental benefits, rural economic development as well as the renewability of biomass feedstocks, it has become critically vital to examine the sustainability of the whole biofuels supply chain. Bio-oil, which is a product of recent innovations in biotechnology, genomics and bioengineering, is an oxygenated compound containing carboxyls, carbonyls and phenolics and is miscible in water. Bio-oil production involves the degradation of biomass in the absence of oxygen through the process of pyrolysis, which in the end produces a fuel which can be used for various energy intensive processes. Though the shift towards biofuels seems beneficial, an in-depth understanding of its short and long term consequences is required. This analysis should encompass the impacts starting from the supply of biomass to production of bio-oil and eventually to its consumption while considering its social acceptance, economic viability and environmental soundness. A hybrid ecological based and process-based LCA has been used to assess the environmental and ecological impacts of wood-derived bio-oil production. This will capture the impacts on ecosystem goods and services as well as the resource consumptions and associated environmental emissions during the life cycle stages. The LCA results will help scientists and policymakers to make decisions to support "drop-in biofuels" technology development in view of meeting the ideals of sustainable development. Our results will be presented and discussed in this conference.

RP193 Critical Analysis of Read-across and Categories Under REACH: A Case Study with Xylenols S. Erler, Smithers Viscient; C. Waites, Sabic Innovative Plastics, Staff Toxicologist; E. Mihaich, Environmental and Regulatory Resources; C. Smith, Smithers Viscient. As part of integrated testing strategies under REACH, a registrant needs to consider the potential for using read-across and the formation of categories to avoid unnecessary testing and prioritize study plans. However, the relevance of read-across and category approaches must be judged on a case-by-case basis, taking into account the the quality of existing data and regulatory context in which the results are used. As a case example, this paper proposes a process for assessing and justifying groupings of xylenols and related chemical families for registration under REACH. Xylenols are a set of isomers with the same functional groups, which share toxicological properties. Previously, xylenols have been subject to groupings under the OECD Existing Chemicals HPV Programme and used for European Union hazard classification purposes. Nevertheless the reporting of groupings, as well as the assessment of extensions of groupings to structurally-related chemistry, requires a methodological approach. An examination of ecotoxicological endpoints through the combination of (Q)SARs and predicted degradation pathways is presented to illustrate the use of structural and computational methods in building a category hypothesis. Consideration is given to the advantages and disadvantages of different options for reporting in REACH registration dossiers. Finally, the potential impact of relying on non-test data is evaluated in terms of implications to environmental hazard assessment and risk management of xylenols.

RP194 Cyclic Volatile Methylsiloxanes (cVMS) and Selected PCB Congener Residues in Body Tissues of American Mink Obtained from Lake Pepin, Minnesota USA K.B. Woodburn, J.A. Durham, R.M. Seston, Dow Corning Corporation, Health & Environmental Sciences; D.E. Powell, Dow Corning Corporation, Health & Environmental Sciences, Dow Corning Corporation, Health & Environmental Sciences (C03101) The concentrations of cyclic volatile methylsiloxane (cVMS) materials and selected polychlorinated biphenyl (PCB) congeners were measured in mink tissue (fat, muscle, and liver) taken from organisms collected in Lake Pepin, Minnesota, USA. This large freshwater watershed has previously been examined for the trophic magnification behavior of the cVMS compounds octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5), and dodecamethylcyclohexasiloxane (D6) in an aquatic food web consisting of benthic invertebrates and fish. Three male and one female mink were captured on Lake Pepin in November 2008 by a licensed trapper. The mink were dissected to remove the liver, perirenal fat, and a portion of quadriceps muscle from a rear leg. The stomach was also removed for content identification to identify dietary preferences immediately prior to death. Average cVMS concentrations in mink (lipid-adjusted) are lower than lipid-adjusted cVMS residues in Lake Pepin whole fish and benthic invertebrate organisms. Possible explanations include a continuation of cVMS trophic dilution observed in Lake Pepin fish, exhalation of cVMS by mink, cVMS metabolism, and dietary dilution with non-aquatic species in the mink diet. By comparison, lipid-adjusted concentrations of PCB congeners (e.g., PCB153 and PCB180) from mink feeding primarily on Lake Pepin aquatic organisms are equal to or greater than their respective levels in fish, benthic invertebrates, zooplankton, or sediment, consistent with the known biomagnifying properties for some PCB congeners. These data collectively indicate that Lake Pepin mink may be demonstrating continued trophic dilution of cVMS in higher trophic level species, a trend that is similar to that reported for cVMS in food webs terminating in seabirds (i.e., kittiwakes and eiders) and grey seals. Additionally, Lake Pepin mink may be demonstrating biomagnification of PCB congeners such as PCB153 and PCB180 in the aquatic food web of the lake, including mink.

RP195 Determination of CBR Values for Three Current-use Pesticides in *Hyalella azteca*: Predictive Techniques vs. Direct Tissue Residue Measurement B. Holzer, Oklahoma State Univ, Dept of Zoology, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology; J.B. Belden, N.L. Cooper, Oklahoma State Univ, Dept of Zoology. Extensive pesticide application has contributed to the contamination of surface water, placing aquatic organisms at an elevated level of risk of toxicant exposure. Most aquatic toxicity assessments use water or sediment chemical concentrations as a "dose metric" to indicate the level of exposure experienced by organisms in aquatic systems. Although, measurement of the amount of chemical present at the site of toxic action would result in the most accurate dose metric, such a measurement is not typically feasible. As an alternative, whole body residue (or critical body residue) analysis may provide a better estimate of effective dose. This is especially true for lipophilic, non-reactive compounds. Although the critical body residue (CBR) approach has been used in previous studies, very little body residue data is available for current use pesticides. The objective of this study was todetermine the toxicity of three pesticides (bifenthrin, pendimethalin, and trifluralin) to an aquatic arthropod (*Hyalella azteca*) using three critical body residue approaches. Method 1 (using predicted BCF and empirical LC_{50} values) and 2 (using empirical BCF and empirical LC_{50} values) were calculated for each compound and compared to the directly measured (LBR_{50}) tissue concentration. Results from this study indicate that both Method 1 and 2 (7.4 and 0.3 µmol/kg bifenthrin; 3.27 and 0.70 mmol/kg pendimethalin; and 0.63 and 0.87 mmol/kg trifluralin, respectively) overestimate CBR values, resulting in an underestimation of toxicity. Thus, the best measure of CBR is empirical determination during toxicity testing.

RP196 Determination of Dioctylsulfosuccinate (DOSS) in Oysters Using Single Quadrupole Mass Spectrometry M. Miller, J. Wang, W. Schnute, Thermo Fisher. A method for analysis of sodium dioctylsulfosuccinate (DOSS), the major component of Corexit dispersant, was developed and applied to both seawater and oyster samples. A HPLC system coupled with a C18 column provided separation of the analyte from the matrix. A

single quadrupole mass spectrometer provided the sensitivity and selectivity to accurately confirm identity and quantitate the target analyte. Samples of simulated seawater and oysters were spiked to evaluate the extraction efficiency and reproducibility. An automated sample extraction device employing pressurized heated solvents was used to speed the process. The extract was diluted, reducing matrix background as well as bringing the final concentration of the analyte in line with the calibrated range of the analysis. Preliminary Data: Linear response was demonstrated in standards ranging across 3 orders of magnitude from low ppb level to ppm concentrations. The method for extraction of DOSS from oysters was evaluated for efficiency of extraction as well as reproducibility. Oysters were homogenized in a blender and aliquots of the resulting emulsion loaded into the extraction cell and spiked with DOSS. A mixture of 1:1 acetonitrile and water proved optimal for analyte solubility and extraction time was minimized by heating to 100 °C and pressurizing to 1700 psi the solvents in the automated extraction instrument. Oyster homogenates were spiked in concentrations ranging from 250ppm down to 2.5ppm of DOSS. At all levels it was necessary to dilute the solvent extract to lower the concentration to levels that were consistent with the instrument calibration curve. The data collected show that the analysis in the oyster matrix was reproducible and had high efficiency for recovery. This demonstrated that the combination of procedures for the extraction and analysis is capable of measuring samples at the current FDA limit of exposure (250 ppm) and well below. Should exposure limits be reduced in the future, there exists the opportunity of reducing or eliminating the dilution of the extracts to achieve a lower reporting limit level.

RP197 Determination of Pesticides from Water Samples in Chilean Rivers A. Giordano; M. Retamal, Universidad de Chile, Centro Tecnológico AGQ América; J. Suarez, Centro Tecnológico AGQ América; P. Richter, Universidad de Chile. There is concern about the quality of water in ecosystems due to increased production and application of pesticides that eventually reach surface waters, making necessary to develop methodologies that can detect organic pollutants in rivers. A multi-residue method has been developed for determination and confirmation of 55 pesticides in water samples by GC-MS/MS (LODs: 0.75-19.8 ng/L). The analytes belonging to different pesticides families were determined in a chromatographic run after an extraction procedure. The method was used to make a comparison between rivers in the Metropolitan Area and in the Bio-Bio Area of Chile, due to agricultural activity. Samples were taken at three points from Mapocho/Maipo rivers (Metropolitan Area) and on a different day sample at three points of Itata/Ñuble rivers (Bio-Bio Area) were taken. The study show presence of diazinon, carbaryl, atrazine, myclobutanil and terbuthylazine in Mapocho river with concentrations between 40-95 ng/L, while in Itata river show presence of diazinon, chlorpyrifos-ethyl, tebuconazole, fenvalerate, cypermethrin and cyhalothrin in concentrations between 2.9-7.6 µg/L.Other pesticides were not detected. Different compounds has been detected in both rivers, because sampling areas have different types of crops: vegetables for Itata river and vineyard/fruit for Maipo river. The difference in concentrations observed may be due to applicaction dates and methodology: in Itata rivers pesticides in vegetables are applied nearest to the soil.

RP198 Differences in Seasonal and Precipitation Patterns for Two Fecal Bacterial Indicators M. Sitzlar, Middle Tennessee State Univ, Molecular Biosciences, Texas A&M Univ, Wildlife and Fisheries; S. Winesett, M. Garmon, M. Barbero, Metro Water Services; F. Bailey, Middle Tennessee State Univ, Dept of Biology *Escherichia coli* (*E. coli*) is the main fecal bacterial indicator (FIB) under the Clean Water Act used to classify waterbodies as impaired for pathogens. One major limitation of *E. coli* as an indicator is the inability to associate fecal sources to their warm-blooded host, causing difficulty in applying appropriate watershed management strategies. *Bacteroides* spp., a potential alternative FIB, has been shown to be highly host specific for human, equine, and bovine 16S rRNA gene targets. It is imperative to look at long-term monitoring data to establish life histories and patterns of FIB under varying conditions to direct regulatory agencies for future source tracking protocols. Past data collected by Metro Water Services, Nashville, TN, USA, found *E. coli* concentrations (colony forming units) to increase during the summer months (June, July, Aug) and to decline substantially in the winter season. We collected both *E. coli* and *Bacteroides* in baseflow and wet weather conditions from March 2010-April 2011 for sixteen impaired streams located in Nashville, TN. Colilert and qPCR methods were used for detection of *E. coli* and *Bacteroides*, respectively. Seasonal and weather differences existed for both *E. coli* and *Bacteroides* ($p < 0.001$). *E. coli* concentrations were higher in wet weather than baseflow scenarios, but *Bacteroides* concentrations did not differ between baseflow and rainfall samples. *E. coli* was statistically higher ($p < 0.001$) in the summer and *Bacteroides* tended to higher in the winter. These results may supplement EPA's water quality criteria development and direct potential seasonal use or seasonal-specific criteria of FIBs. Watershed managers may also find this beneficial for optimal source-tracking conditions.

RP199 Early Life-stage Exposure to Selenium by Egg Injection of Pallid Sturgeon (*Scaphirhynchus albus*) and Shovelnose Sturgeon (*S. platorynchus*) D.M. Papoulias, US Geological Survey, Columbia Environmental Research Center; M. Annis, D. Nicks, US Geological Survey; D.E. Tillitt, US Geological Survey, Columbia Environmental Research Center; M. Schwartz, US Fish and Wildlife Service. Endangered pallid sturgeon and congeneric shovelnose sturgeon found in the lower Platte River, NE and elsewhere in the Missouri River basin have elevated tissue levels of selenium. Their piscivorous-omnivorous diet and long period of recrudescence between spawns facilitates Se bioaccumulation into eggs and hence offspring exposure. Early-life stages of fishes (embryo-larva) are sensitive to Se effects and are thought to be a significant bottleneck limiting sturgeon populations. Therefore, the objective of this study was to determine what concentrations of Se affect survival of young *Scaphirhynchus* sturgeon. Embryos were injected with graded doses of selenomethionine (SeMet nominal doses: 0, 6, 10, 18, 32 µg Se/g dry egg wt) within 24h post-fertilization (PF) to simulate maternal exposure to selenium. Developmental effects were evaluated at 7d PF. Mortality was assessed at 17d PF and mortality and growth were evaluated at 32d PF. Genotoxic effect of Se was evaluated at 32d PF by erythrocyte micronuclei. Actual mean Se concentrations in embryos immediately after injection were estimated to be 9, 12, 17, 23 µg Se/g egg and 6, 7, 13, 17 µg Se/g egg for shovelnose and pallid, respectively. Background egg concentrations were 5 µg/g egg and 3 µg/g egg for shovelnose sturgeon and pallid sturgeon, respectively. Developmental deformities (delayed development, edema, and skeletal deformities) were mostly observed within the first 7d PF at a nominal dose > 10 µg Se/g egg. A higher percentage of pallid larvae than shovelnose larvae presented with developmental deformities and these were lethal. In general, mortalities were highest within the first 17d PF. Shovelnose mortality was significant at estimated doses of 17 and 23 µg/g egg. Pallid sturgeon mortality was significant at the highest estimated dose tested of 17 µg Se/g egg. However, overall pallid survival was low for all doses and time points and fertilization rate for pallid eggs was lower than for shovelnose eggs, suggesting that poor pallid sturgeon egg quality may have confounded results. Growth was not significantly affected in either species. Although the magnitude of the effects differed between the species, the effective selenium concentrations and the associated types of deformities were similar. The results of these studies will assist biologists in determining whether selenium toxicity is a factor limiting recovery of the pallid sturgeon in some parts of its range.

RP200 Ecological Bioavailability of Permethrin and *p,p'*-DDT: Toxicity is Dependent on Type of Organic Matter Fraction J.D. Maul, Texas Tech Univ, The institute of environmental and human health, The Institute of Environmental and, Dept of Environmental Toxicol; A.J. Trimble, Ashland Univ; M.J. Lydy, Southern Illinois Univ, Fisheries and Illinois Aquaculture Center and Dept of Zoology. Allochthonous leaf litter is a primary source of carbon into stream ecosystems, providing a linkage of terrestrial and aquatic systems and a major energetic resource for stream food webs. Leaf litter is fractionated into different components through biological processing (primarily leaf shredding by invertebrates and decomposition) and is important for cycling of organic carbon and stream ecosystem functioning. Use of allochthonous litter inputs drives differentiation of aquatic invertebrate communities into distinct functional feeding groups. These inputs are also a major adsorptive substrate for hydrophobic contaminants; an interaction that occurs from minimally decomposed coarse particular organic matter to very fine organic matter that is suspended or dissolved. This suggests that contaminant distribution may not be homogeneous within stream systems and could be more concentrated in certain locations or resource bases within streams. Likewise, resource utilization among stream macroinvertebrates is not homogenous; leading to the hypothesis that there may exist disproportionate contaminant effects among invertebrate taxa that is dependent upon how and where they use litter-based resources (i.e., bioavailability driven by ecological function). Here, we test this hypothesis by: (1) measuring partitioning of permethrin and *p,p'*-DDT among leaf-based organic matter

fractions and sediments, (2) examining variation in *Hyalella azteca* toxicity among permethrin and *p,p'*-DDT contaminated sediment, leaf, and a mixture, and (3) using SPME to understand bioavailability of freely dissolved fractions in leaf and sediment treatments. *H. azteca* lethal concentrations for 50% of the population (LC_{50}s) for permethrin and *p,p'*-DDT were lowest in the leaf exposure and highest in sediment for permethrin and sediment-leaf mixture for *p,p'*-DDT. Log K_{oc} values for both permethrin and *p,p'*-DDT were greatest within sediment and lowest in coarse leaf material. The SPME results indicated that both compounds had the highest levels of bioavailability in leaf material, lowest levels in sediment, and intermediate levels in the mixtures. These three lines of evidence demonstrate that toxicity, sorption, and bioavailability of permethrin and *p,p'*-DDT varied among organic matter fractions common within stream ecosystems, and supports the idea that ecological traits are important for driving the risk of contaminant impacts in stream systems.

RP201 Ecotoxicity of Textile dye C.I. Acid Orange 7 and Studies in Advanced Oxidative Process L.A. Luna, Campinas State Univ, LEAL – Laboratory of Ecotoxicology and Environmental Microbiology, Campinas State Univ; T.H. Silva, R.F. Nogueira, Paulista State Univ, Dept of Analytical Chemistry; F. Kummrow, Federal Univ of Sao Paulo, Dept of Exact Sciences and Earth; G.A. Umbuzeiro, Campinas State Univ, LEAL – Laboratory of Ecotoxicology and Environmental Microbiology. Dyes have been a concern in freshwater pollution. These substances may reach the water bodies and the exposure may cause toxicity to aquatic organisms and also inhibit photosynthetic process due to light absorbance competition. In that way textile effluents containing dyes must have their color and toxicity removed. The aim of this work was assess the toxicity of the textile azo dye C.I. Acid Orange 7 to *Daphnia similis* as well the effectiveness of photo-Fenton process to degrade this azo dye and remove the toxicity. The assays were carried out according to OECD and the acute toxicity was determined by EC50-48h. The C.I. Acid Orange 7 was obtained with 85% of purity (Sigma©). The EC50-48h to *Daphnia similis* was 86.0 $mg.L^{-1}$, and thus C.I. Acid Orange 7 can be considered harmful to aquatic life according to Global Harmonized System of Classification and Labeling of Chemicals. In a laboratory scale reactor using UV–vis artificial irradiation and Fenton's reagent (Fe^{2}+ and H_2O_2), 500 mL of C.I. Acid Orange 7 solution (60.0 $mg.L^{-1}$) was submitted to the treatment. The degradation of the azo dye and the formation of the byproducts were monitored using high performance liquid chromatography. We have performed toxicity assays in 5, 8 and 30 minutes of treatment to assess the toxicity of byproducts generated. In 60 $mg.L^{-1}$ of untreated dye was observed 10% of immobility. After 5 minutes of treatment 90% of immobility was observed, in 8 minutes 10% and after 30 minutes no immobility was observed. The acute toxicity of 5 minutes effluent sample was higher than the original dye which was not completely degraded according to the chromatographic analysis, thereby these byproducts may be responsible to the toxicity increase. On the other hand, 8 minutes effluent sample showed the same percentage of immobility of untreated dye, however after 30 minutes of treatment the toxicity was removed and the C.I. Acid Orange 7 was completely degraded. The next steps of this research include acute and chronic toxicity assessment to species from different trophic levels and chemical identification of toxic byproducts. Acknowledgements: Financial support, FAPESP – Thematic Project (2008/10449-7) and Master scholarship (2010/12991-3).

RP202 Effect of Herbicide Mixtures on Microbial Communities from Prairie Wetlands: A Whole Wetland Approach S. Sura, Univ of Saskatchewan, Food and Bioproduct Sciences; M.J. Waiser, Environment Canada, Water Science and Technology Directorate; V. Tumber, Environment Canada, Water Science and Technology Directorate; P. Messing, Univ of Manitoba, Ph. D. Candidate; A. Farenhorst, Univ of Manitoba, Associate Professor. The wetlands in the Prairie pothole region of Saskatchewan and Manitoba serve an important role in providing wildlife habitat, water storage and water filtration. These wetlands are regularly interspersed among intensive agricultural operations where herbicides and insecticides with multiple active ingredients are commonly used. Mixtures of herbicides and insecticides are often detected in prairie wetlands. A whole-wetland approach has been used to investigate the effects of herbicide mixtures (2,4-D, MCPA, clopyralid, dicamba, dichlorprop, mecoprop, bormoxynil, and glyphosate) on wetland microbial communities. The herbicide mixture at the recommended field application rate had a significant effect on the phytoplankton productivity of both pelagic and biofilm communities over relatively short time period. Stimulatory effects of auxin-type herbicides in the mixture as a result of 'concentration addition' was evident on primary production. BIOLOG and pigment profiles suggested change in the community structure. The herbicide mixture appears to have affected not only the microbial communities but also invertebrates (higher trophic level) suggesting a resonance effect of changes in the microbial communities.

RP203 Effect of UV Filter Benzophenone-4 on Planktonic Crustacea S. Yoon, S. Nam, Konkuk Univ; Y. An, Konkuk Univ, Dept of Environmental Science. UV filters are widely used in sunscreens to block ultraviolet light. Benzophenone-4 is an ingredient of sunscreens, and is frequently detected in water body. In this study, the acute toxicity of UV filter benzophenone-4 was evaluated using three crustacea to investigate how these common aquatic species were influenced by exposure to benzopheone-4. Test species were *Daphnia magna*, Moina macrocopa, and Simocephalus mixtus. Acute assay was conducted according to OECD TG No.202, and survival and immobilization were measured. All tests species were adversely affected by benzopheone-4, and the 24h-EC50 values for all species were in the range of 247 to 303 mg/L showing similar sensitivity. *Daphnia magna* tended to be more sensitive to benzophenone-4 than Moina macrocopa after 48h exposure. Further studies are needed to investigate the effect of other kinds of UV filters in aquatic ecosystem.

RP204 Effects of 17α-Ethinylestradiol (EE2) on Northern Pike (*Esox lucius*) S. Beitel, S. Wiseman, J. Raine, M. Hecker, Univ of Saskatchewan, Toxicology Centre. Exposure to environmental estrogens and other endocrine-active chemicals have been shown to impact reproduction of freshwater fish species. One environmental estrogen of particular concern is the synthetic estrogen 17α-Ethinylestradiol (EE2), which has 10–50 fold greater potency than natural estrogens. While extensive research has been conducted regarding the interaction of this chemical with model laboratory and some European fish species, little is known about the potential effects of environmental estrogens to freshwater fish species native to North American environments such as northern pike (*Esox lucius*). Pike are ubiquitous in water bodies throughout North America and Europe, and are potentially at risk of exposure to elevated levels of environmental estrogens e.g., in waters downstream of waste water treatment facilities. Therefore, the aim of the present study was to investigate effects of semi-chronic waterborne exposure of northern pike to a model estrogen, EE2, and to compare the responses to those previously reported for standard laboratory model species. Pike were exposed to three concentrations of EE2 (0ng/L, 5ng EE2/L, 100ng EE2/L) for 6 weeks. Blood, liver, gonad, head kidney, and brain were sampled. Blood plasma was analyzed for vitellogenin (Vtg) and concentrations of sex steroid hormones (testosterone, 17b-estradiol) were measured. These results were compared with results previously reported for other species to assess the pike's sensitivity to this chemical, and enable a reliable risk assessment for environmental estrogen exposure. Further characterization of alterations of molecular and biochemical endpoints along the hypothalamus-pituitary-gonad axis as well as histopathological changes in the gonads and liver are ongoing in an effort to establish a comprehensive understanding of the potential impacts of estrogen exposure to northern pike.

RP205 Effects of Dietary Selenomethionine Exposure on Repeat Swim Performance, Metabolic Rate and Energy Metabolism in Adult Zebrafish (*Danio rerio*) J. Kallarakavumkal Thomas, Univ of Saskatchewan, Toxicology Centre, Univ of Saskatchewan, graduate student; D. Janz, Univ of Saskatchewan, Toxicology Centre, Univ of Saskatchewan, Veterinary Biomedical Sciences. Selenomethionine (Se-Met) is the dominant form of selenium (Se) present in food. In a previous study we reported impaired swimming and elevated stored energy (triglycerides and glycogen) in adult zebrafish after chronic sublethal dietary Se-Met exposure. In the present study, we investigated effects of chronic sublethal dietary Se-Met exposure on repeat swimming performance, oxygen consumption (MO2), cost of transport (COT) and energy metabolism in adult zebrafish. Adult fish were fed varying concentrations of Se (1, 3, 10 and 30 μg Se/g, dry weight) in the form of Se-Met for 90 days. At the end of the exposure period, fish from each treatment group were divided into three subgroups: a) no swim, b) swim, and c) repeat swim. Fish from the no swim group were euthanized immediately at 90 days and whole body triglycerides and glycogen were determined. Individual fish from the swim group were placed in a swim tunnel respirometer and swim performance was determined using the critical swimming speed (Ucrit) method. After both Ucrit and MO2 analyses, fish

were euthanized and whole body energy stores were determined. Similarly, individual fish from the repeat swim group were subjected to two Ucrit tests (Ucrit-1 and Ucrit-2) performed with a 60 min. recovery period between tests, followed by determination of energy stores. Impaired swim performance was observed in fish fed greater than 3 µg Se/g in the form of Se-Met, however no differences were observed between Ucrit-1 and Ucrit-2 within each treatment group. Both resting and active metabolic rates (MO2) and COT were significantly greater in fish fed elevated dietary Se-Met. Whole body triglycerides and glycogen increased with increasing dietary Se-Met exposure. Fish from all treatment groups were able to mobilize stored glycogen during repeat swimming, and a similar trend was observed for triglycerides in all except 3 and 10 µg Se/g fed groups. Our ongoing studies are investigating mRNA expression of key enzymes (e.g., fatty acid synthase, 3-hydroxy-acyl-CoA-dehydrogenase and citrate synthase) involved in energy metabolism in liver and muscle. Overall results from this study should provide a better understanding of mechanism(s) underlying altered energy homeostasis in fish exposed to Se-Met.

RP206 Effects of Environmentally Relevant Triclocarban Exposure Concentrations on Survival, Growth and Shredding Activity of the Amphipod *Hyalella azteca* D. Edwards, Texas Tech Univ, The institute of environmental and human health; J.D. Maul, Texas Tech Univ, The institute of environmental and human health, The Institute of Environmental and, Dept of Environmental Toxicol. Triclocarban (TCC) is a common antimicrobial agent added to a wide array of household and personal care products such as soaps, toothpastes, lotions, and deodorants. In 2010, the EPA estimated annual mass of TCC produced in the US was 226,796 kg. Due to its primary use in household and personal care products, the vast majority enters the WWTP cycle and ultimately the environment via effluent and bio-solids applications. Contamination of US streams is widespread and TCC entering the environment through treatment plant effluent has been measured at low µg/L concentrations. Despite the use of TCC in household products for over 45 years, there are few studies regarding its toxicity to aquatic organisms and a disparity of information when compared to other common antimicrobial compounds such as triclosan. Of research published to date, the vast majority concentrates on the fate and persistence of TCC. Our research explores both the chronic and acute effects of TCC on the amphipod *Hyalella azteca*, a leaf shredding macroinvertebrate. Shredding macroinvertebrates are critical to activities throughout the stream continuum and effects on shredding of allochthonous leaf litter has the potential to disrupt a wide range of downstream processes and ecological functions. Preliminary results indicate that TCC is acutely toxic to *H. azteca* at environmentally relevant concentrations. Additionally, our results indicate that relevant concentrations of TCC inhibit growth and feeding behavior of *H. azteca*. *H. azteca* exposed to TCC for 96 hours displayed an LC50 of 4.8 ug/L TCC. *H. azteca* exposed to treatments of 1.25ug/L TCC and 2.5 ug/L consumed 8.5 % and 12 % less leaf material than controls. *H. azteca* exposed to concentrations as low as 0.15 ug/L TCC were significantly smaller, in length, than controls. Results from additional experiments will be discussed. This work will be used as a basis to perform further analysis on the effects of environmentally relevant concentrations of TCC on shredding macroinvertebrates and their ability to process leaf material as a critical process in the stream continuum.

RP207 Effects of Kingston Fly Ash on Freshwater Mussels R. Otter, Middle Tennessee State Univ, Biology, Middle Tennessee State Univ, Dept of Biology; W. Monroe, Middle Tennessee State Univ, Dept of Biology. On December 22, 2008 the largest release of fly ash in United States history occurred at the TVA Kingston Fossil Plant in Roane County, Tennessee. The result was contamination of the Emory River and surrounding area. Efforts to understand the toxicological implications of this spill are currently underway with investigations into the impact of fly ash on a wide range of biota. In this study we investigated the impact of Kingston fly ash on freshwater mussels, both a field and laboratory setting. Our field study consisted of up to a year exposure, in situ, using multiple native freshwater mussel species at both upstream and downstream sampling sites, compared to the location of the spill. Endpoints used to determined impact include survival, a mussel health index, and total glycogen content. Results were species dependent, but overall, all species showed a high survivability throughout the entire exposure period. Laboratory studies utilized a custom static recirculating tank design to expose the freshwater mussel *Utterbackia imbecillis* to varying concentrations of Kingston fly ash. Survival and glycogen concentrations were measured and compared directly to the treatment concentration of fly ash.

RP208 Effects of Metal Exposures on the Antioxidant Status and Tissue Damage in Eastern Oysters, *Crassostrea virginica* B. Khan, M. McCarthy, Univ of North Carolina at Charlotte, Biology; A.H. Ringwood, Univ of North Carolina at Charlotte, 9609 C Vinca Circle. Aquatic ecosystems are exposed to multiple stressors simultaneously. Many estuarine sites which show diurnal dissolved oxygen and pH fluctuations are also exposed to metals which can be toxic to marine organisms. Bivalve mollusks serve as good indicators of metal pollution in estuarine ecosystems. It is known that exposure to these metals can affect the antioxidant status of the tissues and can damage membrane lipids as well as cause DNA damage and modification in marine organisms. The overall purpose of this study was to identify the relationship between tissue metal concentrations and antioxidant status and to estimate oxidative damage in Eastern oysters, *Crassostrea virginica*. Oysters were collected from polluted and relatively clean sites (including NC oyster sanctuary sites), and metal concentrations were measured in gill and hepatopancreas tissues. Glutathione and lipid peroxidation levels were measured as markers of overall antioxidant status and tissue damage respectively. Laboratory studies were also conducted wherein oysters were exposed to metals dissolved in seawater. The same biomarkers were measured to determine the effects of metal exposures on antioxidant status and tissue damage. While oysters from the uncontaminated sites had no evidence of significant tissue damage and showed fairly stable glutathione levels, increased tissue damage and changes in antioxidant status were observed at higher concentrations of dissolved metal. The sites with high fluctuations in dissolved oxygen and pH as well as high concentration of metals showed increased tissue damage and disruption of the antioxidant status in bivalves. The interactions between these stressors are important determinants of the health of oyster populations in estuarine ecosystems.

RP209 Effects of Municipal Wastewater Effluent on Reproductive Function in Wild Fish Exposed in an Effluent Dominated Stream G.R. Tetreault, Univ of Waterloo, Biology; J. Bennett, Environment Canada, National Water Research Institute; M.R. Servos, Univ of Waterloo, Dept of Biology and Canadian Water Network; M.E. McMaster, Environment Canada, National Water Research Institute. Studies by Environment Canada on Wascana Creek in Regina, Saskatchewan, Canada, have determined that during the winter low flow periods the creek is 100% treated sewage making it a model system to understand the effects of MWWE. In this study, we were interested in determining whether MWWE effects reproductive development in fish in Canada, and if so, does the impairment influence the survival of fish populations. In 2007 and 2008, field studies assessed sentinel fish species under pre-spawning, spawning and post-spawn conditions in terms of growth (condition factor), and reproduction (in vitro sex steroid capacity, vitellogenin, gonadosomatic indices, and histology). Comparisons were made in fish collected upstream and downstream of Regina's Wastewater Treatment Plant. Abundant species in this system are the fathead minnow (*Pimephales promelas*) and brook stickleback (Culaea inconstans). Both sexes of spawning fathead minnow collected downstream of the sewage discharge were smaller, had reduced condition and larger liver somatic indices when compared to fish collected upstream of Regina. MWWE exposed males also had elevated levels of vitellogenin and lower scores of secondary sexual characteristics (fewer nuptial tubercles, little or no development of the dorsal pad, and no dorsal fin dot). Exposed female stickleback had increased gonad size and corresponding increased testosterone production but decreased 17__-estradiol productive capacity compared to reference fish. Other alterations in histopathology observed included inflammation of tubules in the kidney and stunted gill lamellae. Post-spawning collections revealed an absence of sufficient mature fathead minnows downstream of the MMWE discharge for site comparisons, although stickleback were abundant and did not demonstrate any significant site differences in performance.

RP210 Effects of Pharmaceutical-Fungicide Mixtures on Shredding Detritivore Responses Under Varying Temperature Regimes M. Willming, Texas Tech Univ, The institute of environmental and human health; J.D. Maul, Texas Tech Univ, The institute of environmental and human health, The Institute of Environmental and, Dept of Environmental Toxicol. Pharmaceuticals and fungicides have been detected in the aquatic environment, and their presence may have implications for bacterial and fungal communities and the invertebrate detritivores responsible for the decomposition

of allochthonous organic matter, a major energy source for many aquatic ecosystems. Few studies have examined how mixtures of antibiotics and fungicides could impact decomposer-detritivore systems. Additionally, in some aquatic systems daily water temperature fluctuations may influence these processes and alter contaminant toxicity, but such diurnal temperature regimes are rarely examined in conjunction with contaminants. In this study *Hyalella azteca* served as a model shredding detritivore and organisms were exposed to pharmaceuticals, triclosan and ciprofloxacin, and fungicides, chlorothalonil and propiconazole, at near environmentally relevant concentrations of compounds both individually and in mixtures. Experiments were performed at a constant temperature, diurnal temperature regime, and a diurnal temperature regime adjusted based on future climate predictions for south-central Texas. Endpoints included survivorship, growth and leaf processing. Results indicated a significantly lower 10-d LC_{50} for organisms exposed to chlorothalonil at a diurnal temperature [(LC_{50} 95% confidence interval) = 70.4 µg/L (63.7 – 79.5)] compared to organisms exposed to chlorothalonil under a constant temperature [LC_{50} = 80.1 µg/L (71.6 – 92.3)], based on the LC_{50} ratio test. There was a trend toward increased leaf processing at higher concentrations of chlorothalonil. Additional results will be presented. Ultimately, effects on aquatic decomposition processes due to such compounds may impact energy and nutrient flow through the aquatic food web, affecting multiple trophic levels. This work will also provide information on the influence of realistic temperature scenarios on contaminant effects in aquatic systems, which is an important initial step for understanding how future temperature alteration due to climate change may influence the assessment of ecological risk of contaminants.

RP211 Effects of Predator Cues on Pesticide Toxicity: Toward an Understanding of the Mechanism of the Interaction G. Qin, Texas Tech Univ, The Institute of Environmental and Human Health and Dept of Environmental Toxicology, Texas Tech Univ; S. Presley, T. Anderson, W. Gao, Texas Tech Univ; J.D. Maul, Texas Tech Univ, The institute of environmental and human health, The Institute of Environmental and, Dept of Environmental Toxicol. Pesticide toxicity may be modified by a number of co-occurring environmental and ecological stressors. Coexposure to predator cues has been shown to potentiate and/or synergize toxicity of pesticides. However, the mechanisms behind these interactions are not well understood. Here we examine the effects of fish predator (bluegill, *Lepomis macrochirus*) cues on toxicity of five different pesticides to the freshwater cladoceran, *Ceriodaphnia dubia*. The purpose for examining patterns among pesticides was to test the idea that the mechanism of the interaction could be explained by a general stress response; that is, the interaction patterns would be similar regardless of the pesticide's mechanism of action [MOA]). Acute 96-h concentration–response experiments were conducted for pesticides with and without fish cues. Predator cues influenced the toxicity of pesticides and the interaction patterns varied among pesticides. Fipronil exhibited a synergistic interaction, while predator cues interacted antagonistically for bifenthrin and thiacloprid. Other compounds previously reported to potentiate toxicity (malathion) were found to act additively. The results demonstrate that factors such as pesticide bioavailability, KOC, and exposure concentration may be important for predicting the occurrence of these interactions and that patterns were not consistent among pesticides varying in MOA. Predator stress is an important component for structuring communities and ecosystem processes. Fully understanding how this process may interact with organic contaminants may best be achieved by examination at toxicokinetic and toxicodynamic scales.

RP212 Effects of Pulp and Paper Discharge in Largemouth Bass: An Evaluation of Effects Across Multiple Levels of Biologial Organization T. Gross, Environmental Resource Consulting, Dr. Timothy S. Gross, Univ of Florida; S. Holm, Georgia-Pacific Corporation, Environmental Affairs; O. Burgess, Univ of Florida, Fisheries and aquatic Sciences, Environmental Resource Consultants. Largemouth bass (*Micropterus salmoides*)have been utilized to assess the effects of exposure to pulp and paper discharge at Georgia Pacific's Palatka mill since 1998 as a model to assess the effects of mill process upgrades. These efforts have focused on controlled treatments and natural exposures, as well as effects at the organism and lower biological levels (i.e., biochemical). Results demonstrate dose dependent effects at the biochemical level (i.e., decreased plasma sex steroids), tissue and cellular level (i.e., decreased GSI), and organism level (i.e., decreased reproductive status) at high exposure scenarios, however, effects for bass exposed under natural conditions are less than predicted from dilution profiles alone. The translation of these effects to higher levels of biological oranization were unclear from these original assessments. Current efforts have focused on an assessment of effects at higher levels of biological organization, including population and community levels. Assessments include the collection of largemouth bass across several sites within the lower St Johns River basin to reflect a wide range of exposures. Collections were conducted across 28 sites and four times annually: January, April, July and October. Measures included: catch per unit effort; sex ratio, size/age distribution; body weight, length and condition index; reproductive status; and biomarkers of reproductive function (i.e., plasma sex steroids, and Vtg). Results demonstrate diminished effects and dose responses with the implementation of process upgrades at the organism level and below, as well as significant increases in animal numbers and catch per unit effort for high exposure sites. Results across all sites demonstrate clear seasonal and annual variance that must be characterized and considered in any assessments of population/community effects. Significant differenecs were also detected for bass populations as a function of habitat type: natural littoral zones and man-made structure littoral zones, however, similar annual and seasonal trends were noted across habitat types. Differences in body wieght, length and condition index; sex ratio; and size/age distributions were not detected regardless of pulp-and-paper expsoure levels. Reduced bass numbers and decreased catch-per-unit effort was noted at the highest expsoure level, however, this is likely due to smaller stream size and different habitat traits.

RP213 Effects of Retene Exposure on Mentum Deformity Incidence in Laboratory Reared *Chironomus riparius* Larvae A.K. Karjalainen, Univ of Jyvaskyla, Dept of Biological and Environmental Science; K. Vuori, Finnish Environment Institute; M. Leppanen, Univ of Eastern Finland; H. Hamalainen, Univ of Jyvaskyla. Alkylphenanthrenes such as retene (7-isopropyl-1-methylphenantrene) are commonly found at elevated concentrations in sediments downstream of pulp and paper mills. Retene toxicity in fish has been suggested to be mechanistically similar to that of dioxins. In rats and humans developmental dental aberrations induced by dioxins (2,3,7,8-tetrachlorodibenzo-*p*-dioxin, TCDD) are mediated via binding to cytosolic Ah receptor. High incidence of mouthpart deformities, especially mentum teeth aberrations, have been observed in midge (*Chironomidae*) larvae inhabiting sediments polluted by pulp and paper mills. Since Ah receptors homologic to vertebrate receptors exist in invertebrates, we hypothesized that retene may also increase the incidence of mentum deformity in midge larvae. We exposed laboratory reared *Chironomus riparius* larvae 14 days to retene spiked sediments at ecologically relevant concentrations of 248.0±67.4 µg/g sediment dry weight (mean±SD), and used the proportion of individuals with a deformed mentum (DI %) as a toxicity endpoint. Further, types and degree of mentum deformities and impact of varying organic carbon concentration of sediment were analysed. Our treatments included 900 individuals that were fed with 1.2 mg fish flake food suspension per larva on days 0 and 7. Unlike in field populations of *Chironomus* larvae, our laboratory animals seem to have high DI % not only in contaminated but also in the control sediments. Concurrently measured larval growth was not affected by the lowest content of 1.4±0.1 % organic carbon of sediment dry weight (mean±SD) alone but was slightly decreased in coexposure to retene. Larval survival in retene-exposures and control treatments was slightly lower in sediment with the lowest carbon content when compared to sediment with the highest carbon content of 23.1±0.1 % of dry weight (mean±SD). Our results suggest no specific receptor-induction of retene in *C. riparius*. Problems related to identification of mentum deformities are discussed.

RP214 Effects of Soluble Epoxide Hydrolase Inhibitors on Cardiac Function and Embryonic Development in Zebrafish, *Danio rerio* N. De La Paz, Univ of California, Riverside, Dept of Environmental Sciences; S. Hwang, B. Hammock, Univ of California, Davis, Dept of Entomology and Cancer Center; D. Schlenk, Univ of California Riverside, Dept of Environmental Sciences. Epoxyeicosatrienoic acids (EETs) are endogenous substrates for soluble epoxide hydrolases (sEHs), which catalyze the formation of dihydroxyeicosatrienoic acids (DHETs). DHETs have critical roles in cardiac development and inflammation within vertebrates. Previous studies have shown that phenyl ureas inhibit sEHs in multiple species. Thus, to better understand the roles sEH and DHETs play in vertebrate development, zebrafish embryos were exposed for 72 h to 0.5, 5, and 50 nM of several sEH inhibitors, 1-(1-acetypiperidin-4-yl)-3-adamantanylurea (APAU), 1-trifluoromethoxyphenyl-3-(1-propionylpiperidin-4-yl) urea (TPPU, *trans*-4-[4-(3-Adamantan-1-yl-ureido)-cyclohexyloxy]-benzoic acid (*t*-AUCB),

and trans-4-{4-[3(4-Triflurомethoxy-phenyl)-ureido]-cyclohexyloxy}-benzoic acid (*t*-TUCB). Morphology, survival and embryonic heart rate were determined for each embryo at 48, 58, and 72 hours post fertilization (hpf). After 48 hours, the highest concentrations of APAU, TPPU, and t-AUCB, diminished heart rate from 81.1 + 0.3 (beats/30sec) in controls to 65.2 +/- 1.9 (APAU), 74.9 +/- 2.3 (TPPU), and 76.4 +/- 0.3 (t-AUCB) . After 48 hours exposure to 5 and 50 nM TPPU curvature of the tail was observed in 30 and 23% of the embryos, respectively. Embryolethality (28% and 60%) was also observed following exposure to 5 and 50 nM TPPU. These results indicate that inhibition of sEH by several distinct structures may deleteriously affect early development in zebrafish although other mechanisms should also be explored.

RP215 Effects of the Biopesticide Candidate *Metarhizium anisopliae* S54, on the Crustacean *Ceriodaphnia dubia* X. Chen, Univ of Lethbridge, Dept of Geography; J.L. Dan, Univ of Lethbridge, Geography. Environment and health concerns about the using of chemical insecticides to reduce large-scales insect pest infestations have led to renewed interest in the development of entomopathogenic fungus for pest control and environmental ecosystem protection. *Metarhizium anisopliae* is a hyphomycetous fungus that is pathogenic to some insect pests. A strain *Metarhizium anisopliae* S54 was isolated from a soil in Alberta, Canada, and has been under development and field testing in 2008-2010. This present study was conducted to assess potential pathogenesis of this fungus to a non-target cladoceran species, *Ceriodaphnia dubia*. Acute relative mortality and population responses to chronic exposure of a commercial agriculture R-11, the chemical pesticide neonicotinoid imidacloprid, biopesticide Azatin and suspended conidia of *Metarhizium anisopliae* S54 on the crustacean, *Ceriodaphnia dubia* were examined. For the acute study, *Ceriodaphnia dubia* was exposed to 0, 0.25 mg/l (1.33×104 conidia/ml), 0.5 mg/l (2.66×104 conidia/ml), 1 mg/l (5.33×104 conidia/ml), 2.5 mg/l (1.33×105 conidia/ml), 5 mg/l (2.66×105 conidia/ml) and 10 mg/l (5.32×105 conidia/ml), with the inoculum being replaced every 24h until 144h. For the chronic population study, *Ceriodaphnia dubia* populations were exposed to Experimental Expected Concentration (EEC) levels of the agricultural adjuvant R-11(0.79 mg/l), chemical pesticide neonicotinoid imidacloprid (0.0174 mg/l), biopesticide Azatin (0.033 mg/l) and suspended conidia of viable *Metarhizium anisopliae* S54 (0.033 mg/l) for 8 days . The number of founding individuals, offspring/female, final population size, and population growth rate were assessed in treated and control groups. Acute relative mortality ranged from 0% in 0.25 mg/l (1.33×104 conidia/ml) concentrations to 5% in 10 mg/l (5.32×105 conidia/ml) concentrations after 144 h treatment. Exposure to imidacloprid caused greater reductions in the production of offspring per female and population size parameters than the other compounds, at the rates tested. The agricultural adjuvant R-11, biopesticide Azatin, and spores of S54 were less challenging to *Ceriodaphnia dubia*, and are not expected to pose any significant risk to aquatic organisms, as represented by the test organism *Ceriodaphnia dubia*.

RP216 Effects of Water Chemistry on the Toxicity of Cu to the Fish Parasite *Ichthyophthirius multifiliis*: Development of a BLM for Therapeutic Application A.C. Ryan, HDR|HydroQual; D. Straus, USDA/ARS, Harry K. Dupree – Stuttgart National Aquaculture Research Center; J. Tomasso, Texas State Univ *Ichthyophthirius multifiliis* (Ich) is a common ectoparasite that invades the skin and gills of freshwater fish. Copper sulfate ($CuSO_4$) is often used to control infestations of Ich in pond aquaculture in the United States. In this study, we determined the acute toxicity of $CuSO_4$ to the free-swimming theronts of Ich in reconstituted waters. Water chemistry characteristics, including calcium, magnesium, and pH were varied independently and spanned relevant ranges. The objective of these experiments was to provide data that would serve as the basis for development of a biotic ligand model (BLM) that could be used to derive therapeutic doses of copper sulfate in aquaculture operations. A BLM for such purposes would be ideal because it could define effective bioavailability-based doses for controlling Ich outbreaks while simultaneously evaluating if copper doses would be safe for fish. Preliminary data analysis suggested that solution chemistry influenced the toxicity of $CuSO_4$ to Ich, and that Ich strain or batch contributed to the variability in the observed effect concentrations. Development of a BLM for Ich may have to be strain-specific, which for aquaculture purposes suggests that the least sensitive Ich strain should be used for BLM development.

RP217 Elucidating the Toxicity and Sub-cellular Fate of Inorganic Selenium in Four Marine Microalgae R.R. Ronchin, K.M. Damian, C.L. Smith, D.F. Jolley, Univ of Wollongong. Selenium (Se) has been associated with a range of toxic effects in aquatic and terrestrial organisms. Currently there is minimal information regarding the physiological response of microalgae to Se. Microalgae are at the base of the aquatic foodweb, hence any accumulated Se may be transferred to higher trophic organisms. This research investigated the toxicity of two inorganic species of Se to the marine microalgae *Dunaliella tertiolecta*, *Nitzschia closterium*, *Phaeodactylum tricornutum* and *Tetraselmis* sp. The algae were exposed to selenite (Se(IV)) and selenate (Se(VI)) under environmentally relevant conditions. Se(VI) was significantly more toxic than Se(IV), with Se(VI) exposures producing mean 72-h IC_{10} values (concentrations that inhibited population growth (IC) by 10%) ranging from 1.2 to 7.6 mg/L for *P. tricornutum* and *D. tertiolecta*, respectively, whereas Se(IV) IC_{10} values ranged from 53 to 150 mg/L, respectively. To determine the intracellular level and distribution of Se, cells were exposed to IC_{10} levels of Se(VI) for 72-h, harvested, washed, and analysed by ICP-MS. *D. tertiolecta* had the greatest intracellular Se with up to 119 x 10^{-15} g Se/cell, compared to < 10 x 10^{-15} g Se/cell for the other microalgae. The sub-cellular distribution (method of Lavoie et al., 2009) of accumulated Se was primarily associated with the organelle and cytosol (~78%), with less Se in the cell debris (~20%) and granule (~2%) fractions for *D. tertiolecta*, *P. tricornutum* and *N. closterium*. However, *Tetraselmis* sp. had the greatest proportion of Se associated with the cell debris fraction (~55%), followed by the organelle and cytosol (~30%) and granule fraction (~4%). Although multiple cell disruption conditions were investigated, it was not possible to rupture algal cell membranes without significant organelle disruption, as confirmed by citrate synthase activity. Hence, identifying the Se in the metabolically sensitive cytosol (i.e., separation of the organelle and cytosol fractions during ultracentrifugation) could not be performed. This demonstrates that Se(IV) and Se(VI) are not toxic to these microalgae at concentrations typical of a contaminated marine environment. Future work should investigate methods to rupture these algal cell membranes without compromising organelle integrity, and repeat these tests using chronic exposures at environmentally significant selenium concentrations. Lavoie, M., S. Faucheur, et al. (2009). Aquatic Toxicology 92: 65-75.

RP218 Endocrine Disrupting Effects of Six Major Organophosphate Flame Retardants in H295R and MVLN Cells, and Zebrafish X. liu, k. Ji, k. choi, Seoul National Univ. Flame retardants have been widely used in construction materials, furniture, plastics, electronic equipments, textiles, and other materials. Because of the ban of polybrominated diphenyl ethers (PBDEs), production and use of organic phosphate flame retardants (OPFR) has increased. Although OPFRs have been detected in the house dust, surface water, fresh water biota, human urine and milk at the levels similar to or greater than those of PBDEs, understanding of potential health effects are limited. We evaluated endocrine disrupting potencies of six major OPFRs including tris-(2-chlorethyl) phosphate (TCEP), tricresyl phosphate (TCP), tris-(2-butoxyethyl) phosphate (TBEP), triphenyl phosphate (TPP), tris-2-chloroisopropyl phosphate (TCPP), and tris(1,3-dichloro-2-propyl) phosphate (TDCPP) using H295R and MVLN cell lines as well as adult zebrafish. In H295R cell line, steroid hormone production and expression of mRNAs that are responsible for steroidogenesis and estrogen metabolism were measured. In fish test, sex hormones and mRNAs of sterodogenic enzymes were determined after 14 d exposure of 4 m old zebrafish to three OPFRs that were identified to be potent in vitro evaluation. With MVLN cell line, estrogen receptor binding activities of the OPFRs were evaluated. In H295R cell, all six OPFRs could induce both estradiol (E2) and testosterone (T) production. In addition, all major steroidogenic genes like 3bHSD, CYP19 were up regulated except CYP17, and sulfotranferase genes including SULT2A1, SULT2B1 and SULT1E1 were downregulated. In MVLN cell, TPP, TCP, and TDCPP could inhibit binding of estrogen to estrogen receptor. In 14 d fish exposure, 0.2 mg/L TCP, or 1 mg/L TDCPP and TPP significantly increased plasma T and E2 concentrations in females, while T decreased and E2 increased in males. The gene transcription of CYP17 and CYP19 was significantly up regulated in both sexes, while VTG was down- and up-regulated in female and male fish, respectively. Exposure to test OPFRs generally lead to feminization of male and musculinization of female fish. Both in vitro and in vivo studies showed that OPFR could affect steroidogenic pathway and alter sex hormone balance. Responses of male and female fish to these chemicals were different, and underlying mechanisms deserve further study.

RP219 Endocrine Disruption or Adaptation? Loss of an Acute Cortisol Stress Response with Chronic Copper Exposure in Rainbow Trout M.S. Tellis, D. Alsop, C. Wood, McMaster Univ, Dept of Biology. The aim of this study was to determine the effects of chronic waterborne Cu exposure on stress-induced acute cortisol release and the associated physiological implications in rainbow trout (*Oncorhynchus mykiss*). Trout were exposed to 30 µg Cu/L in moderately hard water (120 mg/L as $CaCO_3$) over a period of 40 d, following which time, they were challenged with a series of stressors. At 40 d, an approximate 60% increase in Cu levels were observed in the gill and liver, but not in the tissues of the hypothalamus-pituitary-interrenal axis (HPI axis). Fish exposed to Cu did not increase circulating cortisol levels with 1 min air exposure or 24 h isolation, in contrast to controls which increased cortisol by 3-fold. However, this inhibitory effect on cortisol mobilization appeared to have few implications on the ability of Cu-exposed fish to maintain homeostasis. For example, plasma Na^+, Ca^{2+} and glucose levels as well as hepatic glycogen levels were the same post-stress in control and Cu-exposed fish. Trout were also challenged with an exposure to 50% seawater for 48 h, where Cu-exposed trout maintained plasma Na^+, glucose and hepatic glycogen levels. However, Cu-exposed fish experienced decreased plasma K^+ levels throughout the Cu exposure and stress tests. In conclusion, chronic Cu exposure resulted in the abolition of an acute cortisol response after stressor exposure. This did not appear to be due to a toxic effect of Cu on the HPI axis, and did not affect the ability of the fish to maintain ion and carbohydrate homeostasis. The lack of an acute cortisol response may be a coping strategy to reduce costs during the chronic stress of Cu exposure, and not endocrine disruption as a result of toxic injury. (NSERC Strategic Grant, Rio Tinto Alcan, Environment Canada).

RP220 Environmental Hazard Assessment of Petroleum Distillates J.P. Swigert, EcoTox Assessments, LLC; C. Lee, ExxonMobil Biomedical Sciences, Inc.; D.C. Wong, Shell Oil Company – Shell Health; P. Podhasky, American Petroleum Institute. Assessing the environmental hazards of petroleum substances has historically been challenging for these difficult to test substances. The establishment of USEPA and OECD High Production Volume (HPV) chemicals programs compiled new and existing data that provided information necessary to assess the environmental and human health hazards of many chemicals and chemical categories. Where data gaps were identified, testing was conducted to progress robust hazard assessments of these complex petroleum substances. This presentation summarizes the experimental ecotoxicity and biodegradability results for three petroleum categories characterized by the boiling point/hydrocarbon continuum: gasoline (exemplified by principal carbon range of 4 – 12); kerosene (carbon range 9 – 16), and gas oil middle distillates (carbon range 9 – 25). Owing to their variable and complex compositions, petroleum substances possess a wide range of physical-chemical attributes. Aquatic toxicity test results are presented for different petroleum substances using the water accommodated fraction (WAF) preparation technique for exposure solutions. The WAF method of creating exposure solutions allows the ecotoxicity of a substance to be expressed in terms of the amount of product required to produce a particular effect. Other exposure methods such as dilutions of water soluble fractions are not comparable to tests using WAFs because they do not allow the multi-component dissolution behavior of the complex substance to be considered. Similarly for biodegradability testing, many different test methods exist; however, not all are appropriate for testing petroleum substances. Therefore biodegradation data were developed using a test method recommended for volatile substances having low water solubility. Results from these studies provide a reliable basis for characterizing environmental hazard across these distillation fractions and were found to be consistent with model predictions inferred from detailed composition analyses of these streams.

RP221 Evaluating the Joint Toxicity of Lead and Cypermethrin to the Benthic Invertebrate, *Chironomus dilutus* W.T. Mehler, Gradient; J. Du, J. You, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, State Key Laboratory of Organic Geochemistry; M. Lydy, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology. Insecticides and heavy metals are frequently detected in the environment, but few studies have assessed the joint toxicity of organic and inorganic contaminants. Joint toxicity of a pyrethroid insecticide, cypermethrin and a heavy metal, lead was evaluated in the current study. An antagonistic toxic response was observed when the benthic invertebrate, *Chironomus dilutus* were simultaneously exposed to the two contaminants in both water and sediment exposures. Pre-exposure bioassays with midges were also conducted and toxicity of cypermethrin was significantly reduced to midges which were pre-exposed to lead. Additionally, the effect of lead on the bioavailability of cypermethrin to midges was measured using Tenax extraction. No significant difference was noted in the amount of Tenax-extractable cypermethrin when different amounts of lead were added to sediment. Results suggested that altered organism sensitivity may have contributed to the observed antagonistic interaction between cypermethrin and lead, while changes in toxicokinetic processes, such as uptake and biotransformation, on the joint toxicity should be further researched.

RP222 Evaluation of Whether Gemfibrozil is a Peroxisome Proliferator in Fish S.Y. Skolness, Univ of Minnesota, Dept of Biochemistry and Molecular Biology; E. Durhan, K.M. Jensen, M. Kahl, USEPA, Mid-Continent Ecology Division; C. LaLone, USEPA; E. Makynen, D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division. Gemfibrozil is a pharmaceutical that indirectly modulates cholesterol biosynthesis through effects on peroxisome proliferator-activated receptors (PPAR), which are transcriptional cofactors that regulate expression of genes related to lipid metabolism. An enzyme found in the peroxisome known to have its activity regulated by PPAR activation is fatty acyl-coenzyme-A oxidase (FAO). Although, gemfibrozil is a known mammalian hepatic peroxisome proliferator, it may not operate via this mechanism in non-target species such as fish. Because gemfibrozil is commonly detected in surface water, it is important to investigate the effects of the drug on non-target species. The purpose of this study was to determine if gemfibrozil elicits the same pharmacological mechanism in fish as it does humans, by measuring in vitro effects of gemfibrozil on FAO activity in fish. In vitro experiments with liver tissue explants from fish species (fathead minnow and zebrafish) were incubated with various concentrations of gemfibrozil and FAO activity was measured. Initial results suggest that gemfibrozil is a less potent peroxisome proliferator than in mammals, and may not operate via the same pharmacological mechanism in fish as in humans. This study adds to our knowledge of possible effects of a common aquatic pharmaceutical pollutant on fish PPAR actions. The views expressed in the current study are those of the authors and do not reflect the views or policies of the US Environmental Protection Agency, nor does mention of trade names or commercial products does not constitute endorsement or recommendation for use.

RP223 Exposure to Persistent Organic Pollutants Through Ingestion of Marine Debris: The Relevance of Partition Coefficients J. Newsted, C. Berger, D. Kay, J. Phillips, Cardno Entrix. This paper examines the relevant published literature regarding potential marine organism exposure to persistent organic pollutants (POPs) through incidental ingestion of plastic debris. While plastics have the capacity to absorb chemical substances from their surrounding environment, little is known about the factors effecting adsorption and desorption of POPs to plastic debris, the abundance and bioavailability of POPs on plastic debris, and the amount of plastics marine organisms consume. The first step in understanding these dynamics is an evaluation of relevant partition coefficients. Partition coefficients can be used to understand the fate of compounds in the environment and to evaluate the relative contribution of POPs adsorbed to plastics and the total exposure of marine organisms to POPs in the environment. Therefore, we conducted an extensive review of relevant partition coefficients found in the peer-reviewed literature. Since marine organisms will be found in an aqueous environment, we then focused on water to plastic partition coefficients (K_{pw}). The results of our review identified K_{pw}s for 18 specific types of polymers and 203 individual compounds representing 12 different chemical groups. Analyses of these data showed a wide range of values (e.g., 2.14 to 7.09 log K_{pw}) among compounds for any given polymer. Of note, our correlation analysis showed a relationship between log K_{pw} and log K_{ow} (octanol-water partition coefficients) for most polymers. Consequently, log K_{ow} may act as a surrogate for estimating log K_{pw}, which will allow for extrapolation (i.e., modeling). This finding is of particular importance because of the lack of log K_{pw} (water partition coefficient) data for a wide array of plastics. A logical next step is to use log K_{ow} to generate log K_{pw}s through modeling of a wide range of plastics in order to understand the potential for these plastics to adsorb POPs in then environment. Our review of the primary literature is an initial step towards understanding partitioning coefficients and more information is

needed from other sources (plastics companies, federal/state agencies, etc.) to garner a substantiated critical review.

RP224 Forms of Sexual Abnormalities in the Fiddler Crab, *Uca pugilator* E. Zou, Nicholls State Univ, Biological Sciences. Like other brachyuran crustaceans, fiddler crabs, *Uca pugilator*, are normally gonochoristic and exhibit striking sexual dimorphism. Males are characterized by a pair of extremely asymmetrical chelipeds and a narrow abdomen while females typically have a pair of small, identical claws and a broad abdomen, which virtually covers the entire sternum. Recently several sexually abnormal fiddler crabs have been discovered, representing four different forms of sexual abnormalities. All these crabs were obtained from the Gulf Specimen Marine Laboratories, Inc. of Panacea Florida. At present, it is still unknown whether there is an environmental etiology behind these sexual aberrations.

RP225 Fractionation of Cu in Aquatic Foodweb K.Y. Garcia, Univ of Texas El Paso, Biological Sciences; J. Navarrete, Univ of Texas El Paso, Geological Sciences; E. Walsh, Univ of Texas El Paso, Biological Sciences; D. Borrok, Univ of Texas El Paso, Geological Sciences. As an aquatic pollutant, copper has received considerable attention. The toxicity of copper has been demonstrated for a number of algal and rotifer species. Further it has been shown that exposing rotifers to copper in the presence of an algal food source decreases its toxicity. This affect has been detected both when algae are present during copper exposure and when rotifers are feed pre-exposed algae. To better understand the interaction between copper toxicity and trophic transfer, we investigate how copper (Cu) may be fractionated by cellular processes occurring is a simple food web consisting of a grazer, the rotifer *Brachionus plicatilis*, and its alga food source, *Tetraselmis suecica*. Algae were grown in Cu-citrate enriched media to simulate forms of organic bond Cu dissolved in natural waters and fed daily to rotifers for nine days. Algae were harvested daily while rotifers were collected 0, 5, and 8 days after algal inoculation and rinsed three times to remove any residue Cu. Samples were then digested with 70% nitric acid and ultrapure 30% hydrogen peroxide in preparation for ICP-OES analysis of Cu concentration and isotopic analysis. Preliminary results demonstrated that the algae assimilated the heavier δ^{65}Cu isotope while the rotifer internalized the lighter δ^{63}Cu isotope at day 0. However, as time increased rotifers assimilated the heavier isotope from the isotopically heavy algae. These findings, along with those from an earlier study investigating copper uptake by bacteria, may indicate that at lower trophic levels organisms preferentially uptake δ^{65}Cu while primary consumers incorporate the heavier isotope through their diet. Copper mass balances are being calculated and additional experiments will be conducted with freshwater species to confirm these results. Our ultimate goal is to link Cu isotope changes with toxicological indicators such as reduced population growth rates and expression of metal regulating proteins.

RP226 Habitat Effects on Mercury Bioaccumulation in Black Sea Bass (*Centropristis striata*) G. LeBlanc, Roger Williams Univ, Marine Biology; M. Soto, Roger Williams Univ, Marine Biology, UNAM, Instituto de Ciencias del Mar y Limnologia, Roger Williams Univ, Marine Biology, UNAM, Instituto de Ciencias del Mar y Limnologia, Roger Williams Univ, Marine Biology. Mercury (Hg) is a widespread environmental contaminant that bioaccumulates in fish muscle tissue, and therefore poses a risk to human consumers. Understanding the human risk from Hg exposure requires insight into: (1) species-specific Hg concentrations and (2) variability in fish Hg content as a function of life history (e.g., habitat use and diet). In this study, an important recreational fish, the black sea bass (*Centropristis striata*) was collected from inshore (Narragansett Bay Estuary) and offshore (Rhode Island-Block Island Sound; RIS-BIS) habitats using trawls and hook & line. The white muscle tissue of black sea bass (n = 36) was analyzed for total Hg and results were evaluated relative to fish age and habitat use (inshore vs. offshore). The otoliths of the inshore sea bass population were analyzed for strontium (Sr) concentrations to detect evidence of a salinity signature, and thus, a verification of site fidelity in the Bay and RIS-BIS. Visual analysis of stomach contents was also performed to assess variation in diet across habitats, which could account for geographic differences in sea bass Hg contamination. Irrespective of habitat-type, the Hg content of black sea bass muscle tissue was positively correlated with fish age, indicating the bioaccumulation of Hg. Black sea bass collected from inshore habitats, however, had higher Hg levels at a given age than conspecifics from offshore locations. Further, within the inshore habitat, individuals with a lower Sr concentration (lower salinity signature) had higher Hg levels. The cumulative results indicate that Hg concentrations in black sea bass vary significantly over relatively small spatial scales (5 km), and site-specific sea bass Hg levels are correlated with the anthropogenic contaminant sources in the Narragansett Bay. Finally, the diet of the inshore sea bass population was dominated by crabs (50% frequency of occurrence, *FO*), whereas offshore conspecifics fed on crabs (28% *FO*), shrimp (24% *FO*), and algae (16% *FO*). Future work will include the analysis of black sea bass stable isotope signatures and otolith microchemistry (for offshore fish), as well as examining the Hg content of sea bass preferred prey across habitats.

RP227 Hazard Assessment of Inorganic Selenium Under REACH: A Pragmatic Approach P. Van Sprang, ARCHE; N.M. Deleebeeck, Arcadis Belgium, REACH & Product Stewardship Services; K. Oorts, ARCHE. Selenium is an essential element showing a very narrow margin between dietary essentiality and toxicity. So far, the main focus of the extensive research on selenium has been the environmental fate and effects of the element in the aquatic environment. The available scientific knowledge indicates that diet is the primary exposure pathway for both aquatic invertebrates and vertebrates and that selenium toxicity is primarily manifested as reproductive impairment in egg-laying vertebrates (fish and birds) due to maternal transfer. The severity of the observed adverse effects appears to be more related to tissue concentrations than to aquatic concentrations of the element and selenium toxicity seems to be largely species- and site-specific. Therefore, it is generally accepted that a single predicted no effect concentration (PNEC) based on aqueous Se concentrations would not be appropriate for protecting against selenium toxicity in all systems and that selenium requires site-specific risk assessment to a much greater extent than many other contaminants. However, the European REACH Regulation and other regulatory risk assessment methods traditionally require the derivation of a single threshold concentration of a substance for each environmental compartment (e.g., water, soil, sediment) based on toxicity data for the most sensitive species and ecosystem. For selenium, such an approach would entail the risk of defining PNEC values within the deficiency range for many systems. Since REACH and similar regulations are pushing the limits with regard to timely submission of chemical safety reports, they also force difficult substances such as selenium to be assessed in a pragmatic way using the scientific knowledge already available. A pragmatic approach for the aquatic and terrestrial hazard assessment of selenium under REACH will be presented and the potential for further refinement will be discussed.

RP229 How Does Life History Affect Concentrations of PCBs in Arctic Food Fishes? H. Swanson, Univ of Alberta; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology. Arctic char (*Salvelinus alpinus*) and lake trout (*Salvelinus namaycush*) are an important subsistence food source for northerners in the North American Arctic. In coastal Arctic regions, both Arctic char and lake trout have plastic life histories and may adopt either an anadromous (sea-run) or lake-resident life cycle in response to environmental and endogenous cues. Some populations of Arctic char and lake trout are in fact partially anadromous; in these populations, some fishes migrate to sea whereas others do not. There are no genetic differences between sympatric anadromous and resident (i.e., freshwater) fishes, but we have recently shown that mercury concentrations are significantly lower in anadromous fishes than in resident fishes. This appears to be because anadromous fishes have faster growth rates and higher lipid contents than resident fishes. We are currently investigating how life history affects concentrations of polychlorinated biphenyls (PCBs) in Arctic char and lake trout. It is possible that, similar to mercury, PCB concentrations are lower in anadromous fishes due to growth dilution. PCB concentrations may also be higher in anadromous fishes, however, because of relatively higher lipid contents. In this study we investigate the effect of life history on PCB concentrations in Arctic char and lake trout, and we evaluate how northern subsistence fishers may alter their exposure to both mercury and PCBs by targeting different life history types of these fishes.

RP230 Hydrocarbons, Fluorescent Bile Metabolites and MMCs in Hardhead Catfish (*Ariopsis felis*) to Assess Impact in the Coast of Tabasco, Mexico N. Ramirez-Miss, Cinvestav Unidad Merida, Marine Resources Dept; G. Gold-Bouchot, Cinvestav Unidad Merida, Marine Resources. To evaluate the environmental impact of the oil industry in the coast of the Mexican state of Tabasco (Southern Gulf of Mexico), 80 Hardhead Catfish (*Ariopsis felis*) were captured and analyzed. Petroleum hydrocarbons (including PAHs, aliphatics and UCM) in liver, fluorescent metabolites in bile, and

melanomacrophage centers (MMCs) in spleen were determined, as well as total and standard length and weight. After accounting for fish size (standard length or weight), the correlation of hydrocarbon concentrations or bile metabolites with MMCs was assessed. Results for the use of MMCs as an indicator for coastal management are discussed.

RP232 In Vivo and In Vitro Effects of Chlorpyrifos in Grass Shrimp (*Palaemonetes pugio*) and Mysids (*Americamysis bahia*) P. Key, NOAA/National Ocean Service; E. Simonik, Ohio Univ; N. Kish, Univ of South Carolina; M. Fulton, NOAA/National. Ocean Service, Marine Ecotoxicology Division. Organophosphate insecticides (OPs) cause toxicity by inhibiting acetylcholinesterase (AChE) in the nervous systems of both vertebrates and invertebrates. This enzyme catalyzes the hydrolysis of the neurotransmitter, acetylcholine (ACh), from the synaptic cleft. When AChE is inactivated by the binding of an OP, ACh accumulates at the nerve synapse and interferes with normal nervous system function. This quickly leads to twitching of the voluntary muscles, paralysis, and death. Chlorpyrifos is an OP insecticide that continues to be used worldwide in agricultural and residential settings, though in 2001 its use in the United States was greatly restricted. The goal of this study was to assess the in vivo and in vitro effects of chlorpyrifos in two model estuarine crustaceans, the grass shrimp (*Palaemonetes pugio*) and the mysid (*Americamysis bahia*) and compare their sensitivities. Grass shrimp are abundant in estuaries along the Atlantic and Gulf Coasts. They play a vital role in the breakdown of detritus and serve as an important food source for commercially and recreationally important fish species. Mysids also play an important role in estuarine food webs and both crustaceans are widely used in toxicity testing. Results from the in vitro experiments indicated that the target enzyme in the two species was similar in sensitivity to OP-induced inhibition with IC_{50}s of $10^{-8.94}$M and $10^{-9.78}$M for mysids and grass shrimp, respectively. In vivo experiments, however, showed that mysids were significantly more sensitive to chlorpyrifos-induced AChE inhibition after 24h of exposure. The EC_{50}s for AChE inhibition were 0.27 µg/L for mysids and 13.35 µg/L for grass shrimp. The significance of these findings as they relate to chlorpyrifos-induced mortality in each species will be discussed.

RP234 Influence of Pesticide Exposure on Dermo Infection and Stress-related Responses in the Eastern Oyster (*Crassostrea virginica*) P. McClellan-Green, North Carolina State Univ, Ctr for Marine Sciences & Technol *Perkinsus* sp. is a pathogenic protozoan that is the causative agent of the lethal oyster disease Dermo. Oysters infected with this parasite suffer a reduction in shell growth, emaciation, reduced reproductive output and death. Oysters in many coastal habitats, including some in North Carolina, are infected with this dangerous parasite yet very little is known about the interaction between the parasite, host defense mechanisms and stress induced by anthropogenic sources. It has been shown previously that environmental parameters such as temperature stress, salinity and hypoxia suppress the ability of oysters to resist infection by *Perkinsus marinus*. Complicating this picture is the additional influence of anthropogenic factors such as pesticides on the host oyster's ability to mount an immune or defense response. Our study assessed the impact under normal environmental conditions of the 3 widely used pesticides--atrazine, chlorpyrifos and glyphosate--on the ability of oysters to resist Dermo infection. Duplicate sets of oysters were exposed to increasing concentrations (0, 10, 50 or 100 mg/L) of pesticides for 8 days. All oysters were sacrificed on day 8 and the level of infection was determined along with a number of physiological responses including expression of Hsp70 and oxidative stress. Our results indicate that glyphosate exposure results in a 2.5 fold increase in Dermo infections compared to atrazine or chlorpyrifos exposure. The levels of phenoloxidase activity following exposure were not predictive of Dermo infection. In addition, the levels of heat shock protein (Hsp 70) expression varied throughout the treatments and were not indicative of pesticide exposure.

RP235 Interactive Effects of Phosphorus and Copper on *Hyalella azteca* and Periphyton M. Li, Univ of Michigan, School of Natural Resources and Environment, Harvard School of Public Health, Environmental Health; D. Costello, Univ of Michigan, School of Natural Resources & Environment; A. Burton, Univ of Michgan, School of Natural Resources & Environment and Cooperative Institute for Limnology & Ecosystem Research. Eutrophication is known to be frequently associated with metal pollution in aquatic ecosystems. Our research examined the interaction between waterborne copper and phosphorus, with respect to their effects on growth of a freshwater amphipod *Hyalella azteca* in the presence of periphyton. The study design included two tiers: (1) a laboratory stream experiment where natural periphyton communities accumulated Cu under a gradient of Cu and P concentrations (2) a beaker experiment where *H. azteca* fed on the periphyton previously grown in laboratory streams. There was rapid Cu accumulation by periphyton and the total Cu concentration of periphyton was unrelated to the dissolved P treatment. An interaction between Cu and P was observed for *Hyalella* growth where high phosphorus concentration was related to reduced growth at relatively lower Cu concentration. Our findings suggest that eutrophication may result in greater Cu toxicity to benthic macroinvertebrates as a result of dietary exposure from periphyton.

RP236 Laboratory and In Situ Exposures of *Macrocystis pyrifera* (Giant Kelp) Sporophylls Prior to Zoospore Release for Toxicity Testing K. Flocken, A. Cibor, Nautilus Environmental; C. Stransky, AMEC Earth & Environmental. Under the current EPA germination and germ-tube growth test method for *Macrocystis pyrifera* (Giant Kelp), zoospores are released from the sporophylls (reproductive kelp blades) within 24 hours of blade collection, and then directly exposed to a reference toxicant or effluent for 48 hours. Because the zoospores are microscopic, it is extremely difficult to conduct real time in situ exposures which can be used to better characterize dynamic environments (i.e., stormwater plume). In this study, sporophylls were exposed to either copper chloride or raw seawater for a period of 48 hours prior to zoospore release. The initial pilot study included kelp blades exposed to copper in the laboratory setting, and the zoospores subsequently released into laboratory seawater. Follow up studies using SEA-Ring™ technology developed by SPAWAR and in collaboration with AMEC Earth & Environmental repeated this method and were expanded to include in situ blade exposure to the receiving environment at UCSD's Scripps Institution of Oceanography. Zoospores from the field exposed blades were ultimately released into a copper chloride dilution series in the laboratory and allowed to grow-out for 48 hours. Results indicate that density of spore release, germination rate, and germ-tube mean length of zoospores from field-exposed sporophylls show a typical dose response to increasing concentrations of copper. Additionally, laboratory and field exposures exhibited similar sensitivity to one another. The study confirms that in situ exposure of *Macrocystis pyrifera* for toxicity testing is possible at the sporophyll level and may have future implications in stormwater or other projects that may benefit from in situ monitoring methods.

RP237 Latent Effects of Triclosan on Development and Survival in Fathead Minnows, *Pimephales promelas* J. Salierno, Fairleigh Dickinson Univ, Dept of Biological Sciences; M. Lopes, M. Rivera, Fairleigh Dickinson Univ. Triclosan (TCS) is an antimicrobial compound used in personal care products and enters the aquatic environment through waste water treatment plant effluent. The goal of this research was to evaluate TCS exposure on hatching, growth, and development in the fathead minnow *Pimephales promelas*. We conducted a 10d static-renewal LC bioassay in which 24hr, fertilized, eggs were exposed to 6 concentrations of TCS (0-500ppb) in triplicate, including ethanol controls. The resultant LC_1 and LC_{10} (50 and 100ppb) were then used to examine sub-lethal exposure of TCS on juvenile minnow growth and development. We exposed 24hr, fathead minnow eggs to 50 and 100ppb TCS, with ethanol controls, for 10d followed by a 6-week depuration period (N = 4). Development, mortality, and deformities were monitored daily and growth (total length and wet weight) was quantified at the end of the 6-week depuration period. The 10d static-renewal LC_{50} was 149.67ppb, which was lower than previously reported for fathead minnows. The 10d, sub-lethal, TCS exposure had no effect on the time to develop, hatch, or on larval survival compared to the controls ($p = 0.84$). However, differences in minnow growth and deformities were observed. TCS exposed fish after the 10d exposure to sub-lethal concentrations exhibited increased emaciation and spinal deformities compared to control fish ($p = 0.08$). Interestingly, there was a decrease in survival of the TCS exposed fish after the 6 week period, with the 100 ppb exposure treatment having significantly lower rates of survival than both the 50 ppb and control treatments ($p = 0.004$). This reduction in survival displayed a dose response by TCS concentration when compared to controls. No deformities were observed after the 6-week depuration and the significant mortality in exposed fish confounded the length and weight results, which were not analyzed. Mortality was likely a result of spinal deformities reducing foraging ability, leading to emaciation and death. The observed effects occurred at concentrations below the published LC values for TCS exposure in fathead minnows. Results suggest

that TCS exposure may exhibit deleterious effects on fish species at lower concentrations, over longer durations, than previously reported. Further, the observed mortality rates in TCS exposed fish 6-weeks after a 10d exposure demonstrates the need for various exposure paradigms to investigate the effects of TCS on fish.

RP238 Life-Cycle Exposure of *Daphnia magna* to Environmentally Relative Mixtures of Pharmaceuticals D.N. Wolfe, S. Richards, Univ of Tennessee at Chattanooga; M. Hanson, Univ of Manitoba. Due to the global detection of pharmaceuticals in surface water, risk assessments require toxicity testing to be preformed to close knowledge gaps for effects assessment regarding impacts on aquatic food web dynamics. The widespread use of pharmaceuticals has resulted in mixture concentrations of mg/l in effluent and ug/L concentrations in surface water. Their potential toxicological effect on fresh water ecosystems remains largely unknown, especially as complex mixtures. Toxicity data on the effect of pharmaceuticals has expanded in the past decade, but has mainly focused on single, acute pharmaceutical exposures, not environmentally realistic mixtures. By determining the threshold of response for environmentally relavant mixtures, the risk that these compounds may pose to the environment will be determined more accurately. In 2008, thirteen pharmaceuticals were quantified in the Tennessee River, USA and its tributaries, ranging from 0.1757 to 0.0028 ug/l. Using the same ratios of individual compounds, but increased concentrations, the present study conducted chronic life cycle toxicity test on the cladoceran *Daphnia magna*. Tests were performed using 10x, 100x and 1000x the concentrations detected in the Tennessee River, resulting in a total concentration of 6.031, 60.31, and 603.1 ug/l of total pharmaceutical exposure, respectfully. Mortality, time to first brood, size and fecundity were use as endpoints of toxicity. Test solutions were renewed three times a week and neonate removed each day until the conclusion of the experiment. *D. magna* showed a statistically significant decrease in the number of neonate produced when exposed to 100x and 1000x ($p < 0.003$). When *D. magna* was exposed to the 10x concentration, no significant decrease in neonate production was observed. Neither time to first brood nor size was affected at 10x, 100x, or 1000x. Studies are on going to pinpoint the threshold of effects occurring between 10x and 100x. These data will provide risk assessors more accurate data when analyzing non-lethal effects of pharmaceutical mixtures on aquatic ecosystems.

RP239 Measured Mercury Contamination in Freshwater Fish in Rhode Island Compared with Predictions from a Regional Environmental Mercury Model A. Kuhn-Hines, J. Lake, J. Serbst, USEPA, Atlantic Ecology Division; D. Nacci, USEPA, ORD, NHEERL, Atlantic Ecology Division, USEPA, NHEERL, Atlantic Ecology Division; P. Edwards, A. Libby, Rhode Island Dept of Environmental Management, Division of Fish and Wildlife. Edible tissue of largemouth bass collected at 29 freshwater sites across the variable landscape of Rhode Island, USA showed a 27 fold range in total mercury concentrations [Hg], from 0.04 to 1.0 ppm (wet). Twenty-one variables, including water quality data and geographic information system (GIS) layers, were obtained to describe the land use, human population density, soil and bed rock characteristics, impervious surfaces and vegetative cover within the watersheds and one hundred meter buffer zones surrounding these freshwater sites. Regression analyses were performed to determine which landscape and water quality variables or combinations of these variables were associated with size-corrected [Hg] in largemouth bass from the 29 freshwater sites. Preliminary analyses demonstrated that three variables: pH, chloride and Secchi depth or clarity (all negatively associated with fish [Hg]), explain 58% of the variability in largemouth bass [Hg] among sites. Measured [Hg] results were compared with those estimated for the same sites using the MERGANSER model, a USGS-EPA New England (NE) regional model which uses mercury depositional data and estimated values for continuous water quality and landscape variables to predict [Hg] in fish. Average measured values of fish [Hg] for these 29 lakes were generally similar to predicted values (0.50 and 0.48 ppm, respectively), while variance was slightly higher in the measured data set. Fish [Hg] measured and predicted values were moderately well correlated ($r2 = 0.40$), and rank order agreed better for lakes with the lowest and highest fish [Hg] values. The pH value measured at sites, which was not used in calculating MERGANSER model estimates of [Hg] because this information was not available for many NE lakes, could explain a higher % of the variability in the model's estimates of [Hg]. Our results suggest that easily measured water quality variables such as pH, chloride and Secchi depth data could provide important information for the prediction of fish [Hg] in unmeasured lakes. Further, these findings indicate more site specific modeling may be required in regions like Rhode Island where site characteristics vary widely across a relatively small geographic range.

RP240 Mechanism for Disruption of Crustacean Molting by Xenobiotics E. Zou, Nicholls State Univ, Biological Sciences. Agricultural and industrial activities have led to aquatic pollution of various anthropogenic chemicals. Some of these xenobiotics, such as organochlorines, can readily accumulate in aquatic crustaceans. A series of laboratory exposure studies have shown that several environmental xenobiotics are capable of disrupting crustacean molting, with most of the disrupting effects being molt-inhibitory. Initial in vivo mechanistic studies using N-acetyl-β-glucosaminidase (NAG), also known as chitobiase, as a biomarker for ecdysteroid signaling have revealed that xenobiotics inhibit crustacean molting through disturbing the Y-organ-ecdysteroid receptor (EcR) axis. A further analysis utilizing tissue culture and quantitative real-time PCR techniques has demonstrated that the disturbance of such an endocrine axis by certain xenobiotics involves disruption of ecdysteroid signaling in the epidermis. When molt-inhibiting agent Aroclor 1242, 2,4,5-trichlorobiphenyl (PCB29), endosulfan or kepone was administered alone, the expression of NAG gene in cultured epidermal tissues was upregulated, while heptachlor had no effects. Under binary exposure to both 20-hydroxyecdysone and a molt-inhibiting chemical, a condition similar to the natural hormonal milieu of epidermal tissues of animals impacted by such a chemical, both Aroclor 1242 and endosulfan were found to be capable of antagonizing ecdysteroid signaling in cultured epidermal tissues. This antagonizing effect on epidermal ecdysteroid signaling can at least partly explain the inhibitory effects of these two agents on crustacean molting. PCB29, when given together with 20-hydroxyecdysone, produced an additive effect on epidermal ecdysteroid signaling but such an additive effect was not observed when kepone was combined with 20-hydroxyecdysone.

RP241 Mercury and Selenium Relationships in Local Fisheries N. Ares, Roger Williams Univ, Marine Biology; M. Soto, Roger Williams Univ, Marine Biology, UNAM, Instituto de Ciencias del Mar y Limnologia, Roger Williams Univ, Marine Biology, UNAM, Instituto de Ciencias del Mar y Limnologia, Roger Williams Univ, Marine Biology. Mercury (Hg) is a toxic environmental contaminant that negatively affects human health, and exposure occurs through the consumption of finfish. Selenium (Se) has the potential to directly or indirectly interact with Hg, and in the process, have a mitigating effect on Hg toxicity. Hg levels have been investigated in edible muscle filets of fish, e.g., summer flounder (*Paralichthys dentatus*), black sea bass (*Centropristis striata*), tautog (*Tautoga onitis*), and bluefish (*Pomatomus saltatrix*). Information on the Hg content of other tissues, e.g., brain and liver, however, is lacking. The brain is of particular concern because Hg is a neurotoxin, and the liver due to its role in detoxification. Moreover, the relationship between Hg and Se across these different tissues is largely unknown. This study examined Hg and Se concentrations among four estuarine finfish and their respective tissue-types. The specific objectives of this study were to: (1) examine Hg and Se bioaccumulation within three target tissues: muscle, brain, and liver, (2) examine the molar ratios of Se:Hg within tissues, and (3) compare Hg/Se differences among finfish as it relates to species-specific life-history characteristics. From June to August 2007-2010, target fish were collected from the Narragansett Bay estuary (RI, USA). Length (cm) was recorded for each fish, and total Hg was determined using automated atomic absorption spectroscopy. Total Se was measured using inductively coupled plasma mass spectroscopy. Molar ratios of Se:Hg were calculated to determine the protective quality of Se over Hg toxicity, with a ratio ≥1 showing a mitigating effect.

RP242 Microbial Diversity and Mercury Concentrations Within a Subtropical Estuary C.N. Ryan, Texas Tech Univ, Dept of Environmental Toxicology; S. Cox, Texas Tech Univ, Dept of Environmental. Toxicolgy. Microbial communities serve an important role in the overall health and function of estuarine ecosystems. However, the majority of studies evaluating microbial community composition in these areas have been restricted to culture-dependant methods which invariably omit a substantial amount of species. This study evaluates the microbial community structure within a mangrove-dominated estuary ecosystem. Sediment samples (n=11) were collected from the lagoon-side Round Island Park in Vero Beach, FL. Varying microhabitats within the park were sampled, including: red mangrove

(*Rhizophora mangle*) swamp, seagrass beds, sand bars, and a popular public wading area. DNA from each sample was extracted and analyzed via 454 pyrosequencing to identify microbial community composition. Samples were also analyzed for mercury content. A total of 877 bacterial genera were detected, with 35 genera shared between all 11 samples. Three genera (*Fusobacterium*, *Cytophaga*, and *Desulfosarcina*) contributed to differences within the 11 samples. The results of this study provide a greater understanding of the diversity of subtropical estuarine microbial communities.

RP243 Mineralogy and Heavy Metal Mobility of Marine Sediment of Cape Town Harbour, South Africa H.K. Okoro, Cape Peninsula Univ of Technology, Faculty of Applied Sciences; O.S. Fatoki, Cape Peninsula Univ of Technology, Cape Town, South Africa., Dept of Chemistry; F. ADEKOLA, Univ OF ILORIN, Chemistry; B. XIMBA, Cape Peninsula Univ of Technology,, Chemistry; R. SNYMAN, Cape Peninsula Univ of Technology, Dept of Biodiversity and Conservation. Quantitative mineral analysis has been done by Powdered X-ray diffraction (PXRD) and Fourier Transform Infra-Red spectroscopy (FTIR) on marine sediment of Cape Town harbour. The heavy metal mobility was evaluated using ICP-MS and ICP-AES respectively. The results were statistically analysed using SAS 9 software (Cary, NC, USA). The posteriori ANOVA procedure was performed to determine the variation and significance variations in the dependent variables due to sites with a $P \leq 0.05$ were considered significant. Some of the heavy metals analysed showed weak correlation of $r < 0.7$ with the strong correlation coefficients between (Al and Si, Fe, Cu, Zn,); (Si and Fe, Zn); (Fe and Zn); (Sn and Hg, Pb) (Hg and Pb) showing $r > 0.7$ and significant at ($P \leq 0.05$). Inversely lower correlation coefficients $r < -0.3$ existed between (Hg and Al, Si, Fe, Zn) respectively. Scree plot was used to estimate the component variation in the heavy metals from the eingen values. The order of variation is Zn > Cd> Sn > Hg > Pb > Al> Si > Fe > Cu respectively. The enrichment factors of Sn, Pb, Zn, Fe, Cd, Al and Hg revealed anthropogenic inputs of these metals into the marine environment. The enrichment factor of Cu was less than 1 and this suggests that its presence was largely due to natural changes. The results are indications of the contributions of heavy metals contained in the runoffs from the domestic and urban drains, as well as the inflow storm water. Ship repair activities appeared to constitute major factor responsible for the higher metal contamination in the dockyards areas. Mineralogical analysis using FTIR and XRD confirmed the presence of quartz, pyrite, carrolite and calcite as the major constituents of the marine sediment Keywords: Organic matter, mineral analysis, XRD, FT-IR, marine, pollutants, correlation coefficients,

RP244 Modeling Polyunsaturated Fatty Acids (PUFA) in Freshwater Fishes: A Kinetic Approach J. Sawyer, Univ of Toronto, Geography; N. Gandhi, Univ of Toronto, Chemical Engineering; M. Diamond, Univ of Toronto, Geography, Chemical Engineering. Polyunsaturated fatty acids (PUFAs) are crucial for fish because they affect metabolic activity, growth rates and reproduction. PUFAs cannot be synthesized by organisms at rates sufficient to meet their basic biochemical requirements and therefore must be obtained largely through the diet, magnifying through the aquatic food web. We propose a generic, kinetic-based PUFA model to simultaneously examine the fate and transport of omega-6 (18:2n6, 20:4n6) and omega-3 (18:3n3, 20:5n3, 22:6n3) fatty acids in fish, emphasizing freshwater species. Our multi-compartmental model simplifies the physiologic reality of PUFA metabolism, considering the mechanisms of accumulation, egestion, biotransformation and oxidation. PUFAs should be examined independent of other fatty acids as they each have their own distinct characteristics and behaviors. Understanding and quantifying fish tissue fatty acid profiles are of great importance given that PUFA are suggested to play a role in lowering heart disease risks, moderating tissue inflammation, and the development of the nervous, reproductive, and photoreception systems in humans.

RP245 Mountain Top Removal Coal Mining in WV: Integrated Field and Laboratory Studies Elucidating Biological Consequences of a Complex Contaminant Mixture M. Arnold, T. Lindberg, Duke Univ, Nicholas School of the Environment ; Y. Liu, Duke Univ, Pratt School of Engineering; A. Watson, Duke Univ, Nicholas School of the Environment ; H. Hsu-Kim, Duke Univ, Pratt School of Engineering; D.E. Hinton, R. Di Giulio, Duke Univ, Nicholas School of the Environment. The Mud River and its tributaries in West Virginia receive effluent from mountain top removal and valley fill (MTR/VF) coal mining operations. These effluents typically have increased conductivity and concentrations of potentially toxic metals and compounds that may impact organisms living in these receiving waters. The goal of this study is to determine the biological effects of MTR/VF stream contaminants and to identify the key drivers of observed toxicity using the fathead minnow model as a sensitive measure of environmental health with complementary field studies using the creek chub as a sentinel species. Water quality and sediment contamination data have been collected for the Mud River and several tributary streams. Selenium is an essential micronutrient that is beneficial at low concentrations but at higher concentrations can be toxic to organisms, including fish and invertebrates. Concentrations of selenium in the Mud River were above the USEPA chronic exposure water criterion of 5 ppb for 43 of 52 samples at sites along the Mud River. Fish were captured using electroshocking equipment from a site along the Mud River impacted by MTR coal mining. Several of the fish (*Lepomis* sp. hybrids) collected exhibited slight to severe jaw deformities suspected to be caused by selenium exposure while no deformed fish were collected from sites along the Left Fork of the Mud River that are not impacted by MTR/VF operations. Selenium concentrations in the collected fish will be determined using ICP-MS techniques. Histological examination of fish tissues collected from Mud River sites and control streams not impacted by MTR coal mining will be performed to determine if exposure to the mixed contaminants from coal mining has caused alterations in fish development. Adult fathead minnows will be exposed to selenium at levels comparable to those found at sites along the Mud River to identify toxic effects on offspring as well as genetic markers of oxidative stress in both adults and embryos.

RP246 Multi-level Assessment of Sublethal Toxicity of Copper and Benzo[*a*]pyrene Toward Pale Chub W. Kim, Korea Institue of Toxicology, Environmental toxicology Center, Korea Univ, Division of Environmental Science & Ecological Engineering; J. Lee, Korea Istitute of Toxicology, Ecotoxicology lab; J. Kim, E. Lim, Korea Institute of Toxicology; S. Lee, Korea Institute of Toxicology, Ecotoxicology Laboratory; S. Lee, K. Choi, Seoul National Univ; J. Jung, Korea Univ. Multi-level biomarker responses (molecular/biochemical and histological/physiological levels) were studied to assess sublethal toxicity of copper (Cu) and benzo[*a*]pyrene (BaP) toward pale chub, Zacco platypus. No significant differences at the histological or physiological levels were observed among treatment groups, except for kidney tissue exposed to 20 µg Cu/L. However, various molecular/biochemical responses were observed in Z. platypus, and these primarily depended on exposure time. Upon Cu exposure, both DNA single-strand breaks (COMET) and metallothionein (MT) activity were significantly increased for 4 days, while there was no significant change after 14 days of exposure. BaP exposure induced a significant increase in COMET and 7-ethoxyresorufin-O-deethylase (EROD) activity at 4 and 14 days of exposure. Additionally, BaP induced acetylcholinesterase (AChE) activity at 14 days of exposure. Standardized scores of biomarker responses at molecular/biochemical levels were visualized using star plots and computed as the integrated biomarker response (IBR). The IBR values well correlated with the concentrations of Cu and BaP, and the correlations were better at 4 days of exposure ($r^2 = 0.780$ and 0.699, respectively) than 14 days ($r^2 = 0.692$ and 0.548, respectively). These results indicate that short-term exposure may work as well or even better for quantification of various biomarker responses at the molecular/biochemical levels when compared to long-term exposure.

RP247 Multigenerational Exposure of *Heterandria formosa* to 17α-ethinylestradiol: Organism and Population Level Effects Through Two Life Cycles L.M. Carrier, P.L. Klerks, Univ OF LOUISIANA AT LAFAYETTE, Dept of Biology. The presence of endocrine disrupting compounds (EDCs) in the environment has gained major worldwide attention because of the possibility that EDC's may be affecting the reproductive health of wildlife populations and humans. The synthetic estrogen, 17α-ethinylestradiol, is a potent endocrine modulator and is present at biologically active concentrations in aquatic ecosystems. To investigate impacts of EE2 on an aquatic environment, a 150-day in vivo study is examining the potential effects of the synthetic estrogen 17 α-ethinylestradiol (EE2) in the least killifish (*Heterandria formosa*). Newborn fish are being exposed to 1.0ng/L EE2, 5.0ng/L EE2, or a solvent control (100% ethanol) in a static-renewal system with replacement every 72 hours. Effects of EE2 on growth, sex ratio, survival rate, population growth rate, reproduction rate, and time to sexual maturity in the developing fish are being examined through two generations. Reduced growth, female-biased sex ratios, decreased survival, diminished populations, abated reproduction, and a longer time to sexual

maturity are expected for the EE2-exposed fish. Results of the ongoing experiment will be presented at the meeting.

RP248 Parasites and Pollution: A Study of Selenium Uptake in Nematode Infected Rainbow Trout (*Oncorhynchus mykiss*) O. Hursky, M. Pietrock, Univ of Saskatchewan, Toxicology Centre. Given that parasites demonstrate different sensitivity to contaminants and environmental stress there is an increasing interest in using parasites as biological or ecological indicators of their fish host life conditions as well as bioindicators of heavy metal pollution of aquatic ecosystem. The aim of this study was to investigate (1) whether there is a transfer of selenium from intestinal contents of rainbow trout (*Oncorhyncus mykiss*) to nematodes (*Raphidascaris acus*), (2) whether parasites bioconcentrate more selenium than their host and (3) to examine if the combined effect of parasitic infection and Se exposure has an effect on fish health (as determined by Fulton's condition factor, Hepatosomatic Index (HSI), Gross Energy (GE) content and levels of catalase and GST). Rainbow trout were infected with larval stages of nematodes and subsequently exposed to dietary Se for 70 days (4.5 mg Se /kg food w.w.) Selenium concentration of trout muscle tissue and intestinal parasites were determined using ICP-MS. The results indicate that comparing to muscle tissue of their host, *R. acus* accumulate lower levels of Se, therefore is not a good bioindicator of Se accumulation in ecosystem. However, *R. acus* do have an impact on fish health: combined with Se exposure parasitic infection decreases GE content of the fish and alters enzyme levels.

RP249 Pollutant Sensitivity of the Green Floater (*Lasmigona subviridis*), a Freshwater Mussel of Conservation Concern in Mid-Atlantic River Basins, USA D.K. Hardesty, J.M. Besser, USGS; C.G. Ingersoll, USGS, Columbia Environmental Research Center; N. Wang, USGS; T. Augspurger, R. Mair, USFWS. The green floater (*Lasmigona subviridis*) is a species of concern in North Carolina, Virginia, and other mid-Atlantic states due to declining numbers in the wild. The species has a unique life cycle in that females produce transformed juveniles within their gills (not requiring a parasitic stage on a fish host). The pollutant sensitivity of the species is of interest in determining the extent to which water quality may be a limiting factor in their survival and recovery. Also, green floaters might serve as a good organism for use in laboratory toxicity testing, given that no host fish is needed for transformation of juveniles from the glochidia life stage. We conducted 96-hour exposures of < 5 day-old juvenile green floaters to copper, zinc, and chlorine in separate exposures. Control survival was 100% in all tests. The EC50s (immobilization) for copper (26 µg/L at a hardness of 162 mg/L as $CaCO_3$), zinc (472 µg/L at a hardness of 50 mg/L), and chlorine (135 µg/L) indicates green floaters were not particularly acutely sensitive compared to other mussel species. Interestingly, there was considerable "recovery" of effected organisms in clean water for 24 hours following the initial 96-hour exposures to toxicants. This type of a recovery has been observed in older mussels (e.g., 2-month-old), less so for newly released juveniles of all others species which use the obligate fish host for transformation of juveniles.

RP250 Population Level Assessment of the Concomitant Impacts of Temperature and Lead Using *Daphnia magna* N. Melby, US Army ERDC and Mississippi State Univ; J.D. Laird, Us Army Engineer Research & Development Center, SpecPro Incorporated, US Army Engineer Research & Development Center, Environmental Laboratory; D. Meeks, A.J. Kennedy, A. Casper, US Army Engineer Research and Development Center; S. Brasfield, US Army Engineer Research and Development Center, Environmental Laboratory. The focus of this study is to determine the potential for interactive effects of chemical and nonchemical stressors, primarily lead and temperature related to climate change scenarios on military installations using the freshwater cladoceran, *Daphnia magna*. This approach may provide information as to whether predicted changes could affect contaminant management on military installations. Lead was chosen as the chemical stressor because of its importance related to small arms firing ranges on DoD military installations where lead ammunition is used for military training exercises. These metals can leach into the soils which then have the potential to run off into aquatic environments where toxicity effects on the organisms with climate change have yet to be investigated over time in a population model. Endpoints measured for this species include growth, reproduction, and population demographics through numerous 21-day exposures in environmental chambers at varying temperatures and also with lead (II) chloride ($PbCl_2$). Predictions are that the chronic toxicity of metals will increase due to the shift in climate change as multiple stressors on *D. magna*. Temperature only exposures at 20, 23, and 26°C elicited a small negative response in weight and size as well as reproductive effects on the *Daphnia* over 21d. High temperatures result in earlier reproduction, increase in the number of broods per individual, however a decrease in the number of neonates per brood. When the effect of treatment temperature is compared on an individual basis, the 23°C and 26°C organisms begin producing broods two days earlier and produced two more broods than the organisms exposed at 20°C. However, when the mean number of neonates per brood is calculated, a linear negative relationship with temperature resulted. *Daphnia* exposed at higher temperatures have the capability to reproduce earlier but are exposed to the chemical for a longer period of time; therefore, they may be more sensitive due to increased metabolism. Energy is being shunted between maintenance function, growth and/or reproduction for each treatment.

RP251 Potential Effects of Life History Evolution on Ecological Risk Assessment M. Kamo, Advanced Industrial Science and Technology, Advanced Industrial Science and Technology, Research Institute of Science for Safety and Sustainability; T.I. Hayashi, National Institute for Environmental Studies; T. Akita, Graduate Univ for Advanced Studies. We theoretically investigated how the sensitivity of organisms to the toxicity of chemicals varies depending on their life history traits. We considered a simple resource allocation model combined with a logistic growth equation. We assumed that organisms allocated the resources to (1) reproduction, (2) maintenance of their life and (3) mitigation of the adverse effects of chemicals with certain ratio. The ratio was considered to be the life history. We assumed that the ratio was subjected to evolution, and the evolutionary stable strategy (ESS) was investigated. We assumed two situations for evolution to occur. In one situation evolution occurred in the sparse population to mimic a laboratory condition, and in the other situation evolution occurred in crowded population to mimic a natural condition. We first investigated when the evolution occurred in the absences of chemicals. We found that an organism adapted in sparse population spend more resources on reproduction than that adapted in crowded population, and hence became r-strategists. When the effects of chemicals were measured by a toxicity reducing the population growth rate by 10% (EC10), the r-strategists were less sensitive to toxicity of chemicals. The result suggests that use of laboratory-reared organism in toxicity tests leads to the underestimation of ecological risk. When the adaptation occurred in the presence of chemicals, a strategy allocating for the mitigation of the toxicity became ESS. An amount of resource allocation for the mitigation in the evolutionary stable strategists depended on the shape of a function determining the relationship between the amount of resource and the effect of mitigation. In some cases, evolutionary bistability appeared and hence the organism became either chemical tolerant type or non-tolerant type depending on initial conditions of the evolution. Our results explain the diversity in chemical sensitivities within biological species.

RP252 Recovery of Photosynthesis and Growth Rate in Green, Blue-Green, and Diatom Algae After Exposure to Atrazine R. Brain, Syngenta Crop Protection, LLC., Dept of Environmental Risk Characterization; A. Hosmer, Syngenta Crop Protection, LLC.; S.B. Wall, Syngenta Crop Protection, LLC., Ecological Sciences. The effects of atrazine, a photosystem II (PSII) inhibiting herbicide belonging to the s-triazine family, on primary producers are reversible. In laboratory studies, recovery from atrazine exposure concentrations high enough to inhibit PS II has been documented in a variety of aquatic plants belonging to taxonomically diverse growth forms including floating macrophytes (Lemna gibba), submerged rooted macrophytes (Potamogeton perfoliatus and Myriophyllum spicatum), and green algae (Scenedesmus vacuolatus). In green algae, photosynthesis, as measured using pulse amplitude modulation (PAM) fluorometry, recovers immediately and growth recovers within hours. In order to expand upon the existing compliment of species and provide comparable recovery data, studies with green (*Pseudokirchneriella subcapitata*), blue-green (Anabaena flos-aquae), and diatom (Navicula pelliculosa) algae were conducted to evaluate the effects of atrazine on photosynthesis (measured using PAM fluorometry) and growth rate. Algae were grown for 24 to 48 hrs, then exposed to atrazine for 48 hrs and evaluated for recovery for a further 48hrs after removal from exposure. Collectively these studies further corroborate the conclusion that primary producers recover quickly from exposure to atrazine at concentrations high enough to inhibit PSII, where recovery of photosynthesis begins immediately and recovery of growth rate begins within hours. Species

specific differences in sensitivity were observed, though recovery kinetics were largely comparable and consistent.

RP253 Recovery of Wild Small Bodied Fish Populations After a Multi-year Exposure to a Synthetic Estrogen B. Park, Dept of Fisheries & Oceans Canada, Dept of Fisheries and Oceans, Freshwater Institute, Dept of Fisheries and Oceans; V. Palace, Freshwater Institute, Dept of Fisheries and Oceans Canada; K. Wautier, P. Blanchfield, Freshwater Institute, Dept of Fisheries and Oceans; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology. Estrogenic contaminants are routinely detected in surface waters, and can disrupt reproductive endocrine system function in aquatic organisms. To address potential impacts on wild fish populations, we added the synthetic estrogen 17 alpha-ethynylestradiol (EE2) to an experimental lake (L.260) from spring to fall of 2001 to 2003, and monitored various physiological and population parameters from the EE2-treated lake and two reference lakes. Previously we reported that EE2-exposed fish exhibited vitellogenin induction in males, inhibited gonad development in both sexes, testicular oocytes, and histopathological changes in liver and kidney. The fathead minnow (*Pimephales promelas*) population in the treated lake collapsed due to lack of recruitment, whereas these effects were absent in reference fish populations. To assess potential recovery of fish in L.260, we continued to monitor these populations after cessation of the EE2 additions for vitellogenin, histology and population endpoints. Fathead minnow and pearl dace (Margariscus margarita) were collected in spring and/or fall from 2004 to 2010. Preliminary results indicate that reproductive abnormalities were present in both species two years post-exposure in L.260, but were absent in subsequent years. There was no difference among lakes in vitellogenin levels in male fathead minnows caught in the fall of 2010; analyses of samples for other dates and for pearl dace are ongoing. Catch-per-unit-effort (CPUE) of adult fathead minnow returned to pre-experiment levels by the spring of 2007 (4 years post addition). These results indicate that, given time, fathead minnow and pearl dace recovered across all levels of biological organization from the whole lake additions of EE2.

RP254 Relationships Between PCDDs, PCDFs, Dioxin-like PCBs, and Other Compounds of Concern in Fish from the Saginaw Bay Watershed (Lake Huron, MI, USA) R. Holem, J. Newsted, Cardno Entrix; S. Roark, CH2M Hill, Ecotoxicology & Risk Assessement; J. Matousek, Cardno Entrix; D. Tazelaar, Michigan State Univ, Animal Science, Cardno Entrix; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science; D. Kay, Cardno Entrix. Previous investigations have reported elevated concentrations of dioxin-like compounds in sediments, floodplain soils, and tissues of fish collected from the Saginaw Bay watershed. In 2007 fish were collected from the Tittabawassee and Saginaw Rivers and Saginaw Bay of Lake Huron to provide data for human health risk assessment and further characterize contaminant levels in fish fillet tissues. In 2008, fish were collected from the upper Tittabawassee, Pine, Shiawassee, Flint, and Cass Rivers, to provide comparison contaminant data for fish from tributaries of the Tittabawassee and Saginaw Rivers. Concentrations of polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), dioxin-like polychlorinated-biphenyls (dl-PCBs), mercury, arsenic, and a suite of other compounds were measured in nearly 500 fish of the fish collected in 2007 and 2008. Species included carp, channel catfish, black crappie, freshwater drum, largemouth and smallmouth bass, northern pike, yellow perch, sunfishes, and the migratory species walleye, white bass, and white suckers. Average concentrations of ∑PCDDs and ∑PCDFs ranged from 1– 18 and 2 – 60 pg/g wet weight (ww), respectively, while average ∑dl-PCBs ranged from 15 – 150 ng/g ww. Concentrations of ∑PCDDs, ∑PCDFs, ∑dl-PCBs, and tetrachlorodibenzo-*p*-dioxin equivalents (TEQ) were greatest in carp and channel catfish and generally least in freshwater drum and sunfish species. In general, furan concentrations were greatest in fish from the Tittabawassee River while dl-PCBs were greatest in Saginaw River fish. Mercury, 4,4'-DDE, and arsenic were detected in nearly all fish analyzed. Principal components analysis was conducted to examine differences in contaminant patterns between predatory and benthic-feeding species and between migratory and resident species. In addition, contaminant patterns were examined between the different locations with specific focus on differences between the Tittabawassee and Saginaw Rivers and their tributaries.

RP255 Salinity Acclimation Modulates Copper Toxicity in the Sheepshead Minnow, *Cyprinodon variegatus* J.A. Adeyemi, Univ of Louisiana at Lafayette, Dept of Biology; P.L. Klerks, Univ of Louisiana at Lafayette, Dept of Biology. The sheepshead minnow, *Cyprinodon variegatus* is a euryhaline fish that is able to withstand a very wide range of salinities. In two experiments we examined the effects of salinity acclimation on copper toxicity in sheepshead minnows. In the first experiment, fish were pre-exposed to 2.5, 10.5 or 18.5 ppt seawater for 14 days, after which they were exposed to a fixed free cupric ion level (16.6 μM Cu^{2+}). Survival during the 14-day salinity acclimation was high in all the groups. However, fish from these groups responded differently during Cu challenge. Fish pre-exposed to 2.5 ppt salinity were more sensitive (about 70% mortality) compared to fish pre-exposed to 10.5 or 18.5 ppt seawater. In the second experiment, fish were exposed to 14.6 μM Cu^{2+} for 6 hours after the 14-days salinity acclimation. Fish were subsampled across groups for determination of whole-body Cu, liver lipid peroxidation, liver catalase activity and liver glucose levels before (T0) and after (T6) copper exposure. At T0, there were no differences across the groups for most of the endpoints measured in this study, except for liver glucose level that was significantly higher in 2.5 ppt acclimated fish compared to the other groups. At T6 whole-body Cu and liver lipid peroxidation differed significantly among the groups, but there was no difference in liver glucose level or catalase activity. This study showed that while these fish were able to acclimate to substantial salinity changes, this adjustment came with a large metabolic cost that resulted in reduced tolerance during subsequent copper exposure.

RP256 Scaling Up Bioassays for Toxicogenomics: Impacts on *Daphnia magna* Sensitivity to Metals A.J. Kennedy, US Army Engineer Research and Development Center; J.D. Laird, Us Army Engineer Research & Development Center, SpecPro Incorporated, US Army Engineer Research & Development Center, Environmental Laboratory; B. Meeks, US Army Engineer Research and Development Center; K.A. Gust, US Army, Engineer Research and Development Center, Environmental Laboratory, US Army, Engineer Research and Development Center, Us Army Engineer Research & Development Center, ERDC-EL-EP-P; M.S. Wilbanks, Us Army Engineer Research & Development Center; R. Nisbet, Universtity of California, Santa Barbara; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division. As toxicogenomics and dynamic energy budget (DEB) determinations become integrated with traditional ecotoxicological endpoints and environmental risk assessments, modifications to standard bioassays will become necessary. Standard acute or chronic bioassays employing the aquatic receptor *Daphnia magna* do not currently supply adequate tissue mass for conventional microarray-based gene expression assays. Therefore, standard bioassays must be scaled up in terms of number of *D. magna* and chamber size. Further, DEB analyses require accurate determinations of nutritional carbon, which is complicated by the heterogeneous standard feeding ration (i.e., algae and yeast-cerophyl-trout chow, or YCT). To understand how scaled up test methods for toxicogenomics and DEB analysis may impact response to metals, the standard 21-day *D. magna* chronic toxicity test method (one organism per 50 ml exposure vessel) was compared to a modified method (20 organisms per 1000 ml exposure vessels). The model chemicals were copper (Cu) and lead (Pb). Bioassays were conducted at 24 _C and received algae-only feeding rations, denoted 1X (standard ration) and 2X (double the standard ration). *Daphnia magna* were significantly more sensitive to both metals in the modified method relative to the standard method. Removing YCT from the standard feeding ration (1X algae-only) significantly reduced reproduction; however doubling the algae ration (2X) mitigated the effect. Regardless of the test method or metal, significant reductions in survival occurred at first molt and first brood, suggesting these are important stages to consider in genomics and DEB. Using the modified method, *D. magna* survival in Pb exposures was slightly but significantly more sensitive when provided 1X feeding ration (LC50 = 68 [63 – 73] ppb) compared to the 2X ration (LC50 = 79 [74 – 84] ppb). While the 2X feeding ration generally resulted in statistically increased growth and reproduction across all Pb treatments, the 1X feeding ration resulted in a significant sublethal impact at a lower Pb concentration. Findings suggest that when the objective is to relate toxicogenomics to standard ecotoxicological effects or DEB analysis, all endpoints should be generated from the modified method used to generate tissue for toxicogenomics since extrapolation to the standard method may not be directly relatable in terms of response to chemicals.

RP257 Selection of Stream Insect Larvae for Indicating Anthropogenic Impact J. Lake, USEPA, Atlantic Ecology Division; J. Serbst, A. Kuhn, USEPA. This study examined the total mercury concentrations, [Hg], and delta^15N values in macro-invertebrates collected from 35 stream sites in Rhode Island, USA, to determine the organism groups most suitable for use as indicators of anthropogenic impact. Site selection was designed to cover a wide geographical range and to encompass relatively pristine locations in the western part of the state and others from more highly developed and populated areas near the city of Providence. Sites were sampled on an irregular basis over a two-year time period. Samples were collected by dip and kick nets and consisted largely of insect larvae. The distributions of larval insects varied among sites. The most common larval organism groups, found at 30 and 28 sites, respectively, were: hellgrammites, a group that is a combination of dobsonflies and fishflies, and darner dragonflies. The larvae of both of these groups are engulfer-predators. Across sites, relationships between [Hg] and delta^15N varied among the organism groups. Engulfer-predators showed significant negative relationships between [Hg] and delta^15N values, except for skimmer dragonflies, which did not show a significant relationship. The delta^15N value of organisms has been found to reflect the level of nitrogen nutrients in fresh water sites which often results from human wastewater inputs. Therefore, the negative relationships shown for most of the engulfer-predators may reflect anthropogenic impacts across sites. However, pH varies among sites and explains 31% of the variance in [Hg] for hellgrammites. When pH was combined with the delta^15N data for this organism group in a stepwise regression, 43% of the variance in [Hg] was explained. Overall, the frequency of occurrence and the strength of the relationship between [Hg] and delta^15N for hellgrammites appear to support their potential use as an indicator of the magnitude of Hg contamination and anthropogenic impact in streams. At sites where hellgrammites are not found, darner dragonflies could be substituted because the relationships between [Hg] and delta^15N were not significantly different between these two groups.

RP258 Serum SDH Activity as a Biologically Significant Biomarker of Liver Integrity in Fish D. Webb, Curtin Univ, Environment and Agriculture; M. Gagnon, Curtin Univ, Dept of Environment and Agriculture, Curtin Univ (Bentley Campus), Dept of Environment and Agriculture, Curtin Univ, Environment and Agriculture. In order to assess the usefulness of serum dehydrogenase (SDH) activity as a biomarker of liver damage in fish, black bream (*Acanthopagrus butcheri*) were injected with a model hepatotoxicant, pentachlorophenol (PCP) sodium salt. A suite of biomarkers were measured over time, i.e., serum SDH activity, liver somatic index (LSI) and hepatocellular hyperplasia. At 3 days post-injection, serum SDH activity was significantly elevated in the fish group i.p. injected with 30 mg PCP, Kg fish, relative to the negative control group. While SDH activity returned to control levels 6 days post-injection, the LSI increased significantly relative to control levels at this time. Histological damage, measured by hyperplasia, was not detected until day 9 post-injection. This study demonstrates that in black bream exposed to hepatotoxicants, changes in serum SDH activity are detectable before physiological or histological changes became evident. Serum SDH activity can therefore be used as a non-lethal, biologically meaningful early warning indicator of liver integrity.

RP259 Studies on the Recovery of a River Ecosystem in Northern Ontario Previously Exposed to Pulp Mill Effluent T. Arciszewski, Univ of New Brunswick, 5000+; K. Munkittrick, Univ of New Brunswick, Canadian Rivers Institute, Univ of New Brunswick, Dept of Biology. Studies on the impacts of pulp mills have been conducted at many sites in Canada since the late 1980s. Many of these studies have shown depressed circulating steroids and reduced gonad size. Temporary shutdowns and process improvements were often associated with moderate recovery of fish sentinels. In Jackfish Bay, Ontario, short-term shutdowns often elicited recovery of endpoints with high turnover, like mixed function oxygenases (MFOs) in the liver. A shutdown lasting 18 months also showed some reversal in the effects on fish, but not all impacts disappeared. Since 2000, the Canadian pulp and paper industry has contracted by approximately 50 %. With the permanent closure of many of these facilities comes the opportunity to more thoroughly study the recovery of ecosystems previously exposed to pulp mill effluents. At one kraft mill in Smooth Rock Falls, Ontario, Canada (which was closed permanently in July 2006), there was extensive work done while the mill was operating including collections by Environment Canada (Moose River Project; 1991-1997) and four cycles of Environmental Effects Monitoring (EEM; 1995, 1998, 2002, 2005). The existing dataset includes performance data (body condition, growth rate, age, gonadosomatic index (GSI), liver somatic index (LSI), liver enzymes (mixed function oxygenases; MFO), circulating sex steroids, and fecundity) from white sucker (*Catostomus commersoni*) collected in 1993-1998, 2002, and 2005. During the operation of the mill, from 1993 to 2005, strong and recurrent effects were found in female gonad size; significant ($p < 0.05$) effects on GSI of female fish ranged from -5 to -38% compared to an upstream reference site. Given the impacts of the previous discharge of now-closed mills on fish reproduction, we have initiated studies to examine the recovery of the Mattagami River which received the pulp mill effluent from the Smooth Rock Falls mill. To better understand recovery processes and their potential rate, this study will use the same sentinel fish species (white sucker), study locations, and methodology to compare the operational (1993-2005) and post-operational (2011) data sets.

RP260 Subchronic Exposure to PFOA and PFOS in *Zacco platypus*, an Indigenous Korea Freshwater Fish S. Kim, School of Public Health, Seoul National Univ, Environmental Health, Seoul National Univ, Graduate School of Public Health; S. Lee, Seoul National Univ, #306, Graduate School of Public Health; W. Kim, Korea Institute of Toxicology; C. Kim, A. Kim, Seoul National Univ, #306, Graduate School of Public Health; J. Kim, E. Lim, J. Lee, Korea Institute of Toxicology; J. Kim, Korea Research Institute of Bioscience and Biotechnology; S. Lee, Korea Institute of Toxicology; K. Choi, Seoul National Univ, #306, Graduate School of Public Health. Pale chub (*Zacco platypus*) is an indigenous freshwater fish which distributes widely in East Asia including Korea. This fish has been suggested for potential indicator species, however, information on molecular level biomarkers of *Z. platypus* is limited, and its application to ecosystem risk assessment is difficult. We selected several molecular level biomarkers and utilized the molecular biomarkers to assess toxicity mechanisms of PFOA and PFOS for 14-days exposure. Comet assay, acetylcholine esterase (AChE) assay, oxidative stress-related mRNA expression assay, oxidative stress-induced enzyme assay, and lipid peroxidation assay were conducted using several organs of *Z. platypus*.The results of comet assay and acetylcholine esterase assay suggest that PFOA can induce DNA damage and can affect neurotransmission in *Z. platypus* after 14 d exposure at 0.5 and 50 mg/L. Exposure to PFOA lead to increased activity of SOD in muscle, and lipid peroxidation in liver. However, exposure to PFOS did not show such protein level changes in liver. Histological level changes in gill, liver, kidney and gonads were not observed after PFOS exposure. Our study showed that PFOA exposure could lead to damages in DNA and neurotransmission, and oxidative stress may be in part responsible for such damages in *Z. platypus*. Consequences of long term exposure to PFOA deserve further investigation.

RP261 Survival and Growth of Estuarine Fish in Response to Varied Exposures to Chemically Enhanced Dispersed Oil from the Deepwater Horizon Oil Spill R.A. Brewton, Gulf Coast Research Lab, Univ of Southern Mississippi, Coastal Sciences; J. Griffitt, USM, faculty; R. Fulford, Gulf Coast Research Lab, Univ of Southern Mississippi, Coastal Sciences. To assess potential impacts of the 2010 *Deepwater Horizon* oil spill on coastal habitats, we are examining the effects on individual fish in laboratory exposures. Spotted seatrout (*Cynoscion nebulosus*) are considered a good indicator of estuarine health because they occupy a mid-trophic level, are estuarine residents and show great plasticity in their growth due to environmental conditions. Laboratory assays of survival and growth of spotted seatrout as a function of dispersed oil concentration will be conducted at Gulf Coast Research Laboratory (GRCL) Toxicology Research Center using spotted seatrout from the GCRL hatchery. Weathered oil will be produced for experiments by mixing crude oil obtained from British Petroleum with seawater for 24 hours creating a water accommodated fraction (WAF); chemically enhanced weathered oil (CEWAF) will be produced with the same methods using both crude oil and dispersant (Corexit 9500). Juvenile fish (N=144 individuals) will be exposed to either CEWAF, WAF or dispersant alone for 96 hours in a spiked exposure. There will also be a control treatment that receives nothing. At the conclusion of the exposure, individuals will be removed, weighed and measured and morphometric indices will be used to evaluate fish health. 2 individuals from each treatment will be immediately sacrificed by cervical dislocation. The surviving fish will be retained and grown for 6 weeks, and then sacrificed to evaluate if the effect of exposure to CEWAF, WAF or dispersant has on the growth response of the fish. To confirm exposure of the fish to hydrocarbons, biomarker stress responses to

hydrocarbons will be evaluated within these fish; such as Cytochrome P450-1A levels. A second spiked exposure will be done (4 tanks per treatment, 12 individuals per tank) to compare the effect time exposed to CEWAF has on growth with exposure times of t= 12, 48, 72 and 96 hours. 2 fish from each treatment will be sacrificed at the conclusion of the exposure period, and the remaining individuals will be grown for 6 weeks, and then sacrificed. The results obtained from the laboratory assays will be compared to field growth and health data to test for habitat specific correlations between short-term stress and medium-term effects.

RP262 Test of Significant Toxicity: A Better Statistical Application for Assessing Effluent Toxicity D. Denton, USEPA Region 9, c/o SWRCB; J. Diamond, L. Zheng, Tetra Tech, Inc. The US Environmental Protection Agency (USEPA) and state agencies implement the Clean Water Act, in part, by evaluating the toxicity of effluent and surface water samples. A common goal for both regulatory authorities and permittees is confidence in an individual test result (e.g., NOEC, pass/fail, EC25), which is used to make regulatory decisions, such as reasonable potential determinations, permit compliance, and watershed assessments. This paper discusses an additional statistical approach (Test of Significant Toxicity [TST]), based on bioequivalence hypothesis testing, or more appropriately, test of non-inferiority, which examines whether there is a non-toxic effect at a single concentration of concern as compared to a control. Unlike the traditional hypothesis testing approach in whole effluent toxicity (WET) testing, TST is designed to explicitly incorporate both alpha and beta error rates at levels of toxicity that are unacceptable and acceptable, given routine laboratory test performance for a given test method. Regulatory management decisions are used to identify unacceptable toxicity levels for acute and chronic tests and the null hypothesis is constructed such that test power is associated with the ability to correctly declare a truly non-toxic sample as acceptable. This approach provides a positive incentive to generate high quality WET data to make informed decisions regarding regulatory decisions. We illustrate how alpha and beta error rates were established for specific test method designs, and tests the TST approach using both simulation analyses and actual WET data. In general, those WET test endpoints having higher routine (e.g., 50th percentile) within-test control variation on average, have higher method-specific alpha values (Type I error rate) so as to maintain a desired Type II error rate. We delineate the technical underpinnings of this approach and demonstrates the benefits to both regulatory authorities and permitted entities.

RP263 The Effect of Ethynilestradiol on Gonopodium Morphology and Gonadal Histology of *Cnesterodon decemmaculatus* (Pisces, Poeciliidae) B.J. Young, Laboratorio de Transformación de Residuos, IMYZA, INTA. ; G.C. Lopez, Laboratorio de Ictiofisiología y Acuicultura, IIB-INTECH (CONICET-UNSAM); D. Crespo, Laboratorio de Transformación de Residuos, IMYZA, INTA. ; G.M. Somoza, Laboratorio de Ictiofisiología y Acuicultura, IIB-INTECH (CONICET-UNSAM); P. Carriquiriborde, Conicet, Centro de Investigaciones del Medio Ambiente, Facultad de Ciencias Exactas, Universidad Nacionala de la Plata, Quimica, Centro de Investigaciones del Medio Ambiente – UNLP, CONICET, Facultad de Ciencias Exactas, UNLP. Public and scientific concern about EDCs has claimed for the understanding the mechanism underlying adverse effects and the development of ecotoxicological tools for assessing potential environmental impacts. Ethynilestradiol (EE2) is the main estrogenic component of the combined oral contraceptive pills, and its presence in surface waters has been reported worldwide. Holarctic Poeciliid fish has demonstrated to be valuable indicators of exposure to endocrine-modulating substances, because they exhibit a hormone-dependent sexual dimorphism. In the present study, alterations at the morphology of the gonopodium and the gonadal histology of the Neotropical Poeciliid, *Cnesterodon decemmaculatus*, in response to the EE2 were assessed under laboratory conditions. Two experiments were conducted exposing adult fish to environmentally and pharmacologically relevant waterborne concentration of EE2, ranging from 25 to 250 ng/L during a 90 days period. The description of the normal morphology of the gonopodium helped to build a gonopodial index for characterizing developmental stages in the studied species. Nevertheless, gonopodium morphology was not sensitive to environmental EE2 exposure, showing no response after 84 d of exposure. However, testicular histology showed primary oocytes in the outer sector since day 54 in fish exposed to 250 ng EE2/L., The number of oocytes increased and started to invade the central zone of the testis by day 84. Moreover a parenchymatization of the seminal tube lumen was also observed. The study demonstrated the induction of ovotestis ("intersex") by EE2 in *C. decemmaculatus*, encouraging the utilization of this local fish as test species for evaluating the impact of EDCs.

RP264 The Effects of Copper Amended Marine Sediments on an Estuarine Amphipod and Marine Polychaete During Chronic Bioassays A.K. Gerke, K.E. Gaertner, ABC Laboratories, Ecotoxicology; J. Gorsuch, Copper Development Association. With dispersive forms of copper in stormwaters reaching coastal surface waters and the use of copper as an active ingredient in anti-fouling paints, some marine sediments are accumulating copper. Thus, concerns over the potential effects of copper to benthic saltwater organisms have increased during the last decade. However, based on the intricacies of sediment toxicity and the complex behavior of metals in the environment, very few studies have managed to address this issue adequately. In most published studies, the effects of oxidization during the spiking procedure, binding to ligands, as well as sediment to porewater partitioning of metals have greatly been ignored or underestimated. Considering partitioning alone, toxicity has typically been overestimated due to combined sediment and porewater toxicity. Additionally, a majority of studies that have been based on equilibrated sediments neglected to investigate sediment properties which potentially influence toxicity. Recent work has established factors such as organic matter and particle size to affect benthic organisms in the presence of copper. During the past decade efforts have been made to predict toxicity based on ratios of simultaneously extracted metals (SEM) and acid-volatile sulfides (AVS), and organic matter measured as total organic carbon (TOC) or organic matter lost on ignition (LOI). The use of SEM and AVS to predict toxicity does have limitations. To investigate the toxicity of copper in equilibrated marine sediments, we conducted two 28-day chronic copper sediment exposures using two benthic species with different foraging behavior: the estuarine benthic amphipod, *Leptocheirus plumulosus* (ASTM E-1367), and the burrowing marine polychaete, *Neanthes arenaceodentata* (ASTM E-1611). Based on analyzed porewater and sediment concentrations of copper, preliminary results indicate that copper in equilibrated marine sediments is less toxic to these organisms than had been identified for similar species. A full analysis of these findings will be presented.

RP265 The Joint Effects of Sulfonamides and Their Potentiator on *P. phosphoreum*: Differences Between the Acute and Chronic Mixture Toxicity Mechanisms Z. Lin, D. Yin, Tongji Univ, College of Environmental Science and Engineering; X. Zou, Tongji Univ, College of Environmental Science and Engineering, Tongji Univ. Organisms are typically exposed to mixtures of chemicals over long periods of time; thus, chronic mixture toxicity analysis is the best way to perform risk assessment in regards to organisms. However, most studies focus on the acute mixture toxicity. To investigate the difference between chronic mixture toxicity and acute mixture toxicity, *Photobacterium phosphoreum* were exposed to chronic (24 h exposure) and acute (15 min exposure) toxicity of single sulfonamides (SAs) and their potentiator(trimethoprim, TMP), both individually and as mixtures. A comparison of chronic vs. acute mixture toxicity revealed the presence of an interesting phenomenon, that is, that the joint effects vary with the duration of exposure; the acute mixture toxicity was antagonistic, whereas the chronic mixture toxicity was synergistic. This phenomenon was due to the presence of two points of dissimilarity between the acute and chronic mixture toxicity mechanism: (1) the receptor protein of SAs in acute toxicity was Luc, while in chronic toxicity it was Dhps, and (2) there is a difference between actual concentration of binding-Luc in acute toxicity and individual binding-Dhps in chronic toxicity. This deep insight into the difference between chronic and acute mixture toxicity will benefit environmental science, medical science, and other disciplines. The existence of these differences poses a challenge for the assessment of routine combinations in medicine, risk assessment, and mixture pollutant control, in which, previously, only a synergistic effect has been observed between sulfonamides and their potentiator.

RP266 The Observation of Epibionts on Laboratory Cultures of *Hyalella azteca* and its Implications for Organism Performance in Toxicity Tests T.W. Valenti, National Research Council; US Environmental Protection Agency, National Research Council; S. Landers, Troy Univ, Dept of Biological and Environmental Sciences; T. Highland, R. Hockett, US Environmental Protection Agency, Mid-Continent Ecology Division; T.J. Norberg-King, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology

Division; S. Peterson, EMR, biologist; D.R. Mount, US Environmental Protection Agency, ORD. Epibionts are organisms that live on the surface of other living organisms. Several studies have identified epibionts on wild caught marine and freshwater crustaceans and they are often regarded as harmless to host organisms at low densities. However, epibionts may heavily infect laboratory populations of host organisms because cultures are typically carried out in semi-closed systems with high densities of potential host organisms. Under these scenarios, it is possible that the health and fitness of infected host organisms may be adversely affected. At our laboratory, the observation of high densities of epibionts on *Hyalella azteca* (at times > 500, individual) showed some correspondence with reduced performance in control treatments during standardized 10 d sediment toxicity tests. Interestingly, high rates of infestation did not appear to reduce survival or fecundity of adult breeding cultures, but rather were only related to lower rates of growth for 7-8 d old organisms during 10-d experiments. Ongoing efforts are targeted at not only identifying this species of epibiont, but also determining if these epibionts are the direct cause of reduced performance or whether the epibiont infection is a secondary result of another stressor. The objectives of this presentation are to: 1) inform scientists involved with culturing and testing of *Hyalella* about the potential presences of epibionts, 2) review the physical characteristics of the epibionts observed on our culture organisms, 3) describe previous efforts to eradicate or reduce epibionts infection in our cultures, and 4) summarize ongoing efforts to elucidate relationships between epibionts and *Hyalella* performance during 10 d sediment toxicity tests. This abstract does not necessarily reflect USEPA policy.

RP267 Three Years of Continued Data Collection from Three Creeks in the Upper Subwatersheds of the Strawberry River, AR, Fulton Co, USA T.R. Brueggen, Arkansas State Univ; J.L. Bouldin, Arkansas State Univ, Dept of Biological Sciences, Arkansas State Univ, Environmental Sciences Graduate Program, Environmental Sciences Graduate Program, Arkansas State Univ, Dept of Environmental Science. Agricultural activities continue to negatively influence surrounding waterways despite continual studies on the use of Best Management Practices (BMPs) to limit such impacts. A variety of BMPs studied are attempts to control soil erosion therefore limiting the harmful effects linked to excess sediment in waterways. These practices have been shown to be effective at preserving natural water quality. This four year study is focused on six collection sites, three in the upper portion of BMP implementation and three below BMP implementation, located in the upper subwatersheds of the Strawberry River, AR. Multiple BMPs including the exclusion of cattle from waterways while providing alternative water sources and use of no-till method to plant pasture grasses are being implemented. In this presentation, a summary of preliminary data collected from six months of intensive bi-weekly samples and two and half years of monthly samples will be summarized with a comparison between collection sites. Results from chemical testing include total suspended solids and nutrients including ortho-phosphates, nitrates and nitrites. Results from biological testing include *Escherichia coli*, WET testing using *Ceriodaphnia dubia* and *Pimephales promelas* and sediment testing using *Chironomus dilutus*. Significant aqueous toxicity, two lethal and two sublethal effects, was detected in four collections at a varying location each time. Significant sediment toxicity was detected in three collections with all but one site indicating either lethal or sublethal toxicity, at varying times. Additionally, two spring and two fall benthic macro-invertebrate analysis are compared. Results indicate the necessity of an array of long-term analyses to accurately assess the effectiveness of BMPS as results vary both spatially and temporally.

RP268 Total Mercury Concentrations in Mexican Specimens of Sierra and Red Snapper P. Ramirez Romero, Universidad Autonoma Metropolitana, Hidrobiologia, U.A.M. Iztapalapa, Depto. De Hidrobiologia; G. Solorzano-Ochoa, M. Ramirez-Islas, A. de la Rosa Perez, T. Ortuno-Arzate, Instituto Nacional de Ecologìa, CENICA; J.E. Padilla Torres, J.G. Trejo Ramirez, Universidad Autonoma Metropolitana, Hidrobiologia. Mercury is potentially toxic and persistent and can be accumulated and biomagnified. Aquatic ecosystems are particularly vulnerable because mercury can be deposited as Hg^{2+} bounded to particles in suspension that are accumulated as sediments in lakes, lagoons and estuaries, where mercury can be integrated in the trophic chains and end up in organisms consumed by human beings. The objective of the present work was to evaluate the concentration of total mercury in specimens of sierra and red snapper captured in six coastal Mexican towns. Fish samples were obtained in 2009 and 2010 in Ensenada, Mazatlán, and Puerto Madero, on the Pacific Coast and Tampico, Coatzacoalcos, and Puerto Progreso on the Gulf of Mexico. Lyophilized dorsal muscle was analyzed with an AA spectrophotometer; results were compared with international standards for human consumption. Red snapper (*Lutjanus campechanus*, *Lutjanus guttatus*) average Hg concentrations varied from 0.1 to 0.6 ppm with a few specimens above the Mexican quality criteria (1.0 ppm). Sierra (*Scomberomorus maculates*, *Scomberomorus sierra*) mercury concentrations were low in general, with a maximum of 0.6 ppm. The comparison of red snapper average concentrations per year showed a higher mercury concentration in 2010 in Coatzacoalcos Mazatlan and Puerto Madero and for sierra only in the last two sites. Mercury concentrations in sierra and red snapper do not represent a risk for human health in accordance with the Mexican quality criteria, however the apparent trend towards higher concentrations from one year to the next makes it necessary to continue monitoring mercury in edible fish.

RP269 Toxicity of Chemical Mixtures in Stormwater: Malathion and Benzene Toxicity to *Daphnia magna* M. Cains; W.G. Landis, Institute of Environmental Toxicology, Western Washington Univ, Western Washington Univ, Institute of Environmental Toxicology, Western Washington Univ, Institute of Environmental Tox. & Chem. Stormwater is comprised of chemical mixtures from multiple nonpoint runoff sources. The increasing urbanization of land use causes contaminants on the impervious surfaces to be carried away in stormwater and into the nearest waterway. The common landscaping and agricultural practice of over-application of pesticides leaves the excess toxicant to be washed away with the field runoff water. While there is information on individual chemical toxicity, little is known about the toxicity of chemical mixtures. In order to manage risk, it is critical to understand how contaminated stormwater can affect the reproduction and survival of non-target organisms. In this experiment, 21-day chronic *Daphnia magna* toxicity tests were conducted using >98% reagent grade benzene and analytical grade malathion. The chemicals were tested at the following concentration ranges: malathion 0.035-3.00 µg/L and benzene 450 – 28000 µg/L. A mixture of benzene and malathion was also tested to evaluate the potential additive, synergistic, or antagonistic toxicity: malathion 0.035 – 3.0 µg/L in the presence of 7000 µg/L of benzene. No synergistic effect was observed from examination of the concentration-response curves. Concentration-response curves were used in the data analysis since they provide confidence intervals and reflect the current model on toxicant-receptor interaction. The survival and reproduction rate data collected can be used to construct an age-structured population model to determine how the chemicals would change the dynamics of a *Daphnia magna* population.

RP270 Toxicity of Imidacloprid to Juvenile and Adult Ghost Shrimp: Implications for Control in Willapa Bay and Grays Harbor, Washington C. Grue, Washington Cooperative Fish and Wildlife Research Unit, Univ of Washington, School of Aquatic and Fishery Sciences, Univ of Washington, School of Aquatic & Fishery Sciences; J. Grassley, J. Frew, A. Troiano, Univ of Washington. Carbaryl has been used to control burrowing shrimp within oyster beds in Willapa Bay and Gray's Harbor, Washington for six decades. These shrimp destabilize sediments onto which young Pacific oysters are seeded. Imidacloprid (IMI) may be a viable alternative to carbaryl for controlling burrowing shrimp. Its toxicity to non-target fishes is significantly less than carbaryl. However, efficacy has varied among substrates leading to the testing of application rates up to 2.0 lbs ai/ac. Data on the toxicity of IMI to the shrimp species of concern are lacking, preventing comparisons between toxic levels and concentrations of IMI found within sediments post application, and between the sensitivity of the target species and non-target invertebrates. In the first of two tests, we exposed juvenile ghost shrimp (*Neotrypaea californiensis*) to geometrically arranged concentrations of IMI (Nuprid® 2F: 23-1,500 ppb ai) in seawater (17°+2 C, 30 ppt) encompassing the range of concentrations observed in sediments following applications to mudflats in the Bay. We used two replicates of 5 shrimp per concentration for 96 h under static conditions with a water renewal at 48 h. Impairment (immobilization) of shrimp increased with concentration and time, but mortality at the highest concentration (20%) was similar to that in controls (10%). In the second test, adult shrimp were exposed to the same concentrations (4 shrimp/replicate, 3 replicates/concentration) for 24 h; a more likely scenario given loss rates of IMI in sediment post application. Impairment of shrimp also increased with concentration and time, but none of the shrimp died. Results suggest ghost shrimp are not as sensitive to IMI as other invertebrates, and levels necessary to kill the shrimp directly may exceed concentrations in sediments associated with maximum application rates. The

potential for the observed overt "sublethal" effects to result in mortality due to other stressors needs to be investigated.

RP271 Toxicity of Pesticides to African Clawed Frog (*Xenopus laevis*) Embryos and Larvae S. Yu, M. Wages, Texas Tech Univ/TIEHH, Dept of Environmental Toxicology; G.P. Cobb, Texas Tech Univ, TIEHH, Environmental Toxicology. Amphibian declines have been reported world-wide and evidence suggests that environmental contaminants may be a contributing factor to this global phenomenon. Previous research has indicated that pesticide use related to agriculture is associated with population decline of some North American amphibians. Therefore, toxicity data are needed to assess the risk of pesticides to amphibian species, especially during the aquatic embryonic and larval stages. The African clawed frog (*Xenopus laevis*) is a standard model organism for toxicological study, and standard procedures have been developed to evaluate developmental toxicity of chemicals (FETAX test). However, *X. laevis* has been reported to be more tolerant to some contaminants compared with North American amphibians. Therefore, understanding the differential sensitivity is crucial to conduct risk assessment and conservation strategies for amphibians. The current study aimed to determine pesticide toxicity on *X. laevis* and to determine if *X. laevis* represents an appropriate model to evaluate the adverse effects of pesticides on North American species. We conducted 96 h acute toxicity tests with three commonly used pesticides, malathion, endosulfan, and α-cypermethrin on *X. laevis* embryos and larvae. The acute median lethal concentrations (LC50s) were determined as well as malformation and growth. Malathion and endosulfan acute LC50s were estimated to be 4.5 mg/L and 1.4 mg/L, respectively, for embryos. For larvae, LC50s of all three pesticides were 5.4 µg/L for α-cypermethrin, 0.3 mg/L for endosulfan, and 5.9 mg/L for malathion. Malathion caused tail flexure, abnormal gut coiling, and edema in embryos and larvae, while endosulfan primarily produced tail flexure and edema. Similarly, tail flexture and edema were common in embryos and larvae exposed to α-cypermethrin. Pesticide toxicity to *X. laevis* determined in the current study was compared with those reported for other amphibian species. In general, *X. laevis* is less sensitive to malathion and endosulfan than North American amphibians. It is unclear if *X. laevis* is also more tolerant to α-cypermethrin because toxicological data for α-cypermethrin are scarce.

RP272 Toxicity of Two Herbicides to Two Life Stages of Bull Trout and Rainbow Trout H.J. Puglis, USGS, Columbia Environmental Research Center; R.D. Calfee, USGS, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center; E.E. Little, E.L. Beahan, USGS, Columbia Environmental Research Center. Eurasian water milfoil (*Myriophyllum spicatum*) is a highly invasive aquatic plant that has spread throughout aquatic habitats in the United States including western habitats of bull trout (*Salvelinas confluentus*). Bull trout populations are declining and the bull trout was listed as a threatened species by the US Fish and Wildlife Service in 1998. Aquatic herbicides are being considered as a method to eradicate water milfoil; therefore, it is particularly important to understand the sensitivity of bull trout to herbicides that might potentially be applied to control milfoil in their habitats. The toxicity of the herbicides Weedar® 64 (2,4-D) and Renovate® 3 (triclopyr) to bull trout were determined in 96-hour static acute exposures conducted at two stages of juvenile development. Preliminary studies have shown that 2,4-D and triclopyr LC50s are well above the maximum recommended application rates of both herbicides, indicating that bull trout are fairly tolerant. Similar studies were conducted with rainbow trout (*Oncorhynchus mykiss*), a potential surrogate species. Data from these studies will assist local, state and federal agencies protect the threatened bull trout, while eradicating water milfoil.

RP273 Transfer of Mercury Across Ecosystem Boundaries in Arid Streams A.A. Abuzeineh, J.R. Troy, Texas State Univ – San Marcos, Dept of Biology; M.M. Chumchal, Texas Christian Univ, Biology Dept; M.C. Green, Texas State Univ – San Marcos, Dept of Biology; W.H. Nowlin, Texas State Univ – San Marcos, Assistant Professor. Mercury (Hg) is a toxic element with no known biological function found in environments around the world. Through our activities, humans have greatly altered the global Hg cycle and subsequently released large amounts of Hg to the environment. Currently, it is estimated that 2/3 of the Hg cycling in the biosphere is anthropogenically derived. The bioaccumulation and transfer of Hg within food webs has largely been examined in aquatic ecosystems; however, ecotoxicologists and environmental scientists have recently focused on the movement of contaminants across ecosystem boundaries. The input of Hg into aquatic systems occurs largely through atmospheric deposition of inorganic Hg, but the movement of aquatically-derived Hg to terrestrial environments is likely biologically mediated via the movement of organisms crossing ecosystems boundaries (e.g., movement of organisms from aquatic to terrestrial environments). In this study, we assessed the importance of Hg transport from lotic ecosystems via aquatic insect emergences to terrestrial consumers. We examined the Hg concentration in in-stream food web components (fishes and aquatic invertebrates) and in terrestrial consumers which forage in riparian zones, such as bats, birds and spiders. The study sites included two "High Hg" stream ecosystems which have known geological Hg and a past history of Hg mining in the watersheds, and one "Low Hg" stream with little geological Hg and no Hg mining in its watershed. Fishes and aquatic invertebrates at the "High Hg" sites generally exhibited higher Hg concentrations than at the "Low Hg" site. We found significantly higher Hg concentrations in feathers of both resident and migrant birds at the "High Hg" sites. However, we did not detect significant differences in Hg concentrations in insectivorous bats and terrestrial invertebrates among the "High" and "Low" sites. This study supports a growing body of evidence demonstrating the role that aquatic organisms play in movement of toxicants to terrestrial ecosystems.

RP274 Trenbolone Acetate Metabolites May Promote Ovarian Growth in Adult Medaka K.L. Forsgren, Univ of California, Riverside, Dept of Environmental Sciences; S. Qu, D.M. Cwiertny, Univ of California, Riverside, Dept of Chemical and Environmental Engineering; D. Schlenk, Univ of California, Riverside, Dept of Environmental Sciences. Trenbolone acetate, a synthetic androgen, has been used as a growth promoter in beef cattle in the US since 1987. Three biological metabolites are detected in the manure of implanted cattle: 17a-trenbolone, 17b-trenbolone and trendione. 17a-trenbolone is excreted in higher amounts however is a less potent androgen receptor agonist than 17b-trenbolone or trendione. These metabolites have been detected in surface water associated with cattle feedlots. While several studies have investigated the masculinization effects of 17b-trenbolone, few have focused on the reproductive impacts in mature female teleosts. In the current study, adult female medaka (*Oryzias latipes*) were exposed to low (10 ng/L) and high (1000 ng/L) concentrations of 17a-trenbolone, 17b-trenbolone and trendione for 14 days (N = 3). Histological examination revealed that all treatments resulted in a lower percentage of primary ovarian follicles and a higher percentage of maturing follicles compared to control fish. Additionally, after 7 days of exposure, females exposed to 17b-trenbolone and trendione began laying eggs and continued to lay eggs daily throughout the remainder of the experiment. Whole body 11-ketotestosterone (pg/mg) did not differ significantly among treatments, whereas 17a-trenbolone (low and high) and the high dose of 17b-trenbolone significantly increased 17b-estradiol (pg/mg). In contrast, high dose treatment of trendione significantly decreased whole body 17b-estradiol (pg/mg). In vitro vitellogenin mRNA analysis using rainbow trout hepatocytes incubated with each metabolite was used to determine the estrogenicity of the three compounds. 17a-trenbolone (1000 ng/L) was equivalent to 0.25 ng/L estradiol (EEQ) whereas trendione (1000 ng/L) was 3 ng/L EEQ. Future studies will focus on elucidating the underlying mechanism(s) and pathway(s) of the reproductive and endocrine impairment caused by 17a-trenbolone, 17b-trenbolone and trendione.

RP275 Triclosan Exposure to Bacteria Leads to Chlorine Tolerant Strains in Environmental Water Samples J. Roling, S. Blackmon, Bridgewater State Univ, Biological Sciences. Triclosan is an antimicrobial agent added to a variety of medical and consumer care products such as soaps, deodorants, and cleaning supplies. These chemicals are then discharged into rivers, exposing native bacteria to triclosan. Bacterial exposure to triclosan could lead to chlorine resistance. Since chlorination is the standard method used to disinfect drinking water, municipal water sources may not be sterilized from native bacteria. Water samples were obtained downstream a wastewater treatment plant (WWTP) in Bridgewater, MA and reference virgin stream (VS) in Monroe, MA. Bacteria strains were isolated from water samples, exposed to triclosan (0.001 or 0.05mg/mL), and then exposed to chlorine (0.05mg/mL). 33% (112/336) of bacterial strains increased chlorine resistance after one triclosan exposure. 52% (87/168) of the WWTP bacteria strains increased chlorine resistance while only 15% (26/168) of the VS bacteria strains increased chlorine resistance. Although triclosan did increase chlorine tolerance, the triclosan concentration didn't influence the percentage of strains that gained chlorine resistance (38% and 35%

increase). Currently, agar plate assays are being conducted to verify these results.

RP277 Use of Digital Photography as an Objective Aid in Mysid Shrimp Chronic Toxicity Tests M. Foster; S. Garcia, Univ of North Texas, Biology; W.B. Steele, Univ of North Texas, Environmental Science; D.B. Huggett, Univ of North Texas, Dept of Biological Sciences. *Americamysis bahia* (mysid shrimp) are common saltwater toxicity test organisms. Currently, acute and chronic standard testing protocols for mysids are available, with a multi-generational protocol in development. Standard testing protocols require the counting and sexing of the organisms at multiple points throughout the duration of the experiments. Traditionally, the counting and sexing is performed with the naked eye by trained personnel, while the organisms are swimming inside water-filled containment chambers. With the aid of digital photography, accurate mysid counts can be made in a reduced time period when compared to the standard procedure. In our laboratory, organisms are counted and sexed using high resolution pictures taken from a nine megapixel standard digital camera mounted on a metal stand. The primary advantage of using digital photography for biological observations during toxicity tests is that the digital images reduce the lengthy one-on-one training required to quickly and accurately sex and count the organisms. Because digital photographs can be projected onto a larger TV screen or monitor, multiple trainees can be taught simultaneously, thus reducing the amount of time and money spent on training staff. Additionally, digital photography provides an empirical record of protocol identification number(s) that correspond to every test chamber in studies. These photos could be referred to for quality control assurance as well as provide permanent, objective evidence for GLP studies. The use of digital photography has important implications in aquatic invertebrate toxicity testing as this method may enhance the speed and accuracy of biological observations, reduce personnel training time, and improve quality control, all while providing a digital record of every experimental organism used in mysid studies.

RP278 Use of Gene Expression in Longear Sunfish (*Lepomis megalotis*) and Green Sunfish (*Lepomis cyanellus*) as a Biomarker of Pollutant Exposure B.F. Brammell, Asbury Univ, Natural Sciences Dept; D.K. Peyton, K.R. Barnett, J.C. Ferrell, Morehead State Univ, Dept of Biology and Chemistry; A.J. Wigginton, Univ of Kentucky, Dept of Civil Engineering. Biomarkers are effective monitoring tools, allowing researchers to assess physiological responses to pollution thereby contributing to both pollutant detection and an understanding of the biological significance of contamination. We obtained partial sequences of three biomarker genes in both longear sunfish (*Lepomis megalottis*) and green sunfish (*Lepomis cyanellus*), two widely distributed sunfish species. Partial sequences of metallothionien and uridine 5'-diphospho-glucuronosyltransferase for both species and cytochrome P4501A1 for green sunfish have been submitted to Gen Bank. Expression of these genes will be examined using real-time PCR in sunfish collected from contaminated and reference sites of streams surrounding the Paducah Gaseous Diffusion Plant (PGDP) in western Kentucky. The streams surrounding the PGDP that are the focus of this study have a long and well documented history of contamination by both organic and inorganic contaminants. Sediment PCB concentrations in contaminated sites at the time of fish collection were between 10.09 and 14.29 µg/Kg while PCB concentrations as high as of 0.473 µg/g total PCBs were observed in fish tissue. Aqueous copper concentrations in contaminated sites at the time of fish collection were as high as 9.18 µg Cu/L, a level consistent with the induction of the metal sensitive protein metallothionien in similar studies. Gene expression analysis is in progress and will provide valuable information linking contaminant levels to biomarker response.

RP279 Use of the Comet Assay for the Monitoring of Biological Effects of Petroleum Products in the Gulf of Mexico M. Guzman Martinez, Universidad Autonoma Metropolitana, Dept of Hidrobiologia; P. Ramirez Romero, Universidad Autonoma Metropolitana, Hidrobiologia, U.A.M. Iztapalapa, Depto. De Hidrobiologia; L. Elizalde Ramirez, L. Espejel Pina, J.E. Padilla Torres, J.G. Espejel Trejo, Universidad Autonoma Metropolitana, Hidrobiologia; A.D. Nava Montes, Instituto Nacional de Ecologìa, CENICA. Monitoring is an important tool in environmental management; it allows the evaluation of temporal and spatial tendencies of the environmental quality. Biomarkers can be used as tools for the evaluation of exposure and effects in aquatic ecosystems after an oil spill. The single cell electrophoresis method or comet assay evaluates damage to DNA. The objective of this study was to establish a base line of DNA damage in oysters collected in the Gulf of Mexico, an area with high risk of being exposed to oil products. The oyster *Crassostrea virginica* was selected as sentinel organism. Specimens were sampled in Laguna de Terminos, which is located in the Campeche sound where the largest oil field in Mexico is located, and in Alvarado Lagoon where petroleum pollution has been reported in the past. Thirty organisms were collected at each site and brought to the laboratory in an ice box to keep them alive. DNA damage was evaluated using the comet assay technique; images were analyzed using the software Cromagen. The average length of the tails was determined and in this first sampling none or very low damage was determined (1-20 µm), which indicated that the area where the oysters banks are located have an good environmental quality at least during the dry season, when the sampling took place. The next step in this research will be to evaluate this biomarker during the rainy season when pollutants are carried to the sea through this lagoon system.

RP280 UV Filters Endocrine Disruption and Neurotoxicity on the Tropical Damselfish *Abudefduf saxatilis* M. Soto, Roger Williams Univ, Marine Biology, UNAM, Instituto de Ciencias del Mar y Limnologia; G. Rodriguez Fuentes, Centro para el Estudio del Agua, Unidad de Ciencias del Agua-CICY. Oxybenzone, Octysalate and Octynoxate are compounds used in a variety of products as a protection against the UV radiation exposure. Concerns have emerged regarding their environmental safety. Previous studies have shown that they tend to bioaccumulate and act as potential xenoestrogens in aquatic organisms. Until now, nobody has investigated their impact on tropical reef associated species. Reef environments like the Mesoamerican Barrier Reef System are particularly sensitive to the introduction of novel contaminants. This study investigates the estrogenic effect of these three compounds on the abundant reef associated damselfish sergeant major *Abudefduf saxatilis*. Estrogenicity was evaluated using gene expression and protein synthesis analyses to monitor the induction of vitellogenin (VTG) in juvenile fish (< 5cm). Fish were exposed to doses of 5, 25 and 50µg/g of oxybenzone, octysalate, octynoxate and to a mixture in a similar proportion to the one used in personal care products. Since neurotoxicity was observed during a preliminary bioassay, head cholinesterase activity (ChE) was also analyzed. As no genomic information on *A. saxatilis* was available, a first step of the work has been to isolate and sequence VTG, 18S and βactin genes. Although no clear expression of VTG gene was observed by qRT-PCR, all treatments induced the synthesis of the protein measured as Alkali Labile Phosphate (ALP) at levels similar to the positive control 17β-estradiol (E_2) and xenoestrogens reported in other studies ranging between 5 and 10µg/ml. Interestingly, all treatments showed significant cholinesterase inhibition, the mixture showing the major neurotoxic impact with 48,8 ±3,5% inhibition compared to the negative control. E_2 at a dose of 5µg/g, which is often used as positive control for estrogenic effect studies, also produced a cholinesterase inhibition of 54,5 ±3,6 %. Changes in ChE activity by UV filters and E_2 may be linked to the production of reactive oxygen species (ROS), leading to oxidative stress. Further studies are conducted to evaluate the transcriptional pathway for VTG synthesis in *A. saxatilis.* This research shows that oxybenzone, octysalate, octynoxate and their mixture have estrogenic effects on juvenile sergeant major. In addition, we also have demonstrated neurotoxicity. Focus on the estrogenic effect of these compounds may have led to underestimate other ecotoxicological impacts.

RP281 UV Tolerance of High Elevation Copepods of the Colorado Rocky Mountains K. Hudelson, Univ of North Texas, graduate student; B. Barst, Univ of Quebec INRS, Eau Terre Environnement; J. Smith, A. Roberts, Univ of North Texas. Copepods in high elevation lakes and ponds in Colorado are exposed to significant levels of ultraviolet radiation (UV), necessitating development of UV avoidance behavior and photoprotective physiological adaptations. The copepods are brightly pigmented due to accumulation of astaxanthin, a carotenoid which has photoprotective and antioxidant properties. Astaxanthin interacts with a crustacyanin-like protein, shifting the absorbance from 473 nm (hydrophobic free form, appears red) to 632 nm (protein-bound complex, appears blue). In six sites in Colorado, habitat specific coloration patterns related to carotenoprotein complex have been observed. The objective of this study was to determine whether pigment accumulation or carotenoprotein expression has a greater effect on resistance to UV exposure. For each site, copepod tolerance to UV was assessed by survivorship during UV exposure trials. Control organisms were exposed only to the visible spectrum (shielded from UV). Average UV exposure was determined for each habitat. Astaxanthin profiles were generated

for copepods in each site. Ability to withstand UV exposure during exposure trials was significantly different between color morphs ($p < 0.0001$). Red copepods were found to tolerate 2-fold greater levels of UVB than blue or mixed copepods. Additionally, red copepods have much higher levels of total astaxanthin than blue or mixed copepods ($p < 0.0001$). and receive a higher daily UV dose ($p < 0.0003$). Carotenoprotein expression may be an important adaptation to changing UV conditions and may serve as an indicator of increasing UV exposure in high elevation lentic ecosystems.

RP282 Global Guidance Principles for LCA Databases B. Vigon, SETAC; G. Sonnemann, United Nations Environment Programme. In early 2011 participants from 23 countries gathered in Japan for a Pellston workshop to develop global guidance on principles to create, manage, and disseminate datasets for the purpose of supporting life cycle assessments of products and services. The vision for the workshop was to create guidance that would: 1) serve as the basis for improved dataset exchangeability and interlinkages of databases worldwide, 2) increase the credibility of existing LCA data, the generation of more data, and enhance overall data accessibility, and 3) complement other data-related initiatives at the national or regional level, particularly those in developing countries and where more prescriptive guidance has been developed. In addition to providing guidance on technical and operational aspects of datasets and databases, it was discovered that there remain differences in terminology usage and inconsistencies in principles definitions. Part of this situation is caused by the evolution of LCA in different regions/cultures, part by language and part by ambiguity in existing definitions. Thus, one exercise was to develop a terminology glossary and dictionary of principles to provide a basis of reference for participants. Much time and effort was spent assessing the current state-of-practice regarding developing datasets, incorporating them into databases, and then managing those databases. From an operational standpoint, recognition that the target audience of the document is database managers serves to position them as central actors in the data supply chain. Data documentation and review are key elements. Database managers have the role and responsibility to decide not only what the datasets themselves must include but also what additional information is required and what would be recommended or necessary in terms of validation and review. Some workshop participants identified a need for additional data and data management to allow LCA databases to provide more comprehensive answers and to answer more comprehensive questions, such as spatially differentiated models, time-based methods, and issues related to social and economic impacts. Another aspect addressed was the filling of data gaps with data estimations from non-process based approaches. Lastly, one group developed future scenarios on how data and databases could work in concert with the growth of LCA globally and anticipating advances in information technology in the next several years.

RP283 Environmental Assessment of an Integrated Greenhouse Tomato Crop Grown Under Northern Conditions M. Dorais, Agriculture and Agri-Food Canada, Sustainable Production Systems; A. Anton, J. Montero, M. Torrellas, IRTA Carretera de Cabrils. The environmental burdens associated with fossil energy use, in addition to water and fertilization management continue to be major concerns for Northern greenhouse production systems. To reduce the environmental impacts of greenhouse farming under Northern climate conditions and to maintain its competitiveness, the use of renewable energy sources and suitable nutrient and waste management are becoming essential. From this perspective, a closed-loop organic production system that increases the efficiency of water and nutrient use on-farms and utilization of waste biomass was developed and tested in the province of Quebec, Canada. The goal of this study was to assess the environmental impacts of this integrated system compared to a conventional system in order to use its environmental profile as a starting point for improving the sustainability of existing systems. The environmental analysis was conducted with LCA methodology as defined by the ILCD handbook (2010) and the SimaPro v.7.3 software. The functional unit was 1000 kg of tomatoes. The system boundary was from raw materials extraction to the farm gate. The life cycle stages considered were the infrastructure, auxiliary equipment, climate control system, farm operation, fertilizers, pesticides, waste management and packaging. Results from the environmental assessment indicate that high energy demand had the major contributions to all impact categories when fossil energy is used. When biomass was used as renewable energy, biomass transport became the most important environmental impact factor. Increasing the truck capacity as well as reducing the distance from the farm to the biomass source reduced environmental burdens related to energy. Greenhouse structure made the second highest contributions to environmental impact categories. For the organic crop scenario, fertilizers and biopesticides had a negligible impact. Results are discussed in terms of potential alternatives towards zero emission and to reach energy neutral for a Northern greenhouse production system.

RP284 ISO- and Ecologically-based Life Cycle Assessments of Palm Oil Biodiesel Y. Manik, Univ of Maine, Research Group of Industrial Ecology, LCA and System Sustainability (IELCASS); A. Halog, Univ of Maine, Research Group of Industrial Ecology, LCA and System Sustainability (IELCASS), Univ of Maine, Assistant Professor of Industrial Ecology and LCA. In order to assess the sustainability of biodiesel derived from palm oil (*Elaeis guineensis*), two different but complementary life cycle assessments (LCA) have been performed: The attributional LCA based on ISO-14040 standard and the Ecologically-based LCA (Eco-LCA) based on the methodology recently developed in Ohio State Univ. The attributional LCA is a *cradle-to-grave* study seeking to investigate the environmental impacts of palm oil biodiesel life cycle from land preparation for oil palm plantation to biodiesel utilization in passenger cars. The results show that palm oil biodiesel has significant life cycle impacts in global warming and eco-toxicity potentials. The conversion of forest land and methane emission from anaerobic digestion of palm oil mill effluent and energy use in various processes are the most significant processes contributing to global warming potential. The use of herbicides and pesticides in plantation that emits glyphosate and cyphermeterin to the air and agricultural soil significantly contribute to ecotoxicity potential. An Eco-LCA study was performed in order to extend the comprehensiveness of the sustainability assessment taking into account goods and services from ecosystem. The aggregation of ecological inputs were classified based on mass, energy and industrial cumulative exergy (I exergy). The results show the reliance of palm oil biodiesel to the natural capital provided by the ecosystem, including solar energy, carbon dioxide from atmosphere, detrital matter from biosphere, water from hydrosphere, as well as fossil fuels and various form of mineral from lithosphere which are not shown yet in the attributional ISO-LCA.

RP285 Modeling the Development of Greenhouse Gas Effects on Eco-industrial System Through Life Cycle Approach for the Pulp and Paper Industry in Maine N. Bichraoui, Univ of Maine, School of Forest ressources, Univ of Maine, School of Forest Resources; A. Halog, Univ of Maine. This research aims to pursue the vision of future closed loop industrial ecosystems and to develop dynamic scenarios on how to achieve this vision technologically. The method will include a holistic approach to assess the development of low carbon emissions and low water consumption within an industrial network. The research will focus on pulp and paper industry in the state of Maine. Just like other industries, the pulp and paper industry has come under increasing scrutiny for its potential environmental impacts. More than many other industries, however, this industry plays an important role in sustainable development because its chief raw material – wood fiber – is renewable. The industry provides an example on how a resource can be managed to provide a sustainable supply to meet society's current and future product needs. in 2001 Maine was the second largest manufacturer in the US as measured by volume, with roughly 4.5 billion tons in production. In the Northeast Maine is clearly the dominant paper producer.[1]This study is intended as reveal alternative processes to improve production and consumption process with lower environmental impacts. The life cycle assessment method is therefore appropriate because it allows the performance of a holistic analysis of pulp production that takes into account the extraction and processing of raw materials, the manufacturing processes, transport, use, reuse and, finally, recycling and disposal at the end of life. The intended audience consists of this study are forest product professionals along with LCA practionners interested industry and in getting valuable insights in environmental burden for this specific industry. The modeling tools of system dynamics, materials flow analysis and agent-based modeling will be further used in order to capture the complexity of the system and explore the future scenarios of this industrial ecosystem with respect to the human dimension and its impact on normal events such as new actors emerging, takeovers and the introduction of innovative (and sustainable) technologies and policies

RP286 Comparison of the Effects of Carbon Nanotube and Asbestos Exposure on the Immune System of Fathead Minnows K.B. Donohue,

J.G. Laird, D.R. Johnson, J.K. Stanley, J.A. Steevens, US Army Engineer Research and Development Center, Environmental Laboratory; A. Edgington, S.J. Klaine, Clemson Univ, College of Agriculture, Forestry and Life Sciences. Carbon nanotubes (CNT) are widely used in various military, commercial and public sectors; e.g., electronics, aerospace, computer industries, consumer products (sunscreens and cosmetics) and medicine. The unique nano structure of CNT is based on a graphene cylinder, typically a few nanometers in diameter, which can range in length from micrometers to millimeters. Single-walled carbon nanotubes (SWNT) consist of one such cylinder while multi-walled carbon nanotubes (MWNT) consist of 2-50 such concentrically stacked cylinders with a long common axis resulting in fiber-like characteristics in terms of their elongated shape, dimensions and high aspect ratio (ratio of length and width). The needle-like fiber shape of CNT has been compared to that of asbestos, raising concerns about potential toxicity. The objective was to compare the immunological effects of CNT exposure to that of asbestos exposure in *Pimephales promelas*, commonly known as fathead minnows (FHM). FHM were exposed to 0.125mg/L, 0.25mg/L, or 0.5mg/L CNT (MWNT and SWNT) or asbestos (crocidolite and chrysotile for MWNT and SWNT, respectively) in water that was renewed daily. At days 0, 7, and 14, FHM were sacrificed and mucus swabs, blood, and anterior kidneys were collected. Plasma serum was separated from blood cells and used in ELISA assays. Lymphocytes were purified from both blood cells and anterior kidneys by density gradient centrifugation. Lymphocytes were then probed for phagocytic activity using a phagocytosis assay kit. Inflammasome activation was measured by ELISA for IL-1β, one of the first cytokines processed by the inflammasome. Antibody production was measured by ELISA for IgM. Exposure to CNT resulted in decreases in phagocytic activity, mucus antibody production and plasma serum antibody production compared to untreated controls. Asbestos exposure also decreased mucus antibody production but not plasma serum antibody production. Curiously, exposure to chrysotile asbestos resulted in a decrease in induced phagocytosis but not in un-induced phagocytosis at day 14. Inflammasome activation, as measured by IL-1β ELISA, was mostly undetectable; likely indicating that IL-1β processing occurs prior to day 7. Together, these data suggest that like asbestos exposure, exposure to CNT results in an immune response. However, the data demonstrate that further characterization of the systemic immune response to CNT is needed to assess the severity and toxicological impact of CNT.

RP287 Determination of Nanosilver Dissolution Kinetics in an Aqueous Medium A. Harmon, US Army Engineer Research and Develoment Center, Environmental Laboratory; A.J. Kennedy, A. Poda, US Army Engineer Research and Development Center; A.J. Bednar, US Army Engineer Reseach and Development Center; B.D. Meeks, Badger Technical Services. Over the past few years there has been an increase in the manufacturing of nanomaterials. This increase in production of nanomaterials increases the potential for nanomaterials to be released into the environment. There are many unanswered questions regarding the fate of nanoparticles once they enter into the environment and the effect they may have on biological systems. The objective of this research is to determine the rate at which nanosilver will dissolve in environmentally relevant waters. The results from this research will lay the groundwork for fundamental interaction studies that will be performed to parameterize nanoparticle behaviors. Dissolution is a critical process that determines nanosilver effects in the environment and within organisms. Diluted suspensions of nanoparticles with moderately-hard reconstituted water (MHRW) were created from stock solutions in milli-Q water and placed on a shaker table for 0, 0.25, 1, 2, 7, and 14 days. Dilutions of 10% and 50% MHRW were used as the medium. Upon removal from the shaker table total silver measurements and dissolved silver measurements (ultra centrifugation, followed by ICP-MS analysis) were taken. Dynamic Light Scattering (DLS) and Field Flow Fractionation (FFF) were used to determine particle size at each time points by measuring the relative change in particle size over time. Nanocompsix NC80 biopure nanosilver was used in this experiment. In concentrations of 10% and 50% MHRW nanoparticles increased in particle size as time increased. In 10% MHRW particle size ranged from 82.7-91.3 and 91.6-167.7 in 50% MHRW. In days 0-2 there is more total silver than dissolved silver in samples. In days seven and fourteen there is more dissolved silver than total silver possibly due to the crashing out of particles. This research suggests that initially the concentration of dissolved silver will increase once in environmentally relevant media, but the longer term equilibrium between the nanoparticle and dissolved fractions and associated biological effects remains poorly understood and further research is needed.

RP288 In Vitro and In Vivo Effects of Single-walled Carbon Nanotubes Functionalized with Single Strand DNA Over Redox Balance T. Mocan, A. Muresan, A. Filip, Univ of Medicine and Pharmacy, Cluj-Napoca, Romania, Physiology Dept; A. Biris, National Institute of Molecular and Isotopic Technologies, Cluj-Napoca, Romania, Hidrogen Dept; S. Simon, National Institute of Molecular and Isotopic Technologies, Cluj-Napoca, Romania, Hydrogen Dept; D. Daicoviciu, Univ of Medicine and Pharmacy, Cluj-Napoca, Romania, Physiology Dept; N. Decea, Univ of Medicine and Pharmacy, Cluj-Napoca, Romania, Clinicilor 1; R. Moldovan, Univ of Medicine and Pharmacy, Cluj-Napoca, Romania, Physiology Dept; F. Tabaran, Univ of Agricultural Sciences and Veterinary Medicine, Cluj-Napoca, Romania, Morphopathology Dept; A. Stir, Institute of Gastroenterology and Haepatology, Cluj-Napoca, Romania, Clinicilor 1; L. Mocan, Institute of Gastroenterology and Haepatology, Cluj-Napoca, Romania, Nanomedicine Dept; C. Catoi, Univ of Agricultural Sciences and Veterinary Medicine, Cluj-Napoca, Romania, Morphopathology Dept; S. Clichici, Univ of Medicine and Pharmacy, Cluj-Napoca, Romania, Physiology Dept. Single wall carbon nanotubes (SWCNT) represent a material of high medical interest. Recent in vitro studies showed increased oxygen free radical production after cells exposure to SWCNT. However, reports regarding in vivo effects of SWCNT over redox balance as well as concentration effect over in vitro and in *vitro* SWCNT toxicity are still scarce. Our aim was to evaluate the in vitro and in vivo induced by SWCNT functionalized with single strand DNA(ssDNA- SWCNT) solutions. Material and methods: ss-DNA-SWCNT water solution was obtained through sonication. In vitro experiments were carried out on Hep G2 cell line. 5, 10 and 20 mg/L concentrated solutions were prepared. MTT assay and 5-(and-6)-carboxy-2',7'-dichlorofluorescein diacetate (DCFDA) assay were performed. In vivo experiments were carried out on male Wistar rats (170±10g), i.p. injected with 1.5 ml single walled ss-DNA-SWCNT solutions of different concentrations (70g/l, 250 g/l, 390 g/l). Both acute exposure(1 ip. injection of 1.5 ml solution) and repetitive exposure models were designed. Controls were similarly i.p injected with 1.5ml serum. Malondialdehyde (MDA), carbonylated proteins (PC), hydrogen donor ability (HD), sulfhydryl groups (SH) were assessed in blood at 3, 6, 24 and respectively 48 hours after the SWCNT administration. Results: We obtained a significant in vitro and in vivo alterations of oxidative balance peaking at 24 hours from administration. ($p < 0.05$). Results show significant dependence of observed effects on concentration. At 48 hours from exposure, levels of the analyzed markers remained altered. Repetitive exposure induces enhances oxidative stress. However, effect in not correlated with the number of repetitive administrations. Conclusion: Our results support the ability of ss-DNA-SWCNT to generate oxidative stress, the pattern of alterations depending on the concentration of SWCNT solutions. Present work was supported by Romanian National Research Council Grant NANOCITOX 42112/2008.

RP289 Is the Size the Most Decisive Factor in Nanotoxicity of TiO_2 Nanoparticles in Fish? O. Zapata-Perez, Cinvestav Unidad Merida, Secretaria Academica. Recently there has been a concern for small particles in the nano scale and their potential effects in the aquatic environment. Nanomaterials have been increasingly used in industrial production and daily life products. The study of the toxicological aspect of nanoparticles has taken strong interest among scientists around the world. One of the concerns in the nanotoxicological world is the characterization of the nanoparticles; in the present study we synthesize the nanoparticle with the size that we required (7 nm, 14 nm y 21 nm). There are huge gaps associated to the knowledge regarding the toxicity of these new nanoparticles in fish. The challenge for toxicological studies including this one is to identify key points and the possible effects of these nanoparticles, leading to propose experiments to better predict the toxicity and behavior of this and other particles in aquatic and tropical environments. In the present study, nano-TiO_2 was selected as the most representative nanomaterial and thus we evaluated the gene expression related to oxidative stress analyzing Catalase, Super Oxide Dismutase and Glutathione-S-Transferase, in juvenile male tilapias (*Oreochromis niloticus*). We exposed fish to 1.0 mg/L solution with different sizes of TiO_2 nanoparticles. Later on, fish were sacrificed at 3, 6, 12 and 24 h after treatment, and liver were excised. Total RNA from liver was extracted using the Trizol method and cDNA synthesis was performed using oligo-dT anchorage primers. Reactions were analyzed using Taqman probes for each

gene and gene expression was determined using a Real Time Polymerase Chain Reaction. Our results show significant differences among nanoparticle sizes, suggesting that size is a decisive factor regarding organism toxicity, since the smaller nanoparticles showed a higher gene expression.

RP290 Oxidative Stress Signaling Pathways Involved in Toxicity of Silver Nanoparticles and Titanium Dioxide Nanoparticles in the Soil Nematode *Caenohabditis elegans* H. Eom, S. Park, J. Ahn, D. Lim, P.G. Nair, Y. Chung, Univ of Seoul; J. Yi, Seoul National Univ; J. Choi, Univ of Seoul, School of Environmental Engineering. Oxidative stress has often been reported as one of the most important toxicity mechanism related to nanoparticles (NP) exposure, however, most of the studies have been conducted in mammalian models. In the present study, toxicity of silver nanoparticles (AgNP) and titanium dioxide nanoparticles (TiO_2NP) was investigated in the soil nematode, *Caenorhabditis elegans*, focusing on the involvement of signaling pathways related to oxidative stress. LC50s of AgNPs and TiO_2NPs were first estimated and worms were subsequently exposed to sublethal concentrations of both NPs for global gene expression analysis using microarray. Microarray results suggest oxidative stress as an underlying mechanism of NPs in *C. elegans*. Reactive oxygen species (ROS) formation was then tested as a direct evidence of oxidative stress in NPs exposed *C. elegans*. The upstream signaling pathway activated in response to NPs exposure was investigated, paying special attention to the *C. elegans* PMK-1 P38 mitogen-activated protein kinase (MAPK) pathway. The expressions of the downstream genes and transcription factors, known to be regulated by the PMK-1 P38 MAPK was also investigated in *wildtype (N2)* and *pmk-1* loss-of-function mutant (*km25*) *C. elegans* exposed to AgNPs and TiO_2NP. The overall results indicated that AgNPs and TiO_2NPs exposure lead to increased ROS formation, PMK-1, GST activations and reproduction failure in *wildtype (N2) C. elegans*; whereas, none of these phenomena were observed in the *pmk-1 (km25)* mutant. These results suggest that oxidative stress is an important mechanism of AgNPs and TiO_2NP induced toxicity in *C. elegans*, and PMK-1 P38 MAPK plays an important role in it.

RP291 Particle Size and Coatings of Nano Silver in Relation to Bioavailability and Particle Compartmentalization Within *Lumbriculus variegatus* J.G. Coleman, US Army Engineer Reseach and Development Center, US Research and Development Center, Research Biologist; A.J. Kennedy, US Army Engineer Research and Development Center; J. Williams; J.D. Laird, Us Army Engineer Research & Development Center, SpecPro Incorporated, US Army Engineer Research & Development Center, Environmental Laboratory; A.J. Bednar, US Army Engineer Reseach and Development Center; A. Harmon, US Army Engineer Research and Develoment Center, Environmental Laboratory; J.A. Steevens, US Army Engineer Research & Development Center, Waterways Experiment Station. As the production and applications of nano silver increase, it is essential to characterize fate, transport, and effects in environmental systems. Our objective was assess the fate of nano silver in aquatic environments and determine particle transport, location, and bioaccumulation in the freshwater oligochaete, *Lumbriculus variegatus*. To assess aquatic fate, we performed a series of dynamic light scattering (DLS) measurements on various particle suspensions. Suspensions were created in serial dilutions of freshwater media in a range of electrical conductivities (0-280 µS/cm) to assess aggregation potential. Suspensions included 30, 1500 nm particles and a 20-30 nm polyvinylpyrrolidone (PVP) coated silver. Aggregation in 30 and 1500 nm silver increased with conductivity; however, aggregation was minimal for PVP coated silver. *L. variegatus* were exposed to nano-silver or silver nitrate (AgNO3) spiked into sediment (nominally 100 mg/L, n=3) to assess uptake and fate within biological compartments (i.e., particle location in gut wall or tissue). Time points included 2, 4, 7, 14, and 28 days in which *L. variegates* were removed for body burden analysis and hyperspectral imagining. Additionally, *L. variegatus* were depurated for 6, 8, and 24 hours to determine time needed for gut-clearance time of nano-silver. Image analysis of *L. variegatus* cross-sections utilizing Cytoviva® hyperspectral microscopy detected PVP particles within sections. Bioaccumulation data from field flow fractionation and ICP-MS indicated an increasing trend in uptake; further, analyses indicated nano-silver in the organism was in particle form. While body burdens of nano-silver were higher in 1500 nm relative to 30 nm treatments early in the exposure, body burdens for 30 nm particles were higher relative to 1500 nm after 28-days exposures (4.57 and 3.35 mg/kg, respectively). The present study provides information on the potential for nano particle size/coatings to affect distribution within environmentally relevant waters and provides information on particle transport across biological membranes.

RP292 Silver Nanoparticle Toxicity is Associated with Oxidative Dissolution and Strongly Mitigated by Natural Organic Matter X. Yang, Duke Univ, PHD student; J.N. Meyer, Duke Univ, Nicholas School of the Environment ; H.H. Kim, Duke Univ, Civil & Environmental Engineering; A. Gondikas, Duke Univ, Pratt School of Engineering. The rapidly increasing application of silver nanoparticles (Ag NPs) in consumer products and medical applications has raised both ecological and human health concerns. A key question for addressing these concerns is whether Ag NP toxicity is mechanistically unique to nanoparticulate silver, or if it is a result of the release of silver ions. Using *Caenorhabditis elegans*, we have tested a series of differentially coated Ag NPs and found a linear correlation between Ag NP toxicity and oxidative dissolution, but no correlation between size and toxicity. Oxidative dissolution was a key to the toxicity of most Ag NPs, highlighting a critical role for dissolved silver in the toxicity of all tested Ag NPs. Pharmacological rescue and mutant analysis experiments supported these results. Some Ag NPs (typically less soluble due to size or coating) also acted via generation of reactive oxygen species, an effect specific to nanoparticulate silver. However, in no case was the toxicity of any Ag NP greater than would result from complete dissolution of the same mass of silver. We also studied the impact of natural organic matter (NOM) on Ag NP toxicity and found that NOM significantly mitigated Ag NP toxicity.

RP293 Speciation of Atmospheric Particulate Matter in the Los Angeles Basin: Relating Specific Particulate Matter Components and Oxidative Stress Markers D.A. Perkins, Univ of Wisconsin – Madison, Wisconsin State Lab of Hygiene; D.S. Antkiewicz, Univ of Wisconsin – Madison, Wisconsin State Laboratory of Hygiene, Wisconsin State Lab of Hygiene, Environmental Toxicology; J. Hemming, WI State Lab of Hygiene, Environmental Toxicology; M.M. Shafer, Univ of Wisconsin-Madison, Environmental Chemistry & Technology; J.J. Schauer, Univ of Wisconsin–Madison, Environmental Chemistry and Technology Program. Air pollution in the form of atmospheric particulate matter (PM) is a major concern in urban areas and has been linked to adverse human health effects such as asthma, bronchitis, respiratory infections, cardiovascular disease and cancer. An inflammatory response in pulmonary tissues can occur upon exposure to PM due to the formation of excess Reactive Oxygen Species (ROS). Alveolar macrophages are the primary pulmonary cells that respond to PM exposures by phagocytizing particles as well as producing ROS, contributing to the inflammatory reaction. PM species implicated in ROS formation include transition metals, organic carbon and specific organic species, e.g., PAHs and quinones. However, many advances are still needed to fully characterize the role and specific activity of PM components. To identify ROS active species and unravel the mechanisms of ROS/oxidative stress generation, we applied three different assays to water extracts of urban PM samples collected in the LA Basin, CA: an in vitro rat alveolar macrophage respiratory burst assay using the ROS fluorescent probe DCFH-DA, a dithiothreitol (DTT) assay measuring chemical redox activity by monitoring the oxidation of DTT, and an ELISA measuring rat tumor necrosis factor-alpha (TNFa) as a marker of inflammatory response. To assess the role of specific PM components, we coupled these assays with upfront chemical fractionation tools including Chelex (a metals chelator); an ion-exchanger for anionic metals; a dissolved organic matter sorbent; and an iron chelator (DFO). These methods were applied to both unfiltered and 0.2 µm filtered PM extracts. The mass-normalized macrophage-ROS activity of urban PM varied substantially (up to 5 fold) between different LA basin urban environments. Soluble species contributed the majority of cellular ROS activity, though particulate activity was significant at several sites and represented a greater fraction of DTT activity. Chelex, DEAE and iron chelation treatments were effective in reducing ROS activity, however the magnitude and relative effect differed substantially from site to site. No significant decrease in respiratory burst was observed with soluble organic matter removal. In contrast, removal of organic species had an effect on TNFa production. The drivers of toxicity of atmospheric PM are complex and site-specific and reflect the unique PM composition rather than total PM mass.

RP294 The Effects of Silver Nanoparticles on Antioxidant and Oxidative Damage Biomarkers Related to ROS Production in Isolated Tissues and Whole Oysters B. Johnson, Univ of North Carolina Charlotte, Dept of Biology, UNC Charlotte, Biology Dept; S. Gilbert, Univ of

North Carolina at Charlotte, Univ of North Carolina at Charlotte, Dept of Biology; M. McCarthy, UNC-Charlotte; L. Marsden, NC State Univ; N. Levi-Polyachenko, Wake Forest Univ Health Sciences, Dept of Plastic and Reconstructive Surgery; A. Ringwood, Univ of North Carolina Charlotte. The continued manufacturing and use of engineered nanoparticles makes it increasingly important to examine their effects on marine organisms. The purpose of these ongoing studies is to characterize the toxicity of various metal nanoparticle preparations on oysters, *Crassostrea virginica*. Studies are being conducted through specific isolated tissue exposure and also whole oyster exposures. Oyster hepatopancreas and gill tissue were isolated and exposed to the three types of silver nanoparticles (seeds, prisms, and plates) over a range of concentrations. Antioxidant (GSH), lipid peroxidation (LPO), and reactive oxygen species (ROS) levels were then measured. Whole oysters were also exposed to a range of silver nanoparticle concentrations to compare the responses in isolated tissues to those from whole oyster exposures. Silver nanoparticles caused increases in LPO and ROS production in oyster hepatopancreas tissues, and there was evidence of shape dependent differences in toxicity. In contrast, the gills were not affected as much as the hepatopancreas tissues in isolated as well as whole oyster studies. While isolated tissues are valuable assay systems for studying nanoparticle effects, there were some differences between the whole oyster studies and the isolated tissues studies. These kinds of basic studies are essential for addressing the potential impacts of nanoengineered particles on fundamental cellular processes as well as marine organisms.

RP295 Uptake and Retention of Quantum Dots in *Daphnia* is Influenced by Particle Charge A. Feswick, Univ of New Brunswick, Biology; R.J. Griffitt, Univ of Southern Mississippi, Gulf Coast Research Laboratory, Univ of Southern Missippi, Coastal Sciences; K. Seibein, Univ of Florida, MAIC; D.S. Barber, Univ of Florida, Dept of Physiological Sciences. Nanomaterials are a diverse group of compounds whose inevitable release into the environment warrants study of the fundamental processes that govern ingestion, uptake and accumulation of nanomaterials in organisms. Studies have already demonstrated the ability of nanomaterials to transfer to higher trophic levels in aquatic ecosystems. Uncharged (PEG), positively charged (amino-terminated) and negatively charged (carboxyl-modified) cadmium selenide/zinc sulfide quantum dots were used to monitor ingestion, uptake and depuration of nanometals in *C. dubia* over 24 hours of exposure. These studies demonstrated that particles with higher negative charge (carboxy QDots) were taken up more readily by *Daphnia* (259.17 ± 17.70 RFU/20 *Daphnia* given as mean ± S.E.) than either the amine (150.01 ± 18.91) or PEG Qdots (95.17 ± 9.78). This correlated well with fluorescent microscopic images obtained at the 24 hour timepoint. Confocal and electron microscopic analysis clearly demonstrated that all three types of quantum dots could cross the intestinal epithelial barrier and be translocated to other cells. Upon cessation of exposure, elimination of all three materials was biphasic with rapid initial clearance that likely represents elimination of material remaining in the GI tract followed by a much slower elimination phase that likely represents elimination of internalized material. These studies clearly demonstrate that daphnids can take up intact nanomaterials from the water column and that this uptake is strongly influenced by particle charge.
